Example Using Standard Least Squares

In a study of the effect of drugs in treating a disease, thirty patients are randomly divided into three groups of ten. Two of these groups are administered drugs (Drug a and Drug d), whereas the third group is administered a placebo (Drug f). A pretreatment measure, \( x \), is taken on each patient, as well as a posttreatment measure, \( y \). The pretreatment score, \( x \), is included as a covariate, to account for differences in the stage of the disease among patients. This example is taken from Snedecor and Cochran (1967, p. 422).

You are interested in determining if there is a difference in the three Drug groups. You construct a model with response \( y \) and model effects Drug, \( x \), and the interaction of Drug and \( x \). The interaction might account for a situation where drugs have differential effects, based on the stage of the disease. (For background on the Fit Model window and the various personalities, see the “Model Specification” chapter on page 29.)

1. Select Help > Sample Data Library and open Drug.jmp.
2. Select Analyze > Fit Model.
3. Select \( y \) and click \( Y \).

   When you add this column as \( Y \), the fitting Personality becomes Standard Least Squares. An Emphasis option is added with a selection of Effect Leverage, which you can change if desired.

4. Select Drug and \( x \). With these two effects highlighted in the Select Columns list, click Macros and select Full Factorial. The macro adds the two effects and their two-way interaction to the Construct Model Effects list.
5. Click **Run**.

The Fit Least Squares report is shown in Figure 3.3. Note that some of the constituent reports are closed because of space considerations. The Actual by Predicted, Residual by Predicted, and Leverage plots show no discrepancies in terms of model fit and underlying assumptions.
Since there are no apparent problems with the model fit, you can now interpret the statistical tests. Figure 3.4 shows the relevant reports. The overall model is significant, as shown in the Analysis of Variance report.

Although the Regression Plot suggests that Drug and the pretreatment measure, x, interact, the Prob > F value in the Effect Tests report does not support that conclusion. The Effect Tests report also shows that x is significant in explaining y, but Drug is not significant. The study does not detect a difference among the three groups. However, you cannot conclude that Drug has no effect. The drugs might have different effects, but the study size was not large enough to detect that difference.
**Launch the Standard Least Squares Personality**

Standard least squares is one of several analytic techniques that you can select in the Fit Model launch window.

This section describes how you select standard least squares as your fitting methodology in the Fit Model launch window. Options that are specific to this selection are also covered. For more information about the options in the Select Columns red triangle menu, see *Using JMP.*
Fit Model Launch Window

You can specify models with both fixed and random effects in the Fit Model launch window. The options differ based on the nature of the model that you specify.

Fixed Effects Only

To fit models using the standard least squares personality, select Analyze > Fit Model and then select Standard Least Squares from the Personality list. When you enter one or more continuous variables in the Y list, the Personality defaults to Standard Least Squares. Note, however, that other selections are available for continuous Y variables. When you specify only fixed effects for a Standard Least Squares fit, the Fit Model launch window appears as shown in Figure 3.5. This example illustrates the launch window using the Big Class.jmp sample data table.

Figure 3.5 Fit Model Launch Window for a Fixed Effects Model

When the Standard Least Squares personality is selected in the Personality list, an Emphasis option also appears. Emphasis options control the reports that are provided in the initial report window. Based on the model effects that are included, JMP infers which reports you are likely to want. However, any report not shown as part of the initial report can be shown by selecting the appropriate option from the default report’s red triangle menu.

For more information about reports that are available for each Emphasis option, see “Emphasis Options for Standard Least Squares” on page 82.
Random Effects

If the specified model contains one or more random effects, then additional options become available in the Fit Model launch window. Consider the Machine.jmp sample data table. Each of six randomly chosen workers performs work at each of three machines and their output is rated. You are interested in estimating the variation in ratings across the workforce, rather than in determining whether these six specific workers’ ratings differ. You need to treat person and machine*person as random effects when you specify the model.

The Fit Model launch window for this model is shown in Figure 3.6. When the Random Effect attribute is applied to person, a Method option and two options relating to variance components appear in the Fit Model Launch window.

Figure 3.6 Fit Model Launch Window for a Model Containing a Random Effect

Standard Least Squares Options in the Fit Model Launch Window

The following Fit Model launch window options are specific to the Standard Least Squares personality.

**Emphasis** Controls the types of reports and plots that appear in the initial report window. See “Emphasis Options for Standard Least Squares” on page 82.

**Method** (Appears only when random effects are specified.) Estimates the model using one of these methods:

- **REML** See “REML Variance Component Estimates” on page 193.
Launch the Standard Least Squares Personality Fitting Linear Models

EMS  Expected Mean Squares, also called the Method of Moments. See “EMS (Traditional) Model Fit Reports” on page 196.

Unbounded Variance Components  (Appears only when REML is selected as the Method.) Allows variance component estimates to be negative. This option is selected by default. This option should remain selected if you are interested in fixed effects, since bounding the variance estimates at zero leads to bias in the tests for fixed effects. See “Negative Variances” on page 190.

Estimate Only Variance Components  (Appears only when REML is selected as the Method.) Provides a report that shows only variance component estimates. See “Estimate Only Variance Components” on page 191.

Fit Separately  (Appears only for models with multiple Y variables and no random effects.) Fits a separate model for each Y variable using all rows that are nonmissing. See “Missing Values” on page 83.

Emphasis Options for Standard Least Squares

The three options in the Emphasis list control the types of plots and reports that you see as part of the initial report for the Standard Least Squares personality. See the descriptions below. JMP chooses a default emphasis based on the number of rows in the data table, the number of effects entered in the Construct Model Effects list, and the attributes applied to effects. You can change this choice of emphasis based on your needs. For more information about how JMP chooses the emphasis, see “Emphasis Rules” on page 204.

After the initial report opens, you can add other reports and plots from the red triangle menu in the platform report window.

The following emphasis options are available:

Effect Leverage  Shows leverage and residual plots, as well as reports with details about the model fit. This option is useful when your main focus is model fitting.

Effect Leverage is the most comprehensive option. This emphasis divides reports into those that relate to the Whole Model and those that relate to individual model effects. The Whole Model reports are in the left corner of the report window under the Whole Model title, with effect reports to the right.

Effect Screening  Shows a sorted or scaled parameter estimates report along with a graph (when appropriate), the Prediction Profiler, and reports with details about the model fit. This option is useful when you have many effects and your initial focus is to discover which effects are active, as in screening designs.

When Effect Screening is selected, a Box-Cox transformation is calculated. If the confidence interval for the estimated λ does not contain 1, the Box-Cox Transformations report appears. See “Box Cox Y Transformation” on page 169.
Minimal Report  Shows only the regression plot and reports with details about the model fit. This Emphasis is the default when the Random Effect attribute is applied to any model effect.

This option is the least detailed and most concise. You can request reports of specific interest to you from the red triangle menus.

To change which reports or plots appear for all of the Emphasis options, use platform preferences. Go to File > Preferences > Platforms > Fit Least Squares, and use the Set check boxes:

• To prevent an option from appearing in the report, next to an option, select Set but do not select the option.
• To ensure that an option appears in the report, select Set and select the option.

Validation in Standard Least Squares

In JMP Pro, you can specify a Validation column in the Fit Model window. A validation column must have a numeric data type and should contain at least two distinct values.

• If the column contains two values, the smaller value defines the training set and the larger value defines the validation set.

• If the column contains three values, the values define the training, validation, and test sets in order of increasing size.

• If the column contains four or more distinct values, the Validation column is ignored.

The Standard Least Squares personality in JMP Pro supports the use of a Validation column. If you enter a Validation column, a Crossvalidation report is provided. See “Crossvalidation Report” on page 88.

If you enter a Validation column, observations from the Validation and Test sets are marked as ‘v’ and ‘t’, respectively, in plots in the report.

For more information about how a Validation column is used in JMP modeling platforms, see Predictive and Specialized Modeling.

Missing Values

By default, rows that have missing values for Y or any model effects are excluded from the analysis.
**Note:** JMP provides an Informative Missing option in the Fit Model window in the Model Specification red triangle menu. Informative Missing enables you to fit models using rows where model effects are missing. See “Informative Missing” on page 49 in the “Model Specification” chapter.

When your model contains a random effect, Y values are fit separately by default. The individual reports appear in the Fit Group report.

Suppose that your model contains only fixed effects, and the following statements are true:

- You specified more than one Y response.
- Some of these Y responses have missing values.
- You did not select the Fit Separately option in the Fit Model launch window.

Then, JMP prompts you to select one of the following options:

- **Fit Separately** fits each Y using all rows that are nonmissing for that particular Y.
- **Fit Together** fits each Y uses only those rows that are nonmissing for all of the Y variables.

When you select Fit Separately, a Fit Group report contains the individual reports for the Y variables. You can select profilers from the Fit Group red triangle menu to view all the Y variables in the same profiler. Alternatively, you can select a profiler from an individual Y variable report to view only that variable in the profiler.

When you select Fit Together, a Fit Least Squares report contains individual reports for each of the Y variables. However, some parts of the report are combined for all Y variables: the Effect Summary and the Profilers.

---

**Fit Least Squares Report**

When you fit a model using the Standard Least Squares personality, you obtain a Fit Least Squares report. The content of the report is driven by the nature of the data and your selections in the Fit Model launch window.

**Tip:** To always see reports that do not appear by default, select them using `File > Preferences > Platforms > Fit Least Squares.`
Single versus Multiple Responses

When you fit a single response variable Y, the Fit Least Squares window organizes detailed reports in a report entitled “Response Y”. When you fit several responses, reports for individual responses are usually organized in a report entitled “Least Squares Fit”. However, if there is missing response data, and you select the option to Fit Separately, reports for individual responses are organized in a report titled “Fit Group”.

Report Structure Related to Emphasis

When you select the Effect Leverage Emphasis in the Fit Model launch window, the report for a given response is arranged in columns. The left column consists of the Whole Model report, which contains additional reports that pertain to the model. Reports for each effect in the model are shown in the columns to the right of the Whole Model report.

When you select either the Effect Screening or Minimal Report Emphasis in the Fit Model launch window, all reports for each response are arranged in the left column.

Special Reports

This section describes the reports that are available based on the data structure or choices that you made regarding effect attributes.

Singularity Details

When there are linear dependencies among model effects, the Singularity Details report appears as the first report under the Response report title. It contains a table of the linear functions that the model terms satisfy. These functions define the aliasing relationships among model terms. Figure 3.7 shows an example for the Singularity.jmp sample data table.

Figure 3.7 Singularity Details Report

<table>
<thead>
<tr>
<th>Term</th>
<th>Details</th>
</tr>
</thead>
</table>

When there are linear dependencies among effects, estimates of some model terms are not unique. See “Models with Linear Dependencies among Model Terms” on page 199.
Response Surface Report

When an effect in a model has the response surface (&RS) or mixture response surface (&RS&Mixture) attribute, a Response Surface report is provided. See Figure 3.8 for an example of a Response Surface report for the Tiretread.jmp sample data table.

Figure 3.8 Response Surface Report

Coef Table

The Coef table shown as the first part of the Response Surface report gives a concise summary of the estimated model parameters. The first columns give the coefficients of the second-order terms. The last column gives the coefficients of the linear terms. To see the prediction expression in its entirety, select Estimates > Show Prediction Expression from the report’s red triangle menu.

Solution Report

The Solution report gives a critical value (maximum, minimum, or saddle point), if one exists, along with the predicted value at that point. It also alerts you if the solution falls outside the range of the data.

Canonical Curvature Report

The eigenvalues and eigenvectors of the matrix of second-order parameter estimates determine the type of curvature. The eigenvectors show the principal directions of the surface, including the directions of greatest and smallest curvature.

The eigenvalues are provided in the first row of the Canonical Curvature table.

- If the eigenvalues are negative, the response surface curves downward from a maximum.
• If the eigenvalues are positive, the surface shape curves upward from a minimum.
• If there are both positive and negative eigenvalues, the surface is saddle shaped, curving up in one direction and down in another direction. See Figure 3.9 for an example using the Tiretread.jmp sample data table.

Figure 3.9  Surface Profiler Plot with Saddle-Shaped Surface

The eigenvectors listed below the eigenvalues show the orientation of the principal axes. The larger the absolute value of an eigenvalue, the greater the curvature of the response surface in its associated direction. Sometimes a zero eigenvalue occurs. This eigenvalue means that, along the direction described by the corresponding eigenvector, the fitted surface is flat.

**Note:** The response surface report is not shown for response surface models consisting of more than 20 factors. No error message or alert is given. For more information about response surface designs, see the *Design of Experiments Guide*.

**Mixed and Random Effect Model Reports**

When you specify a random effect in the Fit Model launch window, the Method list appears. This list provides two fitting methods: REML (Recommended) and EMS (Traditional). Additional reports as well as Save Columns and Profiler options are shown, based on the model and the method that you select.

For more information about the REML method reports, see “Restricted Maximum Likelihood (REML) Method” on page 191. For more information about the EMS method reports, see “EMS (Traditional) Model Fit Reports” on page 196.
Crossvalidation Report

When you enter a Validation column in the Fit Model launch window, a Crossvalidation report is provided. The report gives the following for each of the sets used in validation:

**Source**  Identifies the set as the Training, Validation, or Test set.

**RSquare**  The RSquare value calculated for observations in the given set relative to the model derived using the Training Set. For the Training Set, this is the usual RSquare value.

For each of the Training, Validation, and Test sets, the RSquare value is computed as follows:

- For each observation in the given set, compute the prediction error. This is the difference between the actual response and the response predicted by the Training set model.

- Square and sum the prediction errors to obtain $SSE_{Source}$ where the subscript $Source$ denotes any of the Training, Validation, or Test sets.

- Square and sum the differences between the actual responses for observations in the $Source$ set and their mean. Denote this value by $SST_{Source}$.

- RSquare for the $Source$ set is:

$$RSquare_{Source} = 1 - \frac{SSE_{Source}}{SST_{Source}}$$

**Note:** It is possible for RSquare values for the Validation and Test sets to be negative.

**RASE**  The square root of the mean squared prediction error. For each of the Training, Validation, and Test sets, RASE is computed as follows:

- For each observation in the given set, calculate the prediction error. This is the difference between the actual response and the response predicted by the Training set model.

- Square and sum the prediction errors to obtain $SSE_{Source}$ where the subscript $Source$ denotes any of the Training, Validation, or Test sets.

- Denote the number of observations by $n$.

- RASE is:

$$RASE_{Source} = \sqrt{\frac{SSE_{Source}}{n}}$$

**Freq**  The number of observations in the Source set.
Least Squares Fit Options

You might have more than one Y and no missing response values, or more than one Y with missing values. When you select Fit Together, the responses are grouped in a report called Least Squares Fit. The red triangle menu includes the following options:

**Profilers**  Shows all responses in a single profiler. You can view the effects of model terms on all responses simultaneously and perform multiple optimization. See “Factor Profiling” on page 163.

**Model Dialog**  Shows the completed launch window for the current analysis.

**Effect Summary**  Shows the interactive Effect Summary report that enables you to add or remove effects from the model. See “Effect Summary Report” on page 182.

See *Using JMP* for more information about the following options:

**Local Data Filter**  Shows or hides the local data filter that enables you to filter the data used in a specific report.

**Redo**  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

**Save Script**  Contains options that enable you to save a script that reproduces the report to several destinations.

**Save By-Group Script**  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.

Fit Group Options

When you have more than one Y and you select Fit Separately, the responses are grouped in a report called Fit Group. The red triangle menu includes the following options:

**Profiler**  Shows all responses in a single profiler. You can view the effects of model terms on all responses simultaneously and perform multiple optimization. See “Profiler” on page 164.

**Contour Profiler**  Shows all responses in a single contour profiler. You can explore the effects of model terms on all responses simultaneously.

**Surface Profiler**  Shows separate surface profiler reports for each response.
Arrange in Rows  Rearranges the reports for the platform analyses in a specified number of rows. This would be used mostly to arrange reports so that more reports fit in a window or on the page of output.

Order by Goodness of Fit  Sorts the reports by significance of fit (RSquare). This option is available only for platforms that surface the RSquare to the platform level. For example, if you generate hundreds of Oneway analyses from one launch window, they appear in a Fit Group and you can sort them so that the strongest relationships appear first.

See Using JMP for more information about the following options:

Local Data Filter  Shows or hides the local data filter that enables you to filter the data used in a specific report.

Redo  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

Save Script  Contains options that enable you to save a script that reproduces the report to several destinations.

Response Options

Red triangle menu options for the response give you the ability to customize reports according to your needs.

Regression Reports  Provides basic reports and report options. See “Regression Reports” on page 91.

Estimates  Provides options for further analyses relating to parameter estimates. See “Estimates” on page 113.

Effect Screening  Provides reports and plots for identifying significant effects. See “Effect Screening” on page 152.

Factor Profiling  Provides profilers, interaction, and cube plots to examine how the response is related to the model terms. Also provides a plot and report for fitting a Box-Cox transformation. See “Factor Profiling” on page 163.

Row Diagnostics  Provides plots and reports for examining residuals. Also reports the PRESS statistic and provides a Durbin-Watson test. See “Row Diagnostics” on page 172.

Save Columns  Saves model results as columns in the data table, except for Save Coding Table, which saves results in a separate data table. See “Save Columns” on page 179.

Model Dialog  Shows the completed Fit Model launch window for the current analysis.
Effect Summary  Shows the interactive Effect Summary report that enables you to add or remove effects from the model. See “Effect Summary Report” on page 182.

See Using JMP for more information about the following options:

Local Data Filter  Shows or hides the local data filter that enables you to filter the data used in a specific report.

Redo  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

Save Script  Contains options that enable you to save a script that reproduces the report to several destinations.

Save By-Group Script  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.

Regression Reports

The Regression Reports menu provides summary information about model fit, effect significance, and model parameters.

Summary of Fit  Shows or hides a summary of model fit. See “Summary of Fit” on page 92.

Analysis of Variance  Shows or hides calculations for comparing the fitted model to a simple mean model. See “Analysis of Variance” on page 93.

Parameter Estimates  Shows or hides a report containing the parameter estimates and $t$ tests for the hypothesis that each parameter is zero. See “Parameter Estimates” on page 94.

Effect Tests  Shows or hides tests for the fixed effects in the model. See “Effect Tests” on page 96.

Effect Details  Shows or hides a report containing details, plots, and tests for individual effects. See “Effect Details” on page 97.

When the Effect Leverage Emphasis option is selected, each effect has its own report at the top of the Fit Least Squares report window. This report includes effect details options as well as a leverage plot. See “Leverage Plots” on page 174.

Lack of Fit  Shows or hides a test assessing if the model has the appropriate effects, when that test can be conducted. See “Lack of Fit” on page 111.
Show All Confidence Intervals  Shows or hides confidence intervals for the following statistics:
- Parameter estimates in the Parameter Estimates report
- Least squares means in the Least Squares Means Table

AICc  Shows or hides AICc and BIC values in the Summary of Fit report. See “Likelihood, AICc, and BIC” on page 559 in the “Statistical Details” appendix.

Summary of Fit

The Summary of Fit report provides details such as RSquare calculations and the AICc and BIC values.

RSquare  Estimates the proportion of variation in the response that can be attributed to the model rather than to random error. Using quantities from the corresponding Analysis of Variance table, RSquare (also called the coefficient of multiple determination) is calculated as follows:

\[
\text{RSquare} = \frac{\text{Sum of Squares(Model)}}{\text{Sum of Squares(C. Total)}}
\]

An RSquare closer to 1 indicates a better fit to the data than does an RSquare closer to 0. An RSquare near 0 indicates that the model is not a much better predictor of the response than is the response mean.

**Note:** A low RSquare value suggests that there might be variables not in the model that account for the unexplained variation. However, if your data are subject to a large amount of inherent variation, even a useful regression model can have a low RSquare value. Read the literature in your research area to learn about typical RSquare values.

Rsquare Adj  Adjusts the RSquare statistic for the number of parameters in the model. Rsquare Adj facilitates comparisons among models with different numbers of parameters. The computation uses the degrees of freedom. Using quantities from the corresponding Analysis of Variance table, RSquare Adj is calculated as follows:

\[
1 - \frac{\text{Mean Square(Error)}}{\text{Sum of Squares (C. Total)}/\text{DF(C. Total)}}
\]

Root Mean Square Error  Estimates the standard deviation of the random error. This quantity is the square root of the Mean Square for Error in the Analysis of Variance report.

**Note:** Root Mean Square Error is commonly known as RMSE.

Mean of Response  Shows the overall mean of the response values.
**Observations (or Sum Wgts)**  Shows the number of observations used in the model.

- This value is the same as the number of rows in the data table under the following conditions: there are no missing values, no excluded rows, and no column assigned to the role of Weight or Freq.
- This value is the sum of the positive values in the Weight column if there is a column assigned to the role of Weight.
- This value is the sum of the positive values in the Freq column if there is a column assigned to the role of Freq.

**AICc**  (Appears only if you have selected the AICc option from the Regression Reports menu or if you have set AICc as a Fit Least Squares preference.) Shows the corrected Akaike Information Criterion value (AICc). See “Likelihood, AICc, and BIC” on page 559 in the “Statistical Details” appendix.

**BIC**  (Appears only if you have selected the AICc option from the Regression Reports menu or if you have set AICc as a Fit Least Squares preference.) Shows the Bayesian Information Criterion value (BIC). See “Likelihood, AICc, and BIC” on page 559 in the “Statistical Details” appendix.

**Analysis of Variance**

The Analysis of Variance report provides the calculations for comparing the fitted model to a model where all predicted values equal the response mean.

**Note:** If either a Frequency or a Weight variable is entered in the Fit Model launch window, the entries in the Analysis of Variance report are adjusted in keeping with the descriptions in “Frequency” on page 38 and “Weight” on page 38.

The Analysis of Variance report contains the following columns:

**Source**  The three sources of variation: Model, Error, and C. Total (Corrected Total).

**DF**  The associated degrees of freedom (DF) for each source of variation. The C. Total DF is always one less than the number of observations, and it is partitioned into degrees of freedom for the Model and Error as follows:

- The Model DF is the number of parameters (other than the intercept) used to fit the model.
- The Error DF is the difference between the C. Total DF and the Model DF.

**Sum of Squares**  The associated Sum of Squares (SS) for each source of variation.

- The total (C. Total) SS is the sum of the squared differences between the response values and the sample mean. It represents the total variation in the response values.
– The Error SS is the sum of the squared differences between the fitted values and the actual values. It represents the variability that remains unexplained by the fitted model.
– The Model SS is the difference between C. Total SS and Error SS. It represents the variability explained by the model.

**Mean Square** The mean square statistics for the Model and Error sources of variation. Each Mean Square is the sum of squares divided by its corresponding DF.

**Note:** The square root of the Mean Square for Error is the same as RMSE in the Summary of Fit report.

**MSE Used** (Appears only when the Error Specification is Pure Error or Specified.) The mean square error used when the default error specification is not selected. This value is used to calculate the F Ratio instead of the mean square error in the Mean Square column.

**DFE Used** (Appears only when the Error Specification is Pure Error or Specified.) The error degrees of freedom used when the default error specification is not selected. This value is used to calculate the Prob > F value instead of the Error DF in the DF column.

**F Ratio** The model mean square divided by the error mean square. The F Ratio is the test statistic for a test of whether the model differs significantly from a model where all predicted values are the response mean.

**Prob > F** The $p$-value for the test. The Prob > F value measures the probability of obtaining an F Ratio as large as what is observed, given that all parameters except the intercept are zero. Small values of Prob > F indicate that the observed F Ratio is unlikely. Such values are considered evidence that there is at least one significant effect in the model.

**Parameter Estimates**

The Parameter Estimates report shows the estimates of the model parameters and, for each parameter, gives a $t$ test for the hypothesis that it equals zero.

**Note:** Estimates are obtained and tested, if possible, even when there are linear dependencies among the model terms. Such estimates are labeled Biased or Zeroed. See “Models with Linear Dependencies among Model Terms” on page 199.

**Term** The model term corresponding to the estimated parameter. The first term is always the intercept, unless the No Intercept option was checked in the Fit Model launch window. Continuous effects appear with the name of the data table column. Note that continuous columns that are part of higher order terms might be centered. Nominal or ordinal effects appear with values of levels in brackets. See “Coding for Nominal Effects” on page 151 and the “The Factor Models” on page 534 in the “Statistical Details” appendix for information about the coding of nominal and ordinal terms.
Estimate  The parameter estimates for each term. These are the estimates of the model coefficients. When there are linear dependencies among model terms, these might be labeled as Biased or Zeroed. See “Models with Linear Dependencies among Model Terms” on page 199.

Std Error  The estimates of the standard errors for each of the estimated parameters.

t Ratio  The tests of whether the true value of each parameter is zero. The $t$ Ratio is the ratio of the estimate to its standard error. Given the usual assumptions about the model, the $t$ Ratio has a Student’s $t$ distribution under the null hypothesis.

Prob>|t|  The $p$-value for the test that the true parameter value is zero, against the two-sided alternative that it is not.

Lower 95%  The lower 95% confidence limit for the parameter estimate. This column appears only if you have the Regression Reports > Show All Confidence Intervals option selected or if you right-click in the report and select Columns > Lower 95%.

Upper 95%  The upper 95% confidence limit for the parameter estimate. This column appears only if you have the Regression Reports > Show All Confidence Intervals option selected or if you right-click in the report and select Columns > Upper 95%.

Std Beta  The parameter estimates for a regression model where all of the terms have been standardized to a mean of 0 and a variance of 1. This column appears only if you right-click in the report and select Columns > Std Beta.

VIF  The variance inflation factor for each term in the model. High VIFs indicate a collinearity issue among the terms in the model.

The VIF for the $i^{th}$ term, $x_i$, is defined as follows:

$$ VIF_i = \frac{1}{1 - R_i^2} $$

where $R_i^2$ is the RSquare, or coefficient of multiple determination, for the regression of $x_i$ as a function of the other explanatory variables. This column appears only if you right-click in the report and select Columns > VIF.

Design Std Error  The square roots of the relative variances of the parameter estimates (Goos and Jones 2011, p. 25):

$$ \sqrt{\text{diag}(X'X)^{-1}} $$

These are the standard errors divided by RMSE. This column appears only if you right-click in the report and select Columns > Design Std Error.
Effect Tests

The Effect Tests report appears only when there are fixed effects in the model. The effect test for a given effect tests the null hypothesis that all parameters associated with that effect are zero. An effect might have only one parameter as for a single continuous explanatory variable. In this case, the test is equivalent to the $t$ test for that term in the Parameter Estimates report. A nominal or ordinal effect can have several associated parameters, based on its number of levels. The effect test for such an effect tests whether all of the associated parameters are zero.

Note the following:

- Effect tests are conducted, when possible, for effects whose terms are involved in linear dependencies. See “Models with Linear Dependencies among Model Terms” on page 199.
- Parameterization and handling of singularities differ from the SAS GLM procedure. For more information about parameterization and handling of singularities, see the “The Factor Models” on page 534 in the “Statistical Details” appendix.

The Effects Test report contains the following columns:

- **Source**: The effects in the model.
- **Nparm**: The number of parameters associated with the effect. A continuous effect has one parameter. The number of parameters for a nominal or ordinal effect is one less than its number of levels. The number of parameters for a crossed effect is the product of the number of parameters for each individual effect.
- **DF**: The degrees of freedom for the effect test. Ordinarily, Nparm and DF are the same. They can differ if there are linear dependencies among the predictors. In such cases, DF might be less than Nparm, indicating that at least one parameter associated with the effect is not testable. Whenever DF is less than Nparm, the note LostDFs appears to the right of the line in the report. If there are degrees of freedom for error, the test is conducted. See “Effect Tests Report” on page 201.
- **Sum of Squares**: The sum of squares for the hypothesis that the effect is zero.
- **F Ratio**: The $F$ statistic for testing that the effect is zero. The $F$ Ratio is the ratio of the mean square for the effect divided by the mean square for error. The mean square for the effect is the sum of squares for the effect divided by its degrees of freedom.
- **Prob > F**: The $p$-value for the effect test.
- **Mean Square**: The mean square for the effect, which is the sum of squares for the effect divided by its DF.

*Note:* Appears only if you right-click in the report and select **Columns > Mean Square**.
Effect Details

The Effect Details report provides details, plots, and tests for individual effects. It consists of separate reports based on the emphasis that you select in the Fit Model launch window.

- **Effect Leverage emphasis**: Each effect has its own report at the top of the Fit Least Squares report window to the right of the Whole Model report. In this case, the report includes a Leverage Plot for the effect.
- **Effect Screening or Minimal Report emphases**: The Effect Details report is provided but is initially closed. Click the disclosure icon to show the report.

The initial content of the report is the Table of Least Squares Means. Depending on the nature of the effect, this table might not be appropriate, and the default report might initially show no content. However, certain red triangle options are available.

Table of Effect Options

The red triangle menu next to an effect name provides the following options. For certain modeling types, some of these options might not be appropriate and are therefore not available.

**LSMeans Table** Shows the statistics that are compared when effects are tested. See “LSMeans Table” on page 98.

This option is not enabled for continuous effects.

**LSMeans Plot** Shows plots of least squares means for nominal and ordinal effects. If the effect is an interaction, this option displays the Least Squares Means Plot Options window. See “LSMeans Plot” on page 100.

**LSMeans Contrast** Shows the Contrast Specification window, which enables you to specify and test contrasts to compare levels for nominal and ordinal effects and their interactions. See “LSMeans Contrast” on page 102.

**LSMeans Student’s t** Shows tests and confidence intervals for pairwise comparisons of least squares means using Student’s t tests. See “LSMeans Student’s t and LSMeans Tukey HSD” on page 105.

**Note:** The significance level applies to individual comparisons and *not* to all comparisons collectively. The error rate for the collection of comparisons is greater than the error rate for individual tests.

**LSMeans Tukey HSD** Shows tests and confidence intervals for pairwise comparisons of least squares means using the *Tukey-Kramer HSD* (Honestly Significant Difference) test (Tukey 1953; Kramer 1956). See “LSMeans Student’s t and LSMeans Tukey HSD” on page 105.
Note: The significance level applies to the collection of pairwise comparisons. The significance level is exact if the sample sizes are equal and conservative if the sample sizes differ (Hayter 1984).

**LSMeans Dunnett**  Shows tests and confidence intervals for pairwise comparisons against a control level that you specify. Also provides a plot of test results. See “LSMeans Dunnett” on page 108.

**Test Slices**  For each level of each column in the interaction, jointly tests pairwise comparisons among all the levels of the other classification columns in the interaction. See “Test Slices” on page 109.

Note: Available only for interactions involving nominal and ordinal effects.

**Power Analysis**  Shows the Power Details report, which enables you to analyze the power for the effect test. See “Power Analysis” on page 110.

**LSMeans Table**

Least squares means are values predicted by the model for the levels of a categorical effect where the other model factors are set to neutral values. The neutral value for a continuous effect is defined to be its sample mean. The neutral value for a nominal effect that is not involved in the effect of interest is the average of the coefficients for that effect. The neutral value for an uninvolved ordinal effect is defined to be the first level of the effect in the value ordering.

Least squares means are also called adjusted means or population marginal means. Least squares means can differ from simple means when there are other effects in the model. In fact, it is common for the least squares means to be closer together than the sample means. This situation occurs because of the nature of the neutral values where these predictions are made.

Because least squares means are predictions at specific values of the other model factors, you can compare them. When effects are tested, comparisons are made using the least squares means. For more information about least squares means, see “Least Squares Means across Nominal Factors” on page 539 in the “Statistical Details” appendix and “Ordinal Least Squares Means” on page 549.

For main effects, the Least Squares Means Table also includes the sample mean (Figure 3.10).

**Example of a Least Squares Means Table**

1. Select Help > Sample Data Library and open Big Class.jmp.
2. Select Analyze > Fit Model.
3. Select weight and click Y.
4. Select age, sex, and height and click Add.
5. From the Emphasis list, select Effect Screening.
6. Click Run.
7. The Effect Details report appears near the bottom of the Fit Least Squares report and is initially closed. Click the disclosure icon next to the Effect Details report title to show the report.

The Effect Details report, shown in Figure 3.10, shows reports for each of the three effects. Least Squares Means tables are given for age and sex, but not for the continuous effect height. Notice how the least squares means differ from the sample means.

**Figure 3.10** Least Squares Mean Table

The Least Squares Means report contains the following columns:

- **Level**: The categorical levels or combination of levels.
- **Least Sq Mean**: An estimate of the least squares mean for each level.
- **Estimability**: (Appears only when a least squares mean is not estimable.) A warning if a least squares mean is not estimable.
- **Std Error**: Shows the standard error of the least squares mean for each level.
- **Lower 95%**: Shows the lower 95% confidence limit for the least squares mean. This column appears only if you have the Regression Reports > Show All Confidence Intervals option selected or if you right-click in the report and select Columns > Lower 95%.
- **Upper 95%**: Shows the upper 95% confidence limit for the least squares mean. This column appears only if you have the Regression Reports > Show All Confidence Intervals option selected or if you right-click in the report and select Columns > Upper 95%.
Mean  Shows the response sample mean for the given level. This mean differs from the least squares mean if the values for other effects in the model do not balance out across this effect.

**LSMeans Plot**

The LSMeans Plot option produces a Least Squares Means Plot for nominal and ordinal main effects and their interactions. If the effect is an interaction, this option displays the Least Squares Means Plot Options window. See “Least Squares Means Plot Options” on page 100.

The Least Squares Means Plot red triangle menu contains the following options:

- **Show Confidence Limits**  Shows or hides confidence limits for each estimate in the plot.
- **Show Connected Points**  Shows or hides one or more lines that connect the least squares means for each level in the plot.
- **Remove**  Removes the Least Squares Means Plot report for the specified effect.

**Least Squares Means Plot Options**

When you select the LSMeans Plot option from the red triangle menu of an interaction effect, the Least Squares Means Plot Options window appears.

**Figure 3.11  Least Squares Means Plot Options Window**

If you click OK without selecting anything in the window, one LSMeans Plot appears. The horizontal axis of the plot consists of the levels of the factors nested to obtain a separate effect for each combination. To create an interaction plot, select the box next to Create an Interaction Plot. The Choose Terms for Overlay option enables you to select which effect is displayed as the overlay variable in the interaction plot.

For a three-way interaction term, a second panel of options appears after you choose an overlay variable for the interaction plot. If you click OK without selecting anything in the second panel, one interaction plot appears. Alternatively, use the second panel of options to create separate interaction plots for each level of the effect that you select under Choose Terms for Separate Plots.
Figure 3.12  Least Squares Means Tables and Plots for Two Effects

Example of an LS Means Plot
To create the report in Figure 3.12, follow these steps:

1. Select Help > Sample Data Library and open Popcorn.jmp.
2. Select Analyze > Fit Model.
3. Select yield and click Y.
4. Select popcorn, oil amt, and batch and click **Macros > Full Factorial**. Note that the Emphasis changes to Effect Screening.

5. Click **Run**.

6. Click the Effect Details disclosure icon to show the details for the seven model effects.

7. Click the batch red triangle and select **LSMeans Plot**.

8. Click the popcorn*batch red triangle and select **LSMeans Plot**. The Least Squares Means Plot Options window appears.

9. In the Least Squares Means Plot Options window, click the box next to Create an Interaction Plot.

10. Under Choose Terms for Overlay, select popcorn.

11. Click **OK**.

12. To transpose the factors in the plot for popcorn*batch, repeat step 8 and step 9.

13. Under the Choose Terms for Overlay, select batch and click **OK**.

**Figure 3.13** LSMeans Plot for Interaction with Factors Transposed

Figure 3.13 shows the popcorn*batch interaction plot with the factors transposed. Compare it with the plot in Figure 3.12. These plots depict the same information but, depending on your interest, one might be more intuitive than the other.

**LSMeans Contrast**

A *contrast* is a linear combination of parameter values. In the Contrast Specification window, you can specify multiple contrasts and jointly test whether they are zero (Figure 3.14).
JMP builds contrasts in terms of the least squares means of the effect. Each column of the contrast is normalized to have sum zero and so that the sum of the absolute values equals two. If a contrast involves a covariate, you can specify the value of the covariate at which to test the contrast.

The Contrast Specification box shows the name of the effect and the names of the levels in the effect. The contrast values are initially set to zero and appear next to cells containing + and - signs. Click these buttons to compare levels.

Each time you click the + or - button, the contrast coefficients are normalized to make their sum zero and their absolute sum equal to two, if possible. To compare additional levels, click the New Column button. A new column appears in which you define a new contrast. After you are finished, click Done. The Contrast report appears (Figure 3.15). The overall test is a joint $F$ test for all contrasts.

**Note:** If you attempt to specify more than the maximum number of contrasts possible, the test automatically evaluates.

The Contrast report provides the following details about the joint $F$ test:

- **SS** The sum of squares for the joint test.
- **NumDF** The numerator degrees of freedom.
- **DenDF** The denominator degrees of freedom.
- **F Ratio** The ratio of SS divided by NumDF divided by the mean square error.
- **Prob > F** The $p$-value for the significance test.

**Test Detail Report**

The Test Detail report (Figure 3.15) shows a column for each contrast that you tested. For each contrast, the report gives its estimated value, its standard error, a $t$ ratio for a test of that single contrast, the corresponding $p$-value, its sum of squares, and a confidence interval for the contrast estimate.

**Parameter Function Report**

The Parameter Function report (Figure 3.15) shows the contrasts that you specified expressed as linear combinations of the terms of the model.

**Example of LSMeans Contrast**

To illustrate the LSMeans Contrast option, form a contrast that compares the first two age levels with the next two levels.
Follow these steps to create the report shown in Figure 3.14.

1. Select Help > Sample Data Library and open Big Class.jmp.
2. Select Analyze > Fit Model.
3. Select weight and click Y.
4. Select age, sex, and height, and click Add.
5. Select age in the Select Columns list, select height in the Construct Model Effects list, and click Cross.
6. Click Run.
   The Fit Least Squares report appears.
7. Click the age red triangle and select LSMeans Contrast.

**Figure 3.14** LSMeans Contrast Specification for age

8. Click “+” for the ages 12 and 13.
9. Click “-” for ages 14 and 15.
   This contrast tests whether the mean weights differ for the two age groups, based on predicted values at a height of 62.55.
10. Note that there is a text box next to the continuous effect height. The default value is the mean of the continuous effect.
11. Click Done.
12. Open the Test Detail and Parameter Function reports.

The Contrast report is shown in Figure 3.15. The test for the contrast is significant at the 0.05 level. You conclude that the predicted weight for age 12 and 13 children differs statistically from the predicted weight for age 14 and 15 children at the mean height of 62.55.
**Figure 3.15  LSMeans Contrast Report**

**LSMeans Student’s t and LSMeans Tukey HSD**

The LSMeans Student’s t and LSMeans Tukey HSD (*honestly significant difference*) options test pairwise comparisons of model effects.

- The LSMeans Student’s t option is based on the usual independent samples, equal variance t test. Each comparison is based on the specified significance level. The overall error rate resulting from conducting multiple comparisons exceeds that specified significance level.
- The LSMeans Tukey HSD option conducts Tukey HSD tests. For these comparisons, the significance level applies to the entire collection of pairwise comparisons. For this reason, confidence intervals for LS Means Tukey HSD are wider than those for LSMeans Student’s t. The significance level is exact if the sample sizes are equal and conservative if the sample sizes differ (Hayter 1984).
Figure 3.16 shows the LSMeans Tukey report for the effect age in the Big Class.jmp sample data table. (To obtain this report, run the **Fit Model** data table script, click the age red triangle, and select **LS Means Tukey HSD**.) By default, the report shows the Crosstab Report and the Connecting Letters Report.

**Figure 3.16** LSMeans Tukey HSD Report

The Crosstab Report

Both options display a matrix, called the Crosstab Report, where each cell contains the difference in means, the standard error of the difference, and lower and upper confidence limits. The significance level and corresponding critical value are given above the matrix. The default significance level is 0.05, but you can specify a different significance level in the Fit Model launch window. Cells that correspond to pairs of means that differ statistically are shown in red.
The Connecting Letters Report

A Connecting Letters Report appears by default beneath the Crosstab matrix. Levels that share, or are connected by, the same letter do not differ statistically. Levels that are not connected by a common letter do differ statistically.

In Figure 3.16, levels 17, 12, 16, 13, and 15 are connected by the letter A. The connection indicates that these levels do not differ at the 0.05 significance level. Also, levels 16, 13, 15, and 14 are connected by the letter B, indicating that they do not differ statistically. However, ages 17 and 14, and ages 12 and 14, are not connected by a common letter, indicating that these two pairs of levels are statistically different.

Tip: Right-click in the connecting letters report and select Columns to add columns containing connecting letters (Letters), standard errors (Std Error), and confidence interval limits (Lower X% and Upper X%). In the Letters column, the connecting letters are concatenated into a single column. The significance and confidence levels are determined by the significance level that you specify in the Fit Model launch window using the Set Alpha Option.

LSMeans Student’s t and LSMeans Tukey HSD Options

The red triangle options that appear in each report window show or hide optional reports. All of the options below are available for LSMeans Student’s t. The first four options are available for LSMeans Tukey HSD. For both LSMeans Student’s t and LSMeans Tukey HSD, the Crosstab Report and the Connecting Letters Report are shown by default.

Crosstab Report  Shows a two-way table that provides, for each pair of levels, the difference in means, the standard error of the difference, and confidence limits for the difference. The contents of cells containing significant differences are highlighted in red.

Connecting Letters Report  Illustrates significant and non-significant comparisons with connecting letters. Levels not connected by the same letter are significantly different. Levels connected by the same letter are not significantly different.

Save Connecting Letters Table  Creates a data table whose columns give the levels of the effect, the connecting letters, the least squares means, their standard errors, and confidence intervals. The table contains a script called Bar Chart that produces a colored bar chart of the least squares means with their confidence intervals superimposed. The levels are arranged in decreasing order of least squares means.

Figure 3.17 shows the bar chart for an example based on Big Class.jmp. Run the Fit Model data table script, click the age red triangle, and select LSMeans Tukey HSD. Select Save Connecting Letters Table from the LSMeans Differences Tukey HSD report. Run the Bar Chart script in the data table that appears.
**Ordered Differences Report**  Ranks the differences from largest to smallest, giving standard errors, confidence limits, and \( p \)-values. Also plots the differences on a bar chart with overlaid confidence intervals.

**Detailed Comparisons**  Gives individual detailed reports for each comparison. For a given comparison, the report shows the estimated difference, standard error, confidence interval, \( t \) ratio, degrees of freedom, and \( p \)-values for one- and two-sided tests. Also shown is a plot of the \( t \) distribution, which illustrates the significance test for the comparison. The area of the shaded portion is the \( p \)-value for a two-sided test.

**Figure 3.17**  Bar Chart from LSMeans Differences HSD Connecting Letters Table

---

**LSMeans Dunnett**

Dunnett’s test (Dunnett 1955) compares a set of means against the mean of a control group. The error rate applies to the collection of pairwise comparisons. The LSMeans Dunnett option conducts Dunnett’s test for the levels of the given effect. Hsu’s factor analytical approximation is used for the calculation of \( p \)-values and confidence intervals (Hsu 1992).

When you select LSMeans Dunnett, you are prompted to enter a control level for the effect. The LS Means Differences Hsu-Dunnett report shows the significance level, the value of the test statistic (Q), and the control level.

A report for the LSMeans Dunnett option for effect treatment in the Cholesterol.jmp sample data table is shown in Figure 3.18. Here, the response is June PM and the level of treatment called Control is specified as the control level.
Figure 3.18  LSMeans Dunnett Report

The report has two options:

**Control Differences Report**  The Control Differences report is shown by default. For each level of the effect, a table shows the following information: the level being compared to the control level, the estimated difference, the standard error of the difference, a confidence interval, and the *p*-value for the comparison.

**Control Differences Chart**  For each level other than the control, a point shows the difference between the LS Mean for that level and the LS Mean for the control level. Upper and lower decision limits (UDL, LDL) are plotted. The report has a Show Summary Report option and Display options. The Show Summary Report option gives the plot detail. The Display options enable you to modify the plot appearance.

**Test Slices**

The Test Slices option is enabled for interaction effects composed of nominal or ordinal columns. For each level of each nominal or ordinal column in the interaction, this option produces a report that jointly tests all pairwise comparisons of settings involving that level. The test is effectively a test of differences within the specified “slice” of the interaction.

Suppose that you are interested in an A*B*C interaction, where one of the levels of A is “Small”. The Test Slice report for the slice A = Small jointly tests all pairwise comparisons of the B*C levels when A = Small. It enables you to detect differences in levels within an interaction.
The Test Slice reports follow the same format as do the LSMeans Contrast reports. See “LSMeans Contrast” on page 102.

**Power Analysis**

Opens the Power Details window, where you can enter information to obtain retrospective or prospective details for the \( F \) test of a specific effect.

*Note:* To ensure that your study includes sufficiently many observations to detect the required differences, use information about power when you design your experiment. Such an analysis is called a prospective power analysis. Consider using the DOE platform to design your study. Both DOE > Sample Size and Power and DOE > Evaluate Design are useful for prospective power analysis. For an example of a prospective power analysis using standard least squares, see “Prospective Power Analysis” on page 215.

Figure 3.19 shows an example of the Power Details window for the Big Class.jmp sample data table. Using the Power Details window, you can explore power for values of alpha (\( \alpha \)), sigma (\( \sigma \)), delta (\( \delta \)), and Number (study size). Enter a single value (From only), two values (From and To), or the start (From), stop (To), and increment (By) for a sequence of values. Power calculations are reported for all possible combinations of the values that you specify.

Figure 3.19  Power Details Window

See “Power Analysis” on page 209.

The Power Details window report contains the following columns and options:

**Alpha (\( \alpha \))**  The significance level of the test. This value is between 0 and 1, and is often 0.05, 0.01, or 0.10. The initial value for Alpha, shown in the first row, is 0.05, unless you have selected Set Alpha Level and set a different value in the Fit Model launch window.

**Sigma (\( \sigma \))**  An estimate of the residual error in the model. The initial value shown in the first row, provided for guidance, is the RMSE (the square root of the mean square error).
Delta ($\delta$)  The effect size of interest. See “Effect Size” on page 210. The initial value, shown in the first row, is the square root of the sum of squares for the hypothesis divided by the square root of the number of observations in the study (that is, $\delta = \sqrt{\frac{SS}{n}}$).

Number ($n$)  The sample size. The initial value, shown in the first row, is the number of observations in the current study.

Solve for Power  Solves for the power as a function of $\alpha$, $\sigma$, $\delta$, and $n$. The power is the probability of detecting a difference of size $\delta$ by seeing a test result that is significant at level $\alpha$, for the specified $\sigma$ and $n$. See “Computations for the Power” on page 562 in the “Statistical Details” appendix.

Solve for Least Significant Number  Solves for the smallest number of observations required to obtain a test result that is significant at level $\alpha$, for the specified $\delta$ and $\sigma$. See “Computations for the LSN” on page 560 in the “Statistical Details” appendix.

Solve for Least Significant Value  Solves for the smallest positive value of a parameter or linear function of the parameters that produces a $p$-value of $\alpha$. The least significant value is a function of $\alpha$, $\sigma$, and $n$. This option is available only for one-degree-of-freedom tests. See “Computations for the LSV” on page 561 in the “Statistical Details” appendix.

Adjusted Power and Confidence Interval  Retrospective power calculations use estimates of the standard error and the test parameters in estimating the $F$ distribution’s noncentrality parameter. Adjusted power is retrospective power calculation based on an estimate of the noncentrality parameter from which positive bias has been removed (Wright and O’Brien 1988).

The confidence interval for the adjusted power is based on the confidence interval for the noncentrality estimate.

The adjusted power deals with a sample estimate, so it and its confidence limits are computed only for the $\delta$ estimated in the current study. See “Computations for the Adjusted Power” on page 563 in the “Statistical Details” appendix.

Lack of Fit

The Lack of Fit report gives details for a test that assesses whether the model fits the data well. The Lack of Fit report appears only when it is possible to conduct this test. The test relies on the ability to estimate the variance of the response using an estimate that is independent of the model. Constructing this estimate requires that response values are available at replicated values of the model effects. The test involves computing an estimate of pure error, based on a sum of squares, using these replicated observations.
In the following situations, the Lack of Fit report does not appear because the test statistic cannot be computed:

- There are no replicated points with respect to the X variables, so it is impossible to calculate a pure error sum of squares.
- The model is saturated, meaning that there are as many estimated parameters as there are observations. Such a model fits perfectly, so it is impossible to assess lack of fit.

The difference between the error sum of squares from the model and the pure error sum of squares is called the lack of fit sum of squares. The lack of fit variation can be significantly greater than pure error variation if the model is not adequate. For example, you might have the wrong functional form for a predictor, or you might not have enough, or the correct, interaction effects in your model.

The Lack of Fit report contains the following columns:

**Source** The three sources of variation: Lack of Fit, Pure Error, and Total Error.

**DF** The degrees of freedom (DF) for each source of error:

- The DF for Total Error is the same as the DF value found on the Error line of the Analysis of Variance table. Based on the sum of squares decomposition, the Total Error DF is partitioned into degrees of freedom for Lack of Fit and for Pure Error.
- The Pure Error DF is pooled from each replicated group of observations. In general, if there are \( g \) groups and if each group has identical settings for each effect, the pure error DF, denoted \( \text{DF}_{PE} \), is defined as follows:

\[
\text{DF}_{PE} = g \sum_{i=1}^{g} (n_i - 1)
\]

where \( n_i \) is the number of replicates in the \( i^{th} \) group.
- The Lack of Fit DF is the difference between the Total Error and Pure Error DFs.

**Sum of Squares** The associated sum of squares (SS) for each source of error:

- The Total Error SS is the sum of squares found on the Error line of the corresponding Analysis of Variance table.
- The Pure Error SS is the total of the sum of squares values for each replicated group of observations. The Pure Error SS divided by its DF estimates the variance of the response at a given predictor setting. This estimate is unaffected by the model. In general, if there are \( g \) groups and if each group has identical settings for each effect, the Pure Error SS, denoted \( \text{SS}_{PE} \), is defined as follows:

\[
\text{SS}_{PE} = g \sum_{i=1}^{g} \text{SS}_i
\]
where \( SS_i \) is the sum of the squared differences between each observed response and the mean response for the \( i^{th} \) group.

- The Lack of Fit SS is the difference between the Total Error and Pure Error sum of squares.

**Mean Square**  The mean square for the Source, which is the Sum of Squares divided by the DF. A Lack of Fit mean square that is large compared to the Pure Error mean square suggests that the model is not fitting well. The \( F \) ratio provides a formal test.

**F Ratio**  The ratio of the Mean Square for Lack of Fit to the Mean Square for Pure Error. The \( F \) Ratio tests the hypothesis that the variances estimated by the Lack of Fit and Pure Error mean squares are equal, which is interpreted as representing “no lack of fit”.

**Prob > F**  The \( p \)-value for the Lack of Fit test. A small \( p \)-value indicates a significant lack of fit.

**Max RSq**  The maximum RSquare that can be achieved by a model based only on these effects. The Pure Error Sum of Squares is invariant to the form of the model. So the largest amount of variation that a model with these replicated effects can explain equals:

\[
\frac{SS(C. \text{ Total}) - SS(Pure \text{ Error})}{SS(C. \text{ Total})} = 1 - \frac{SS(Pure \text{ Error})}{SS(C. \text{ Total})}
\]

This formula defines the Max RSq.

---

### Estimates

The Estimates menu provides additional detail about model parameters. To better understand estimates, you might want to review how JMP codes nominal and ordinal effects. See “Details of Custom Test Example” on page 204, “Nominal Factors” on page 535 in the “Statistical Details” appendix, and “Ordinal Factors” on page 547 in the “Statistical Details” appendix).

If your model contains random effects, then only the options below that are appropriate are available from the Estimates menu.

The Estimates menu provides the following options:

**Show Prediction Expression**  Shows or hides the Prediction Expression report, which contains the equation for the estimated model. See “Show Prediction Expression” on page 115 for an example.

**Sorted Estimates**  Shows or hides the Sorted Parameter Estimates report, which can be useful in screening situations. If the design is not saturated, this report is the Parameter Estimates report with the terms, other than the Intercept, sorted in decreasing order of significance. If the design is saturated, then Pseudo \( t \) tests are provided. See “Sorted Estimates” on page 116.
Expanded Estimates  (Available only when at least one of the effects is not continuous.)
Shows or hides the Expanded Estimates report, which expands the Parameter Estimates report by giving parameter estimates for all levels of nominal effects. See “Expanded Estimates” on page 120.

Indicator Parameterization Estimates  (Available only when there are nominal columns among the model effects.) Shows or hides the Indicator Function Parameterization report, which contains parameter estimates with the nominal effects in the model parametrized using the classical indicator functions. See “Indicator Parameterization Estimates” on page 122.

Sequential Tests  Shows or hides the Sequential (Type 1) Tests report that contains the sums of squares as effects are added to the model sequentially. Conducts $F$ tests based on the sequential sums of squares. See “Sequential Tests” on page 123.

Custom Test  Enables you to test a custom hypothesis. See “Custom Test” on page 124.

Multiple Comparisons  Enables you to specify comparisons among effect levels. These comparisons can involve a single effect or you can define flexible custom comparisons. You can compare to the overall mean, to a control mean, or you can obtain all pairwise comparisons using Tukey HSD or Student’s $t$. When you specify the Student’s $t$ method, you can also perform equivalence tests to identify pairwise differences that are of practical importance. See “Multiple Comparisons” on page 126.

Compare Slopes  (Available only when there is one nominal term, one continuous term, and their interaction effect for the fixed effects.) Produces a report that enables you to compare the slopes of each level of the interaction effect in an analysis of covariance (ANCOVA) model. See “Compare Slopes” on page 141.

Joint Factor Tests  (Available only when the model contains interactions.) For each main effect in the model, shows or hides a joint test on all of the parameters involving that main effect. See “Joint Factor Tests” on page 141.

Inverse Prediction  Enables you to predict values of explanatory variables for one or more values of the response. See “Inverse Prediction” on page 142.

Cox Mixtures  (Available only when the model contains mixture effects.) Produces parameter estimates for the Cox mixture model. Using these to derive factor effects and estimate the response surface shape relative to a reference point in the design space. See “Cox Mixtures” on page 146.

Parameter Power  Adds columns to the Parameter Estimates report that give power and other details relating to the corresponding hypothesis tests. See “Parameter Power” on page 148.

Correlation of Estimates  Shows or hides a correlation matrix for all parameter estimates in the model. See “Correlation of Estimates” on page 150.
**Error Specification** (Available only when there are no random effects.) Specifies the error variance and the error degrees of freedom that are used for standard errors and tests in the Fit Least Squares report. Note that the Studentized Residuals plot and the Box Cox Transformations report are not affected by changing the Error Specification. When the Error Specification is Pure Error or Specified, an additional column appears in the Analysis of Variance report. See “Analysis of Variance” on page 93.

**Default Estimate** Uses the standard root mean square error and error degrees of freedom from the model to calculate all tests and standard errors.

**Pure Error** Uses the Pure Error mean square and associated degrees of freedom from the Lack of Fit report to calculate all tests and standard errors. See “Lack of Fit” on page 111.

**Caution:** If the pure error degrees of freedom is 1, a warning message is displayed indicating that tests are weak and confidence limits are large.

**Specified** Uses user-specified values for the error variance and error degrees of freedom to calculate all tests and standard errors.

### Show Prediction Expression

The Show Prediction Expression option shows the equation used to predict the response. Figure 3.20 shows an example for the Drug.jmp sample data table. This expression is given as a typical JMP formula. For example, to predict the response for someone on Drug a with \( x = 10 \), you would calculate, with some rounding: \(-2.696 - 1.185 + 0.987(10) = 5.99\).

**Tip:** To specify the number of digits in the prediction formula, go to File > Preferences > Tables and change the Default Field Width value.

![Figure 3.20 Prediction Expression](image)

To obtain the preceding report, follow these steps:

**Example of a Prediction Expression**

1. Select Help > Sample Data Library and open Drug.jmp.
2. Select Analyze > Fit Model.
3. Select y and click Y.
4. Select Drug and x, and then click Add.
5. Click Run.
6. Click the Response y red triangle and select Estimates > Show Prediction Expression. The report in Figure 3.20 appears.

**Sorted Estimates**

The Sorted Estimates option produces a version of the Parameter Estimates report that is useful in screening situations. If the design is not saturated, the Sorted Estimates report gives the information found in the Parameter Estimates report, but with the terms, other than the Intercept, sorted in decreasing order of significance (second report in Figure 3.21). If the design is saturated, then Pseudo t tests are provided. These are based on Lenth’s pseudo standard error (Lenth 1989). See “Lenth’s PSE” on page 118.

**Example of a Sorted Estimates Report**

1. Select Help > Sample Data Library and open Reactor.jmp.
2. Select Analyze > Fit Model.
3. Select Y and click Y.
4. Make sure that 2 appears in the Degree box near the bottom of the window.
5. Select F, Ct, A, T, and Cn and click Macros > Factorial to Degree.
6. Click Run.
7. Click the Response Y red triangle and select Estimates > Sorted Estimates.
The Sorted Parameter Estimates report also appears automatically if the Emphasis is set to Effect Screening and all of the effects have only one parameter.

Note the following differences between the Parameter Estimates report and the Sorted Parameter Estimates report (both shown in Figure 3.21):

- The Sorted Parameter Estimates report does not show the intercept.
- The effects are sorted by the absolute value of the \( t \) ratio, showing the most significant effects at the top.
- A bar chart shows the \( t \) ratio with vertical lines showing critical values for the 0.05 significance level.

**Sorted Estimates Report for Saturated Models**

Screening experiments often involve fully saturated models, where there are not enough degrees of freedom to estimate error. In these cases, the Sorted Estimates report (Figure 3.21) gives relative standard errors and constructs \( t \) ratios and \( p \)-values using Lenth’s pseudo standard error (PSE). These quantities are labeled with *Pseudo* in their names. See “Lenth’s PSE” on page 118 and “Pseudo t-Ratios” on page 118. A note explains the change and shows the PSE.
The report contains the following columns:

**Term**  The model term whose coefficient is of interest.

**Estimate**  The parameter estimates are presented in sorted order, with smallest \( p \)-values listed first.

**Relative Standard Error**  If there are no degrees of freedom for residual error, the report gives relative standard errors. The relative standard error is computed by setting the root mean square error equal to 1.

**Pseudo \( t \)-Ratio**  A \( t \) ratio for the estimate, computed using pseudo standard error. The value of Lenth PSE is shown in a note at the bottom of the report.

**Pseudo \( p \)-Value**  A \( p \)-value computed using an error degrees of freedom value (DFE) of \( m/3 \), where \( m \) is the number of parameters other than the intercept. The value of DFE is shown in a note at the bottom of the report.

**Lenth’s PSE**

Lenth’s *pseudo standard error* (PSE) is an estimate of residual error due to Lenth (1989). It is based on the principle of effect sparsity: in a screening experiment, relatively few effects are active. The inactive effects represent random noise and form the basis for Lenth’s estimate.

The value is computed as follows:

1. Consider the absolute values of all non-intercept parameters.
2. Remove all parameter estimates whose absolute values exceed 3.75 times the median absolute estimate.
3. Multiply the median of the remaining absolute values of parameter estimates by 1.5.

**Pseudo \( t \)-Ratios**

When relative standard errors are equal, Lenth’s PSE is shown in a note at the bottom of the report. The Pseudo \( t \)-Ratio is calculated as follows:

\[
\text{Pseudo } t\text{-Ratio} = \frac{\text{Estimate}}{\text{PSE}}
\]

When relative standard errors are not equal, the TScale Lenth PSE is computed. This value is the PSE of the estimates divided by their relative standard errors. The Pseudo \( t \)-Ratio is calculated as follows:

\[
\text{Pseudo } t\text{-Ratio} = \frac{\text{Estimate}}{\text{TScale Lenth PSE } \times \text{Relative Std Error}}
\]

Note that, to estimate the standard error for a given estimate, TScale Lenth PSE is adjusted by multiplying it by the estimate’s relative standard error.
Example of a Saturated Model

1. Select **Help > Sample Data Library** and open Reactor.jmp.
2. Select **Analyze > Fit Model**.
3. Select Y and click **Y**.
4. Select the following five columns: F, Ct, A, T, and Cn.
5. Click the **Macros** button and select **Full Factorial**.
6. Click **Run**.
7. Click the Response Y red triangle and select **Estimates > Sorted Estimates**.

Note that Lenth’s PSE and the degrees of freedom used are given at the bottom of the report. The report indicates that, based on their Pseudo p-Values, the effects Ct, Ct*T, T*Cn, T, and Cn are highly significant.

**Figure 3.22** Sorted Parameter Estimates Report for Saturated Model
Expanded Estimates

In dealing with parameter estimates, you must understand how JMP codes nominal and ordinal columns. For more information about how nominal columns are coded, see “Details of Custom Test Example” on page 204. For more information about how ordinal columns are coded and modeled, see “Nominal Factors” on page 535 in the “Statistical Details” appendix and “Ordinal Factors” on page 547 in the “Statistical Details” appendix.

Use the Expanded Estimates option when there are nominal terms in the model and you want to see details for the full set of estimates. The Expanded Estimates option provides the estimates, their standard errors, $t$ ratios, and $p$-values.

Example of an Expanded Estimates Report

1. Select Help > Sample Data Library and open Drug.jmp.
2. Select Analyze > Fit Model.
3. Select $y$ and click $Y$.
4. Select Drug and $x$, and then click Add.
5. Click Run.
6. Click the Response $y$ red triangle and select Estimates > Expanded Estimates.

The Expanded Estimates report, along with the Parameter Estimates report, is shown in Figure 3.23. Note that an estimate for the term Drug[f] appears in the Expanded Estimates report. The null hypothesis for the test is that the mean for the Drug f group does not differ from the overall mean. The test for Drug[f] is significant at the 0.05 level, suggesting that the mean response for the Drug f group differs from the overall response. See “Interpretation of Tests for Expanded Estimates” on page 121.

Figure 3.23 Comparison of Parameter Estimates and Expanded Estimates
Interpretation of Tests for Expanded Estimates

Suppose that your model consists of a single nominal factor that has \( n \) levels. That factor is represented by \( n-1 \) indicator variables, one for each of \( n-1 \) levels. The parameter estimate corresponding to any one of these \( n-1 \) indicator variables is the difference between the mean response for that level and the average response across all levels. This representation is due to how JMP codes nominal variables (see “Details of Custom Test Example” on page 204). The parameter estimate is often interpreted as the effect of that level.

For example, in the Cholesterol.jmp sample data table, consider the single factor treatment and the response June PM. The parameter estimate associated with the term, or indicator variable, treatment[A] is the difference between the mean of June PM for treatment A and the overall mean of June PM.

The effects across all levels of a nominal variable are constrained to sum to zero. Consider the effect of the last level in the level ordering, namely, the level that is coded with –1s. The effect of this level is the negative of the sum of the effects across the other \( n-1 \) levels. It follows that the effect of the last level is the negative of the sum of the parameter estimates across the other \( n-1 \) levels.

The Expanded Estimates option in the Estimates menu calculates missing estimates, tests for all effects that involve nominal columns, and shows them in a text report. You can verify that the mean (or sum) of the estimates across the levels of any such effect is zero. In particular, this relationship indicates that these estimates, and their associated tests, are not independent of each other.

In the Drug.jmp report shown in Figure 3.23, the estimates for the terms associated with Drug are based on a model that includes the covariate x.

Notes:

- The estimate for Drug[a] is the difference between the least squares mean for Drug a and the overall mean of y.
- The estimate for Drug[f], given in the Expanded Estimates report, is the negative of the sum of the estimates for Drug[a] and Drug[d].
- The \( t \) test for Drug [f] presented in the Expanded Estimates report tests whether the response for the Drug f group differs from the overall mean response.
- If nominal factors are involved in high-degree interactions, the Expanded Estimates report can be lengthy. For example, a five-way interaction of two-level nominal factors produces only one parameter estimate but has \( 2^5 = 32 \) expanded effects, which are all identical up to sign changes.
Indicator Parameterization Estimates

This option displays the Indicator Function Parameterization report, which gives parameter estimates for the model where nominal columns are coded using indicator (SAS GLM) parameterization and are treated as continuous. Ordinal columns remain coded using the usual JMP coding scheme. The SAS GLM and JMP coding schemes are described in “The Factor Models” on page 534 in the “Statistical Details” appendix.

In the JMP coding scheme, the estimate that corresponds to the indicator for a level of a nominal variable is an estimate of the difference between the mean response at that level and the mean response over all the levels. To see the JMP coding, select **Save Columns > Save Coding Table** from the Standard Least Squares red triangle menu.

In the indicator coding scheme, the estimate that corresponds to the indicator for a level of a nominal variable is an estimate of the difference between the mean response at that level and the mean response at the last level. The last level is the level with the highest value order coding; it is the level whose indicator function is not included in the model.

*Caution:* Standard errors and t-ratios given in the Indicator Function Parameterization report differ from those in the Parameter Estimates report. This is because the estimates are estimating different parameters.

To create the report in Figure 3.24, follow the steps in “Example of an Expanded Estimates Report” on page 120. But instead of selecting Expanded Estimates, select **Indicator Parameterization Estimates**.

**Figure 3.24** Indicator Parameterization Estimates

The JMP coding scheme is used for nominal variables throughout JMP with the exception of the Generalized Regression personality of Fit Model. For more information about the coding scheme for nominal variables in the Generalized Regression personality, see “Launch the Generalized Regression Personality” on page 290 in the “Generalized Regression Models” chapter.

Note that there might be differences in models derived using the JMP versus the SAS GLM parameterization. Some models are equivalent. Other models (such as no-intercept models, models with missing cells, models with nominal or ordinal effects, and mixture models) might show differences.
Sequential Tests

The Sequential Tests report shows sums of squares and tests as effects are added to the model sequentially. The order of entry is defined by the order of effects as they appear in the Fit Model launch window’s Construct Model Effects list. The report in Figure 3.25 is for the Drug.jmp sample data table.

![Sequential Tests Report]

The sums of squares that form the basis for sequential tests are also called Type I Sums of Squares. They are computed by fitting models in steps following the specified entry order of effects. Consider a specific effect. Compute the model sum of squares for a model containing all effects entered prior to that effect. Then compute the model sum of squares for a model containing those effects and the specified effect. The sequential sum of squares for the specified effect is the increase in the model sum of squares.

Refer to Figure 3.25, showing sequential sums of squares for the Drug.jmp sample data table. In the Fit Model launch window, Drug was entered first, followed by x. A model consisting only of Drug has model sum of squares equal to 293.6. When x is added to the model, the model sum of squares becomes 871.4974. The increase of 577.8974 is the sequential sum of squares for x.

The tests shown in the Sequential (Type 1) Tests report are F tests based on sequential sums of squares, also called Type I Tests. The F Ratio tests the specified effect, where the model contains only that effect and the effects listed above it in the Source column.

The sequential sums of squares sum to the model sum of squares. Another nice feature is that, under the usual model assumptions, the values are statistically independent of each other. However, they do depend on the order of terms in the model and, as such, are not appropriate in many situations.

Sequential tests are considered appropriate in the following situations:

- balanced analysis of variance models specified in proper sequence (that is, two-way interactions follow main effects in the effects list, and so on)
- purely nested models specified in the proper sequence
- polynomial regression models specified in the proper sequence.

The tests given in the Parameter Estimates and Effect Tests reports are based on Type III Sums of Squares. Here the sum of squares for an effect is the extra sum of squares explained by the effect after all other effects have been entered in the model.
Custom Test

To test one or more custom hypotheses involving any model parameters, select **Custom Test** from the Estimates menu. In this window, you can specify one or more linear functions, or *contrasts*, of the model parameters.

The results include individual tests for each contrast and a joint test for all contrasts. See Figure 3.26. The report for the individual contrasts gives the estimated value of the specified linear function of the parameters and its standard error. A $t$ ratio, its $p$-value, and the associated sum of squares are also provided. Below the individual contrast results, the joint test for all contrasts gives the sum of squares, the numerator degrees of freedom, the $F$ ratio, and its $p$-value.

**Caution:** These tests are conducted using residual error. If you have random effects in your model and if you use EMS instead of REML, then these tests might not be appropriate.

**Note:** If you are testing for effects that are involved in higher-order effects, consider using a test for least squares means, rather than a custom test. Least squares means are adjusted for other model effects. You can test least squares means contrasts under Effect Details.

**Custom Test Report Components**

The Custom Test specification window has the following components:

- **Editable text box** The space beneath the Custom Test title bar is an editable area for entering a test name.

- **Parameter** Lists the model terms. To the right of the list of terms are columns of zeros corresponding to the corresponding parameters. Enter values in these cells to specify the linear functions for your tests.

- **The “=” sign** The last line in the Parameter list is labeled =. Enter a constant into this cell to complete the specification for each contrast.

- **Add Column** Adds columns of zeros so that you can jointly test several linear functions of the parameters.

- **Done** Click the Done button to perform the tests. The report changes to show the test statistic value, the standard error, and other statistics for each test column. The joint $F$ test for all columns is given in a box at the bottom of the report.
Custom Test Report Options

The Custom Test red triangle menu contains the following options:

**Power Analysis**  Provides a power analysis for the joint test. This option is available only after the test has been conducted. See “Parameter Power” on page 148.

**Remove**  Removes the Custom Test report.

**Note:** Select **Estimates > Custom Test** repeatedly to conduct several joint custom tests.

Figure 3.26 shows an example of the specification window with three contrasts, using the Cholesterol.jmp sample data table. Note that the constant is set to zero for all three tests. The report for these tests is shown in Figure 3.27.

Example of a Custom Test

The Cholesterol.jmp sample data table gives repeated measures on 20 patients at six time periods. Four treatment groups are studied. Typically, this data should be properly analyzed using all repeated measures as responses. This example considers only the response for June PM.

Suppose that you want to test three contrasts. You want to compare the mean responses for the following:

- treatment A to treatment B
- treatments A and B to the control group
- treatments A and B to the control and placebo groups

To test these contrasts using Custom Test:

1. Select **Help > Sample Data Library** and open Cholesterol.jmp.
2. Select **Analyze > Fit Model**.
3. Select **June PM** and click **Y**.
4. Select **treatment** and click **Add**.
5. Click **Run**.
6. Click the red triangle next to Response June PM and select **Estimates > Custom Test**.
7. In the Custom Test specification report, click **Add Column** twice to create two additional columns.
8. Fill in the editable area with a test name and enter values in the three columns as shown in Figure 3.26.

To see how to obtain these values, particularly those in the third column, see “Interpretation of Parameters” on page 536 in the “Statistical Details” appendix.
9. Click **Done**.

The results shown in Figure 3.27 indicate that all three hypotheses are individually, as well as jointly, significant.

**Figure 3.27** Custom Test Report Showing Tests for Three Contrasts

Multiple Comparisons

Use this option to obtain tests and confidence levels that compare means defined by levels of your model effects. The goal of multiple comparisons methods is to determine whether group means differ, while controlling the probability of reaching an incorrect conclusion. The Multiple Comparisons option lets you compare group means with the overall average (Analysis of Means) and with a control group mean. You can also conduct pairwise comparisons using either Tukey HSD or Student’s *t*. When you specify the Student’s *t* method, you can also perform equivalence tests to identify pairwise differences that are of practical importance.
The Student’s $t$ method controls only the error rate for an individual comparison. As such, it is not a true multiple comparison procedure. All other methods provided control the overall error rate for all comparisons of interest. Each of these methods uses a multiple comparison adjustment in calculating $p$-values and confidence limits.

If your model contains nominal and ordinal effects, you can conduct comparisons using Least Squares Means estimates, or you can define specific comparisons using User-Defined Estimates. If your model contains only continuous effects, you can compare means using User-Defined Estimates.

**Tip:** Suppose that a continuous effect consists of relatively few levels. If you are interested in comparisons using Least Squares Means Estimates, consider assigning that effect an ordinal (or nominal) modeling type.

**Launch the Option**

An example of the control window for the Multiple Comparisons option is shown in Figure 3.28. This example is based on the Big Class.jmp data table, with weight as Y and age, sex, and height as model effects. Two classes of estimates are available for comparisons: Least Squares Means Estimates and User-Defined Estimates.
Least Squares Means Estimates

This option compares least squares means and is available only if there are nominal or ordinal effects in the model. Recall that least squares means are means computed at some neutral value of the other effects in the model. (For a definition of least squares means, see “LSMeans Table” on page 98.) You must select the effect of interest. In Figure 3.28, Least Squares Means Estimates for age are specified. There is an option to show the least squares means plot. See “Least Squares Means Plot Options” on page 100.

Figure 3.28  Launch Window for Least Squares Means Estimates

User-Defined Estimates

The specification of User-Defined Estimates is illustrated in Figure 3.29. Three levels of age and both levels of sex have been selected. Also, two values of height have been manually entered. The Add Estimates button has been clicked, resulting in the listing of all possible combinations of the specified levels. At this point, you can specify more estimates and click the Estimates button again to add them to the list of Estimates for Comparison.
When you use User-Defined Estimates, effects with no specified levels are set according to the modeling type:

- Continuous effects are set to the mean of the effect.
- Nominal and ordinal effects are set to the first level in the value ordering.

**Note:** In this section, we use the term *mean* to refer to either estimates of least squares means or user-defined estimates.
Choose Least Squares Means Plot Options

Select **Show Least Squares Means Plot** to obtain a least square means plot. If your effect is an interaction term, then you have the option to create an interaction plot. You select the term for the overlay. If you do not select the interaction plot, then the least squares plot will nest the effect terms. See “Least Squares Means Plot Options” on page 100.

Choose Initial Comparisons

Once you have specified estimates, you can choose the types of comparisons that you would like to see in your initial report by making selections under Choose Initial Comparisons. Or click OK without making any selections.

**Comparisons with Overall Average - ANOM**  
Compares each effect least squares mean with the overall least squares mean. (Analysis of Means).

**Comparisons with Control - Dunnett’s**  
Compares each effect least squares mean with the least squares mean of a control level.

**All Pairwise Comparisons - Tukey HSD**  
Tests all pairwise comparisons of the effect least squares means using the Tukey HSD adjustment for multiplicity.

**All Pairwise Comparisons - Student’s t**  
Tests all pairwise comparisons of the effect least squares means with no multiplicity adjustment.

Each of these selections opens a report with an area at the top that shows details specific to the report. This information includes the quantile, or critical value. For the true multiple comparisons procedures, the method used for the multiple comparison adjustment is shown. If you have specified User-Defined Estimates, the report displays a list of effects that do not vary relative to the specified estimates and the levels at which these effects are set. Unless you have specified otherwise, any continuous effect is set to its mean. Any nominal or ordinal effect is set to the first level in its value ordering.

If you click OK without selecting from the Choose Initial Comparisons list, the Multiple Comparisons report opens, showing the Least Squares Means Estimates table or the User-Defined Estimates table. From the Multiple Comparison red triangle menu, all of the options listed above are available. The available reports and options are described below.
Least Squares Means or User-Defined Estimates Report

By default, the Multiple Comparisons option displays a Least Squares Means Estimates report or a User-Defined Estimates report, depending on the type of estimates that you selected in the launch window. For each combination of levels of interest, this table gives an estimate of the mean, as well as a test and confidence interval. Specifically, this table contains the following:

**Levels of the Categorical Effects** The first columns in the report identify the effect or effects of interest. The values in the columns specify the groups being analyzed.

**Estimate** An estimate of the mean for each group.

**Std Error** The standard error of the mean for each group.

**DF** The degrees of freedom for a test of whether the mean is 0.

**Lower 95%** The lower confidence limit for the mean. You can change the confidence level by selecting Set Alpha Level in the Fit Model window.

**Upper 95%** The upper confidence limit for the mean.

**t Ratio** The t ratio for the significance test. This column appears only if you right-click in the report and select Columns > t Ratio.

**Prob>|t|** The p-value for the significance test. This column appears only if you right-click in the report and select Columns > Prob>|t|.

**Arithmetic Mean Estimate** (Appears only in the Least Squares Means Estimates report.) An estimate of the arithmetic mean for each group.

**N** (Appears only in the Least Squares Means Estimates report.) The number of observations used to calculate the mean for each group.

**Note:** You can obtain t ratios and p-values by right-clicking in the table and selecting Columns.

Comparisons with Overall Average

This option compares the means for the specified levels specified to the overall mean for these levels. It displays a table showing confidence intervals for differences from the overall mean and a chart showing decision limits. The method used to make the comparisons is called analysis of means (ANOM) (Nelson et al. 2005). ANOM is a multiple comparison procedure that controls the joint error rate for all pairwise comparisons to the overall mean. See Figure 3.30 for a report based on the Lipid Data.jmp sample data table.
ANOM might appear similar to analysis of variance. However, it is fundamentally different in that it identifies levels with means that differ from the overall mean for all levels. In contrast, analysis of variance tests for differences in the means themselves.

At the top of the Comparisons with Overall Average report, you find:

- **Quantile**  The value of Nelson’s $h$ statistic used in constructing the decision limits.
- **Adjusted DF**  The degrees of freedom used in constructing the decision limits.
- **Avg**  The average mean. For least squares estimates, the average mean is a weighted average of the group least squares means. This weighted average represents the overall mean at the neutral settings where the group least squares means are calculated.

Specifically, the average least squares mean is a weighted average with weights inversely proportional to the diagonal entries of the matrix $L(X'X)^{-1}L'$. Here $L$ is the matrix of coefficients used to compute the group least squares means. For a technical definition of least squares means, see the GLM Procedure chapter in SAS Institute Inc. (2020b).

For user-defined estimates, the average mean is defined similarly. However, in this case, $L$ is the matrix of coefficients used to define the estimates.

- **Adjustment**  Describes the method used to obtain the critical value:
  - **Nelson**  Provides exact critical values and $p$-values. Used whenever possible, in particular, when the estimates are uncorrelated.
  - **Nelson-Hsu**  Provides approximate critical values and $p$-values based on Hsu’s factor analytical approximation is used (Hsu 1992). Used when exact values cannot be obtained.
  - **Sidak**  Used when both Nelson and Nelson-Hsu fail.

For technical details, see the GLM Procedure chapter in SAS Institute Inc. (2020b).

Three options are available from the Comparisons with Overall Average report menu:

- **Differences from Overall Average**
  For each comparison of a group’s mean to the overall mean, this report provides the following details:
  - The levels being compared
  - Difference - the estimated difference
  - Std Error - the standard error of the difference
  - Lower and Upper limits for the confidence interval
  - t Ratio - the ratio of the Difference and Std Error columns
Comparisons with Overall Average Decision Chart

This decision chart plots a point at the mean for each group. A horizontal line is plotted at the average mean. Upper and lower decision limits are plotted. Suppose that a point corresponding to a group mean falls outside these limits. This occurrence indicates that the group mean differs from the overall mean, based on the analysis of means test at the specified significance level. The significance level is shown below the chart.

The Comparisons with Overall Average Decision Chart report menu has these options:

**Show Summary Report**  Produces a table showing the estimate, decision limits, and the limit exceeded for each group

**Display Options**  Gives several options for controlling the display of the chart.

Calculate Adjusted P-Values

Adds a column that contains $p$-values (Prob>|t|) to the Comparisons with Overall Average report. Note that computing exact critical values and $p$-values for unbalanced designs requires complex integration and can be computationally challenging. When calculations for such a quantile fail, the Sidak quantile is computed but $p$-values are not available.

Example of Comparisons with Overall Average

Consider the Lipid Data.jmp sample data table. You are interested in whether any of the four Smoking History categories are unusual in that their mean Coffee intake (cups/day) differ from the overall average coffee intake while controlling for alcohol use and heart history. You specify a model with Coffee intake (cups/day) as the response and Smoking History, Alcohol Use, and Heart History as model effects.

1. Select **Help > Sample Data Library** and open Lipid Data.jmp.
2. Select **Analyze > Fit Model**.
3. Select **Coffee intake (cups/day)** and click **Y**.
4. Select **Smoking History**, **Alcohol Use**, and **Heart History**, and click **Add**.
5. Click **Run**.
6. Click the red triangle next to Response Coffee intake (cups/day) and select **Estimates > Multiple Comparisons**.
7. From the Choose an Effect list, select Smoking History.
8. In the Choose Initial Comparisons list, select **Comparisons with Overall Average - ANOM**.
9. Click **OK**.

The results shown in Figure 3.30 indicate that the least squares means for non-smokers and cigarette smokers differ significantly from the overall average in terms of coffee intake.
Comparisons with Control

If you select Comparisons with Control - Dunnett’s, a window opens, asking you to specify a control group. If you selected Least Squares Means Estimates, the list consists of all levels of the effect you that you selected. If you selected User-Defined Estimates, the list consists of the combinations of effect levels that you specified.

After you choose a control group and click OK, the Comparisons with Control report appears in your Fit Least Squares report. This option compares the means for the specified settings to the control group mean. It displays a table showing confidence intervals for differences from the control group and a chart showing decision limits. Dunnett’s method is used to make the comparisons. Dunnett’s method is a multiple comparison procedure that controls the error rate over all comparisons (Hsu 1996; Westfall et al. 2011).

When exact calculation of \( p \)-values and confidence intervals is not possible, Hsu’s factor analytical approximation is used (Hsu 1992). Note that computing exact critical values and \( p \)-values for unbalanced designs requires complex integration and can be computationally intensive. When calculations for such a quantile fail, the Sidak quantile is computed.
In addition to the list of effects that do not vary for the specified estimates, at the top of the Comparisons with Control report you also find:

**Quantile**  The critical value for Dunnett’s test.

**Adjusted DF**  The degrees of freedom used in constructing the confidence intervals.

**Control**  The setting that defines the control group. This is a single level if you have selected a single effect; it is a combination of levels if you specified a user-defined combination of more than one effect.

**Adjustment**  The method used to obtain the critical value:

- **Dunnett**  Provides exact critical values and $p$-values. Used whenever possible, in particular, when the estimates are uncorrelated.

- **Dunnett-Hsu**  Provides approximate critical values and $p$-values based on Hsu’s factor analytical approximation (Hsu 1992). Used when exact values cannot be obtained.

- **Sidak**  Used when both Dunnett and Dunnett-Hsu fail.

  For technical details, see the GLM Procedure chapter in SAS Institute Inc. (2020b).

Three options are available from the Comparisons with Control report menu:

**Differences from Control**

For each comparison of a group mean to the control mean, this report provides the following details:

- The levels being compared
- Difference - the estimated difference
- Std Error - the standard error of the difference
- Lower and Upper limits for the confidence interval
- $t$ Ratio - the ratio of the Difference and Std Error columns

**Comparisons with Control Decision Chart**

This decision chart plots a point at the mean for each group being compared to the control group. A horizontal line shows the mean for the control group. Upper and lower decision limits are plotted. When a point falls outside these limits, it corresponds to a group whose mean differs from the control group mean based on Dunnett’s test at the specified significance level. That level is shown beneath the chart.

The Comparisons with Control Decision Chart report menu has these options:

**Show Summary Report**  Produces a table showing the estimate, decision limits, and the limit exceeded for each group
Display Options  Gives several options for controlling the display of the chart.

Calculate Adjusted P-Values

Adds a column that contains p-values (Prob>|t|) to the Comparisons with Control report. Note that computing exact critical values and p-values for unbalanced designs requires complex integration and can be computationally challenging. When calculations for such a quantile fail, the Sidak quantile is computed but p-values are not available.

All Pairwise Comparisons

The All Pairwise Comparisons option shows either a Tukey HSD All Pairwise Comparisons or Student’s t All Pairwise Comparisons report (Hsu 1996; Westfall et al. 2011). Tukey HSD comparisons are constructed so that the significance level applies jointly to all pairwise comparisons. In contrast, for Student’s t comparisons, the significance level applies to each individual comparison. When making several pairwise comparisons using Student’s t tests, the risk that one of the comparisons incorrectly signals a difference can well exceed the stated significance level.

At the top of the Tukey HSD All Pairwise Comparisons report you find:

Quantile  The critical value for the test. Note that, for Tukey HSD, the quantile is $q / (\sqrt{2})$, where $q$ is the appropriate percentage point of the Studentized range statistic.

Adjusted DF  The degrees of freedom used in constructing the confidence intervals.

Adjustment  Describes the method used to obtain the critical value:

- **Tukey**  Provides exact critical values and p-values. Used when the means are uncorrelated and have equal variances, or when the design is variance-balanced.

- **Tukey-Kramer**  Provides approximate critical values and p-values. Used when exact values cannot be obtained.

For technical details, see the GLM Procedure chapter in SAS Institute Inc. (2020b).

At the top of the Student’s t All Pairwise Comparisons report you find the Quantile, or critical value, for the t test and DF, the degrees of freedom used for the t test.

All Pairwise Differences Report

Both Tukey HSD and Student’s t compare all pairs of levels. For each pairwise comparison, the All Pairwise Differences report shows:

- The levels being compared
- Difference - the estimated difference between the means
- Std Error - the standard error of the difference
• **t Ratio** - the $t$ ratio for the test of whether the difference is zero
• **Prob > |t|** - the $p$-value for the test
• **Lower and Upper limits** for a confidence interval for the difference in means

**All Pairwise Comparisons Scatterplot**

This plot, sometimes called a *diffogram* or a *mean-mean scatterplot*, displays the confidence intervals for all means pairwise differences. (See Figure 3.32 for an example.) Colors indicate which differences are significant.

The plot shows a reference line as an upwardly sloping line on the diagonal. This line represents points where the two means are equal. Each line segment corresponds to a confidence interval for a pairwise comparison. The coordinates of the point displayed on the line segment are the means for the corresponding groups. Hover over one of these points to show a tooltip that identifies the groups being compared and shows the estimated difference. If a line segment crosses the line on the diagonal, then the means can be equal and the comparison is not significant.

The Pairwise Comparisons Scatterplot has the following option:

**Show Reference Lines**  Displays reference grid lines for the points on the scatterplot. This is not recommended if there are many points in the scatterplot. If there are many points, it is better to hover over the points to view the tooltip labels.

**All Pairwise Differences Connecting Letters**

Use this option to display a report that illustrates significant and non-significant comparisons with connecting letters. Levels not connected by the same letter are significantly different. Levels connected by the same letter are not significantly different.

**Save All Pairwise Differences Connecting Letters Table**

This option creates a data table whose columns contain the levels of the effect, the connecting letters, the least squares means, their standard errors, and confidence intervals. The data table contains a script called Bar Chart that produces a colored bar chart of the least squares means with their confidence intervals superimposed. The levels are arranged in decreasing order of least squares means.

**Equivalence Tests**

Use this option to conduct one or more equivalence tests. Equivalence tests are useful when you want to detect differences that are of *practical* interest. You must specify a threshold difference for group means for which smaller differences are considered practically equivalent. In other words, if two group means differ by this amount or less, you are willing to consider them equivalent.
Once you have specified this value, the Equivalence Tests report appears. The bounds that you have specified are given at the top of the report. The report consists of a table giving the equivalence tests and a scatterplot that displays them. The equivalence tests and confidence intervals are based on Student’s \( t \) critical values.

**Note:** Equivalence tests are available only for the Student’s \( t \) method.

### Equivalence TOST Tests

The Two One-Sided Tests (TOST) method is used to test for a practical difference between the means (Schuirmann 1987). Two one-sided pooled-variance \( t \) tests are constructed for the null hypotheses that the true difference exceeds the threshold values. If both tests reject, the difference in the means does not statistically exceed either threshold value. Therefore, the groups are considered practically equivalent. If only one or neither test rejects, then the groups might not be practically equivalent.

For each comparison, the Equivalence TOST Tests report gives the following information:

- **Difference** - the estimated difference in the means
- **Lower Bound \( t \) Ratio, Upper Bound \( t \) Ratio** - the lower and upper bound \( t \) ratios for the two one-sided pooled-variance significance tests
- **Lower Bound \( p \)-Value, Upper Bound \( p \)-Value** - \( p \)-values corresponding to the lower and upper bound \( t \) ratios
- **Maximum \( p \)-Value** - the maximum of the lower and upper bound \( p \)-values
- **Lower and Upper limits** for a \( 1 - 2\alpha \) confidence interval for the difference in the means.

**Note:** Equivalence TOST tests are available only for the Student’s \( t \) method.

### Equivalence Tests Scatterplot

Using colors, this scatterplot indicates which means are practically equivalent and which are not practically equivalent as determined by the equivalence test. This plot is sometimes called a *diffogram* or a mean-mean scatterplot.

The plot shows a solid reference line on the diagonal as well as a shaded reference band. The width of the band is twice the practical difference. The coordinates of the point on the line segment are the means for the corresponding groups. There is an implied third axis on the diagonal where each line segment corresponds to a \( 1 - 2\alpha \) confidence interval for a pairwise comparison. Hover over one of these points to show a tooltip that indicates the groups being compared and the estimated difference. When a line segment is entirely contained within the diagonal band, it follows that the means are practically equivalent.

**Note:** Equivalence tests scatterplots are available only for the Student’s \( t \) method.
The Equivalence Tests Scatterplot has the following option:

**Show Reference Lines** Displays reference lines for the points on the scatterplot. This is not recommended if there are many points in the scatterplot. If there are many points, it is better to hover over the points to view the tooltip labels.

**Remove**

This option removes the Equivalence Tests report from the Student’s t All Pairwise Comparisons report.

**Example of Tukey HSD All Pairwise Comparisons**

Consider the Lipid Data.jmp sample data table. You are interested in Cholesterol differences for gender and non-smokers versus former smokers (Smoking History equal to no and quit, respectively) across two ages (25 and 35) and average height.

1. Select **Help > Sample Data Library** and open Lipid Data.jmp.
2. Select **Analyze > Fit Model**.
3. Select **Cholesterol** and click **Y**.
4. Select **Gender**, **Age**, **Height**, and **Smoking History**, and click **Add**.
5. Click **Run**.
6. Click the red triangle next to Response Cholesterol and select **Estimates > Multiple Comparisons**.
7. From the Type of Estimates list, click **User-Defined Estimates**.
8. From the Choose Gender levels list, select **female** (it should already be selected by default) and **male**.
9. From the Choose Smoking History levels list, select **no** and **quit**.
10. In the **Age** list, enter the ages 25 and 35 in the first two rows.

   Do not enter any values in the list entitled **Height**. Because no values for **Height** are specified, the mean value of the **Height** column is used in the multiple comparisons report.
11. Click **Add Estimates**.

   Note that all possible combinations of the levels that you specified appear in the Estimates for Comparison report.
12. In the Choose Initial Comparisons list, select **All Pairwise Comparisons - Tukey HSD**.

   Check that your window is completed as shown in Figure 3.31.
13. Click **OK**.

The All Pairwise Differences report indicates that two of the 28 pairwise comparisons are significant. The All Pairwise Comparisons Scatterplot, shown in Figure 3.32, shows the confidence intervals for these comparisons in red. You can hover over any of the points to determine which pairwise comparison the point represents. The tooltips also contain the difference between the two levels in the comparison. The two red points in Figure 3.32 represent the points comparing 35-year-old former smokers to 25-year-old non-smokers, for both females and males.
Figure 3.32  All Pairwise Comparisons Scatterplot for User-Defined Comparisons

Compare Slopes

The Compare Slopes option appears when there is one nominal term, one continuous term, and their interaction effect for the fixed effects. This option produces a report that enables you to compare the slopes in an analysis of covariance (ANCOVA) model. The report compares the slopes of each level of the interaction effect to the overall slope. The comparison uses analysis of means (ANOM) with the overall average. For more information about the analysis of means (ANOM) report, see “Comparisons with Overall Average” on page 131.

The overall average slope is a weighted average of the slopes, where the weights are inversely proportional to the variances of the slope estimates. These variances are the squared values of the Std Error column in the Differences from Overall Average Slope table.

Joint Factor Tests

The Joint Factor Test option appears when interaction effects are present. For each main effect in the model, JMP produces a joint test of whether all the coefficients for terms involving that main effect are zero. This test is conditional on all other effects being in the model. Specifically, the joint test is a general linear hypothesis test of a restricted model. In that model, all parameters that correspond to the specified effect and the interactions that contain it are set to zero.
Example of a Joint Factor Tests Report

1. Select Help > Sample Data Library and open Big Class.jmp.
2. Select Analyze > Fit Model.
3. Select weight and click Y.
4. Verify that 2 appears in the Degree box.
5. Select age, sex, and height and click Macros > Factorial to Degree.
6. Click Run.
7. Click the Response weight red triangle and select Estimates > Joint Factor Tests.

Figure 3.33 Joint Factor Tests Report

<table>
<thead>
<tr>
<th>Term</th>
<th>DF</th>
<th>Sum of Squares</th>
<th>F Ratio</th>
<th>Prob &gt; F</th>
</tr>
</thead>
<tbody>
<tr>
<td>age</td>
<td>15</td>
<td>6156.2127</td>
<td>2.8488</td>
<td>0.0139*</td>
</tr>
<tr>
<td>sex</td>
<td>7</td>
<td>2113.1080</td>
<td>2.1091</td>
<td>0.0879</td>
</tr>
<tr>
<td>height</td>
<td>7</td>
<td>9217.8156</td>
<td>9.2002</td>
<td>&lt;0.001*</td>
</tr>
</tbody>
</table>

Note that the test for age has 15 degrees of freedom. This test involves the five parameters for age, the five parameters for age*sex, and the five parameters for height*age. The null hypothesis for this test is that all 15 parameters are zero.

Inverse Prediction

*Inverse prediction* occurs when you use a statistical model to infer the value of an explanatory variable, given a value of the response variable. Inverse prediction is sometimes referred to as *calibration*.

By selecting Inverse Prediction on the Estimates menu, you can estimate values of an independent variable, X, that correspond to specified values of the response (Figure 3.37). In addition, you can specify values for other explanatory variables in the model (Figure 3.37). The inverse prediction computation provides confidence limits for values of X that correspond to the specified response value. You can specify the response value to be the mean response or simply an individual response. For an example, see “Example of Inverse Prediction” on page 143.

Analyzing Multiple Explanatory Variables

When the model includes multiple explanatory variables, you can predict the value of X for the specified values of the other variables. You might want to predict the amount of running time that results in an oxygen uptake of 50 when one’s resting pulse rate is 60. You might want separate inverse predictions for both males and females. Specify these requirements using the inverse prediction option.
The inverse prediction window shows the list of explanatory variables to the left. (See Figure 3.37 for an example.) Each continuous variable is initially set to its mean. Each nominal or ordinal variable is set to its lowest level (in terms of value ordering). You must remove the value for the variable that you want to predict, setting it to missing. Also, you must specify the values of the other variables for which you want your inverse prediction to hold (if these differ from the default settings). In the list to the right in the window, you can supply one or more response values of interest. For an example, see “Example of Predicting a Single X Value with Multiple Model Effects” on page 145.

**Note:** The confidence limits for inverse prediction can sometimes result in a one-sided or even an infinite interval. For technical details, see “Inverse Prediction with Confidence Limits” on page 564 in the “Statistical Details” appendix.

### Example of Inverse Prediction

In this example, you fit a regression model that predicts oxygen uptake from Runtime. Then you estimate the Runtime values that result in specified oxygen uptake values. There is only a single X, Runtime, so you start by using the Fit Y by X platform to obtain a visual approximation of the inverse prediction values.

1. Select **Help > Sample Data Library** and open Fitness.jmp.
2. Select **Analyze > Fit Y by X**.
3. Select Oxy and click **Y, Response**.
4. Select Runtime and click **X, Factor**.
5. Click **OK**.
6. Click the Bivariate Fit of Oxy By Runtime red triangle and select **Fit Line**.
   Use the crosshairs tool as described below to approximate the Runtime value that results in a mean Oxy value of 50.
7. Select **Tools > Crosshairs**.
8. Click on the prediction line and then drag the crosshairs tool to find the inverse prediction for Oxy = 50.

Figure 3.34 shows that a Runtime of about 9.77 gives an inverse prediction of about 50 for Oxy.
To obtain an exact prediction for Runtime, along with a confidence interval, use the Fit Model launch window:

1. From the Fitness.jmp sample data table, select **Analyze > Fit Model**.
2. Select Oxy and click Y.
3. Select Runtime and then click Add.
4. Click Run.
5. Click the Response Oxy red triangle and select **Estimates > Inverse Prediction**.
6. Enter four values for Oxy as shown in Figure 3.35.
7. Click OK.

Figure 3.35  Completed Inverse Prediction Specification Window
The Inverse Prediction report gives predicted Runtime values that correspond to each specified Oxy value. The report also shows upper and lower 95% confidence limits for these Runtime values, relative to obtaining the mean response.

Figure 3.36 Inverse Prediction Report

The exact predicted Runtime resulting in an Oxy value of 50 is 9.7935. This value is close to the approximate Runtime value of 9.77 found in the Bivariate Fit report shown in Figure 3.34. The Inverse Prediction report also gives a plot showing the linear relationship between Oxy and Runtime and the confidence intervals.

Example of Predicting a Single X Value with Multiple Model Effects

This example predicts the Runtime that results in oxygen uptake of 50 when RstPulse is 60. The Runtime is predicted for both males and females.

1. From the Fitness jmp sample data table, select Analyze > Fit Model.
2. Select Oxy and click Y.
3. Select Sex, Runtime, and RstPulse and then select Add.
4. Click Run.
5. Click the Response Oxy red triangle and select Estimates > Inverse Prediction.
6. Delete the value for Runtime, because you want to predict that value.
7. Select the All box next to Sex to estimate Runtime for all levels of Sex.
8. Replace the mean for RstPulse with 60.
9. Enter the value 50 for Oxy as shown in Figure 3.37.
10. Click OK.
Figure 3.37 Inverse Prediction Specification for a Multiple Regression Model

The report, shown in Figure 3.38, gives the predicted values of Runtime for both females and males. The report also includes 95% confidence intervals for Runtime values that give a mean response of 50.

Figure 3.38 Inverse Prediction Report for a Multiple Regression Model

The plot shows the linear fits for females and males, given that RstPulse is 60. The two confidence intervals are shown in red and blue, respectively.

Cox Mixtures

Note: This option is available only for mixture models.
Standard least squares fits mixture models using the parameterization suggested in Scheffé (1958). The parameters for this model cannot easily be used to judge the effects of the mixture components. The Cox Mixture model is a reparameterized and constrained version of the Scheffé model. Using its parameter estimates, you can derive factor effects and the response surface shape relative to a reference point in the design space. See Cornell (1990) for a complete discussion.

The Cox Mixture option opens a window where you enter the reference mixture. If you enter components for the reference mixture that do not sum to one, then the components are proportionately scaled so that they do sum to one. The rescaled mixture is shown in the report as the Reference Mixture. The component effects also appear in the report. A Cox component effect is the difference in the predicted response as the factor goes from its minimum to maximum values along the Cox effect direction.

**Example of Cox Mixtures**

1. Select **Help > Sample Data Library** and open Five Factor Mixture.jmp.
2. Select **Analyze > Fit Model**.
3. Select Y1 and click **Y**.
4. Select X1 through X5.
5. Select **Macros > Mixture Response Surface**.
6. Click **Run**.
7. Click the Response Y1 red triangle and select **Estimates > Cox Mixtures**.
8. In the Reference Mixture specification window, enter the following values:
   - Next to X1, type 0.15.
   - Next to X2, type 0.25.
   - Next to X3, type 0.4.
   - Next to X4, type 0.1.
   - Next to X5, type 0.1.
9. Click **OK**.
The report shows the parameter estimates for the Cox mixture model, along with standard errors and hypothesis tests. The reference mixture appears on the right. The component effects appear below, along with the component ranges.

**Parameter Power**

The *power* of a statistical test is the probability that the test will be significant, if a difference actually exists. The power of the test indicates how likely your study is to declare a true effect to be significant. The Parameter Power option addresses *retrospective* power analysis.

**Note:** To ensure that your study includes sufficiently many observations to detect the required differences, use information about power when you *design* your experiment. This type of analysis is called *prospective* power analysis. Consider using the DOE platform to design your study. Both DOE > Sample Size and Power and DOE > Evaluate Design are useful for prospective power analysis. For an example of a prospective power analysis using standard least squares, see “Prospective Power Analysis” on page 215.
The power of a test to detect a difference is affected by the following factors:

- the sample size
- the unknown residual error variance
- the significance level of the test
- the size of the effect to be detected

Suppose that you have already conducted your study, analyzed your data, and found that an effect of interest is not significant. You might be interested in the size of the difference that you might have been likely to detect or the power of the test that you conducted. Or you might want to know the number of observations that you would have needed to detect a difference of a given size with high probability.

The Parameter Power option inserts three columns of values relating to retrospective power analysis in the Parameter Estimates report. The least significant value (LSV0.05), the least significant number (LSN0.05), and a power calculation (AdjPower0.05) are provided.

The Parameter Power calculations apply to a new sample that has the same variability profile as the observed sample.

**Caution:** The results provided by the LSV0.05, LSN, and AdjPower0.05 should not be used in prospective power analysis. They do not reflect the uncertainty inherent in a future study.

- LSV0.05 is the least significant value. This number is the smallest absolute value of the estimate that would make this test significant at significance level 0.05. To be more specific, suppose that the number of observations, the mean square error and that the sum of squares and cross-products matrix for the design remain unchanged. Then, if the absolute value of the estimate had been less than LSV0.05, the Prob>|t| value would have exceeded 0.05. (See “The Least Significant Value (LSV)” on page 213.)

- LSN is the least significant number. This number is the number of observations that would make this test significant at significance level 0.05. Specifically, suppose that the estimate of the parameter, the mean square error, and the sum of squares and cross-products matrix for the design remain unchanged. Then, if the number of observations had been less than the LSN, the Prob>|t| value would have exceeded 0.05. (See “The Least Significant Number (LSN)” on page 212.)

- AdjPower0.05 is the adjusted power value. This number is an estimate of the probability that this test will be significant. Sample values from the current study are substituted for the parameter values typically used in a power calculation. The adjusted power calculation adjusts for bias that results from direct substitution of sample estimates into the formula for the non-centrality parameter (Wright and O’Brien 1988). (See “The Adjusted Power and Confidence Intervals” on page 213.)
The LSV, LSN, and adjusted power are useful in assessing a test’s sensitivity. These retrospective calculations also provide an enlightening instructional tool. However, you must be cautious in interpreting these values (Hoenig and Heisey 2001).

For more information about LSV, LSN, and adjusted power, see “Power Analysis” on page 209. For an example of a retrospective analysis, see “Example of Retrospective Power Analysis” on page 214.

Correlation of Estimates

The Correlation of Estimates command on the Estimates menu computes the correlation matrix for the parameter estimates. These correlations indicate whether collinearity is present.

For insight on the construction of this matrix, consider the typical least squares regression formulation. Here, the response ($Y$) is a linear function of predictors ($x$’s) plus error ($\varepsilon$):

$$ Y = \beta_0 + \beta_1 x_1 + \ldots + \beta_p x_p + \varepsilon $$

Each row of the data table contains a response value and values for the $p$ predictors. For each observation, the predictor values are considered fixed. However, the response value is considered to be a realization of a random variable.

Considering the values of the predictors fixed, for any set of $Y$ values, the coefficients, $\beta_0, \beta_1, \ldots, \beta_p$, can be estimated. In general, different sets of $Y$ values lead to different estimates of the coefficients. The Correlation of Estimates option calculates the theoretical correlation of these parameter estimates. (For technical details, see “Details of Custom Test Example” on page 204.)

The correlations of the parameter estimates depend solely on the predictor values and a term representing the intercept. The correlation between two parameter estimates is not affected by the values of the response.

A high positive correlation between two estimates suggests that a collinear relationship might exist between the two corresponding predictors. Note, though, that you need to interpret these correlations with caution (Belsley et al. 1980, p. 185, 92-94). Also, a rescaling of a predictor that shifts its mean changes the correlation of its parameter estimate with the intercept’s value.

Example of Correlation of Estimates

1. Select Help > Sample Data Library and open Socioeconomic.jmp.
2. Select Analyze > Fit Model.
3. Select Median House Value and click Y.
4. Select Total Population, Median School Years, Total Employment, and Professional Services and click Add.
5. In the Emphasis list, select **Minimal Report**.

6. Click **Run**.

7. Click the red triangle next to Response Median House Value and select **Estimates > Correlation of Estimates**.

**Figure 3.40** Correlation of Estimates Report

<table>
<thead>

</tbody>
</table>

The report shows high negative correlations between the parameter estimates for the Intercept and Median School Years (–0.9818). High negative correlations also exist between Total Population and Total Employment (–0.9746).

### Coding for Nominal Effects

When you enter a column with a nominal modeling type into your model, JMP represents it internally as a set of continuous indicator variables. Each variable assumes only the values –1, 0, and 1. (Note that this coding is one of many ways to use indicator variables to code nominal variables.) If your nominal column has \( n \) levels, then \( n-1 \) of these indicator variables are needed to represent it. (The need for \( n-1 \) indicator variables relates directly to the fact that the main effect associated with the nominal column has \( n-1 \) degrees of freedom.) Full details are covered in “Nominal Factors” on page 535 in the “Statistical Details” appendix.

**Tip:** You can view the coding by selecting Save Columns > Save Coding Table from the red triangle menu for the main report. See “Save Coding Table” on page 181.

Suppose that you have a nominal column with four levels. Take, as an example, the treatment column in the Cholesterol.jmp sample data table. The treatment column has four levels: A, B, Control, and Placebo. Each of the first three levels is represented by an indicator variable. These indicator variables are named treatment[A], treatment[B], and treatment[Control].

The indicator variable for a given level assigns the values 1 to that level, –1 to the last level, and 0 to the remaining levels. Table 3.1 shows the definitions of the treatment[A], treatment[B], and treatment[Control] indicator variables for this example. For example, consider the indicator variable treatment[A]. As shown in Table 3.1, this variable assigns the following values:

- The value 1 is assigned to rows that have treatment = A
• The value 0 is assigned to rows that have treatment = B or Control
• The value –1 is assigned to rows that have treatment = Placebo

The order of the levels is determined either by the Value Order column property, if you have assigned one, or by the default ordering assigned by JMP. The default ordering is typically the numeric sorting order for numbers and the alphanumeric sorting order for character data. However, certain categorical values, such as the names of months, are sorted appropriately by default. For more information about value ordering, see Using JMP.

These variables are used to parametrize the model. They do not typically appear in the data table, but the estimated coefficients for these variables are given in the Parameter Estimates and other reports. Although many other codings are possible, this coding has proven to be practical and interpretable.

For information about the coding of ordinal effects, see “Ordinal Factors” on page 547 in the “Statistical Details” appendix.

Effect Screening

A screening design often provides no degrees of freedom for error. So classical tests for effects are not available. In such cases, Effect Screening is particularly useful.

For these designs, most inferences about effect sizes assume that the estimates for non-intercept parameters are uncorrelated and have equal variances. These assumptions hold for the models associated with many classical experimental designs. However, there are situations where these assumptions do not hold. In both of these situations, the Effect Screening platform guides you in determining which effects are significant.
The Effect Screening platform uses the principle of *effect sparsity* (Box and Meyer 1986). This principle asserts that relatively few of the effects that you study in a screening design are active. Most are inactive, meaning that their true effects are zero and that their estimates are random error.

The following Effect Screening options are available:

**Scaled Estimates**  
Gives parameter estimates corresponding to factors that are scaled to have a mean of zero and a range of two. See “Scaled Estimates and the Coding of Continuous Terms” on page 153.

**Normal Plot**  
Identifies parameter estimates that deviate from normality, helping you determine which effects are active. See “Normal Plot Report” on page 159.

**Bayes Plot**  
Computes posterior probabilities for all model terms using a Bayesian approach. See “Bayes Plot Report” on page 160.

**Pareto Plot**  
Plots the absolute values of the orthogonalized and standardized parameter estimates, relating these to the sum of their absolute values. See “Pareto Plot Report” on page 162.

### Scaled Estimates and the Coding of Continuous Terms

A parameter estimate is highly dependent on the scale of its corresponding factor. When you convert a factor from grams to kilograms, its parameter estimate changes by a multiple of a thousand. When you apply the same change to a squared (quadratic) term, its parameter estimate changes by a multiple of a million.

To better understand and compare effect sizes, you should examine parameter estimates in a scale-invariant fashion. It makes sense to use a scale that relates the size of a parameter estimate to the size of the effect of its corresponding term on the response. There are many approaches to doing this.

The Effect Screening > Scaled Estimates option in the report’s red triangle menu gives coefficients corresponding to scaled factors. The factors are scaled to have a mean of zero and a range of two. Figure 3.41 shows a report for Drug.jmp.

If the sample values for the factor are such that the maximum and minimum values are equidistant from the sample mean, then the scaled factor ranges from –1 to 1. This scaling corresponds to the traditional coding used in the design of experiments. In the case of regression with a single factor, the scaled parameter estimate is half of the predicted response change as the factor travels its whole range.

Scaled estimates are important in assessing the impact of model terms when the data involve uncoded values. For orthogonal designs, the scaled estimates are identical to the estimates for the uncoded data.
**Note:** The Coding column property scales factor values linearly so that their coded values range from −1 to 1. Parameter estimates are given in terms of these coded values, so that scaled estimates are not required in this situation. (Unlike the transformation used to obtain scaled estimates, the coded values might not have mean zero.)

**Example of Scaled Estimates**

1. Select Help > Sample Data Library and open Drug.jmp.
2. Select Analyze > Fit Model.
3. Select y and click Y.
4. Select Drug and x and add these to the Construct Model Effects list.
6. Click Run.
7. Click the Response y red triangle and select Effect Screening > Scaled Estimates.

The report indicates that the continuous factor, x, is centered by its mean and scaled by its half-range.

**Figure 3.41 Scaled Estimates Report**

The model fits three parallel lines, one for each Drug group. The x values range from 3 to 21. The Scaled Estimate for x, 8.8846543, is half the difference between the predicted value for x = 21 and the predicted value for x = 3 for any one of the Drug groups. You can verify this fact by selecting Save Columns > Prediction Formula from the report’s red triangle menu. Then add rows to obtain predicted values for each of the Drug groups at x = 21 and x = 3.

So, over the range of x values in this particular data set, the impact of x is to vary the response over a range of about 17.8 units. Note that the parameter estimate for x based on the raw data is 0.9871838; it does not permit direct interpretation in terms of the response.

**Plot Options**

The Normal, Bayes, and Pareto Plot options provide reports that appear as part of the Effect Screening report. These reports can be constructed so that they correct for unequal variances and correlations among the estimates.
Note: The Normal, Bayes, and Pareto Plot options require that your model involves at least four parameters. One of these parameters can be the intercept.

Transformations

When you select any of the plot options, the following information appears directly beneath the Effect Screening report title:

- If the estimates have equal variances and are uncorrelated, these two notes appear:
  - The parameter estimates have equal variances.
  - The parameter estimates are not correlated.
- If the estimates have unequal variances or are correlated, then an option list replaces the relevant note. The list items selected by default show that JMP has transformed the estimates. If you want to undo either or both transformations, select the appropriate list items.

Lenth PSE Values

A Lenth PSE (pseudo standard error) table appears directly beneath the notes or option lists. (For a description of the PSE, see “Lenth’s PSE” on page 118.) The statistics that appear in the Lenth table depend on the variances and correlation of the parameter estimates.

When the parameter estimates have equal variances and are uncorrelated, the Lenth table provides the following statistic:

Lenth PSE  The Lenth pseudo standard error for the estimates.

When the parameter estimates have unequal variances or are correlated or both, the Lenth table provides the following statistics:

- **t-Test Scale Lenth PSE**  The Lenth pseudo standard error computed for the transformed parameter estimates divided by their standard errors in the transformed scale.
- **Coded Scale Lenth PSE**  The Lenth pseudo standard error for the transformed parameter estimates.

Parameter Estimate Population Report

The Parameter Estimate Population report gives tests for the parameter estimates. The tests are based on transformations as specified in the option lists.

- The option **Using estimates standardized to have equal variances** applies a normalizing transformation to standardize the variances. This option is selected by default when the variances are unequal.
• The option **Using estimates orthogonalized to be uncorrelated** applies a transformation to remove correlation. This option is selected by default when the estimates are correlated. The transformation that is applied is identical to the transformation that is used to calculate sequential sums of squares. The estimates measure the additional contribution of the variable after all previous variables have been entered into the model.

• If the notes indicate that the estimates have equal variances and are not correlated, no transformation is applied.

The columns that appear in the table depend on the selections initially described in the notes or option lists. The report highlights any row corresponding to an estimate with a $p$-value of 0.20 or less. All versions of the report give Term, Estimate, and either $t$-Ratio and Prob>|t| or Pseudo $t$-Ratio and Pseudo $p$-Value.

**Term**  Gives the model term whose parameter estimate is of interest.

**Estimate**  Gives the estimate for the parameter. Estimate sizes can be compared only when the model effects have identical scaling.

**$t$-Ratio**  Appears if there are degrees of freedom for error. This value is the parameter estimate divided by its standard error.

**Prob>|t|**  Gives the $p$-value for the test. If a transformation is applied, this option gives the $p$-value for a test using the transformed data.

**Pseudo $t$-Ratio**  Appears when there are no degrees of freedom for error. If the relative standard errors of the parameters are equal, Pseudo $t$-Ratio is the parameter estimate divided by Lenth’s PSE. If the relative standard errors vary, it is calculated as shown in “Pseudo $t$-Ratios” on page 118.

**Pseudo $p$-Value**  Appears when there are no degrees of freedom for error. The $p$-value is derived using a $t$ distribution. The degrees of freedom are $m/3$, rounded down to the nearest integer, where $m$ is the number of parameters.

If **Using estimates standardized to have equal variances** is selected and the note indicating that the parameter estimates are not correlated appears, the report shows a column called Standardized Estimate. This column provides estimates of the parameters resulting from the transformation used to transform the estimates to have equal variances.

If both **Using estimates standardized to have equal variances** and **Using estimates orthogonalized to be uncorrelated** are selected, the report gives a column called Orthog Coded. The following information is provided:

**Orthog Coded**  Gives the estimate of the parameter resulting from the transformation that is used to orthogonalize the estimates.

**Orthog $t$-Ratio**  Appears if there are degrees of freedom for error. Gives the $t$ ratio for the transformed estimates.
**Pseudo Orthog t-Ratio**  Appears if there are no degrees of freedom for error. It is a \( t \) ratio computed by dividing the orthogonalized estimate, Orthog Coded, by Coded Scale Lenth PSE.

**Effect Screening Report**

Figure 3.42 shows the Effect Screening report that you create by running the Fit Model script in the Bicycle.jmp sample data table. Note that you would select **Effect Screening > Normal Plot** in order to obtain this form of the report. The notes directly beneath the report title indicate that no transformation is required. Consequently, the Lenth PSE is displayed. Because there are no degrees of freedom for error, no estimate of residual error can be constructed. For this reason, Lenth’s PSE is used as an estimate of residual error to obtain pseudo \( t \) ratios. Pseudo \( p \)-values are given for these \( t \) ratios. Rows for non-intercept terms corresponding to the three estimates with \( p \)-values of 0.20 or less are highlighted.

**Figure 3.42  Effect Screening Report for Equal Variance and Uncorrelated Estimates**

**Effect Screening Report for Unequal Variances and Correlated Estimates**

In the Odor.jmp sample data table, run the Model script and click **Run**. To create the report shown in Figure 3.43, click the Response Y red triangle and select **Effect Screening > Normal Plot**. You can also create the report by clicking the Response Y red triangle and selecting the Bayes Plot or Pareto Plot options.

The notes directly beneath the report title indicate that transformations were required both to standardize and orthogonalize the estimates. The correlation matrix is shown in the Correlation of Estimates report.

The report shows the \( t \)-Test Scale and Coded Scale Lenth PSEs. But, because there are degrees of freedom for error, the tests in the Parameter Estimate Population report do not use the Lenth PSEs. Rows for non-intercept terms corresponding to the three estimates with \( p \)-values of 0.20 or less are highlighted. A note at the bottom of the Parameter Estimate Population report indicates that orthogonalized estimates depend on their order of entry into the model.
### Correlations of Estimates Report

The Correlations of Estimates report appears only if the estimates are correlated (Figure 3.43). The report provides the correlation matrix for the parameter estimates. This matrix is similar to the one that you obtain by selecting the Estimates > Correlation of Estimates red triangle option. However, to provide a more compact representation, the report does not show column headings. See “Correlation of Estimates” on page 150.

### “Transformation to make uncorrelated” Report

The “Transformation to make uncorrelated” report appears only if the estimates are correlated. The report gives the matrix used to transform the design matrix to produce uncorrelated parameter estimates. The transformed, or orthogonally coded, estimates are obtained by pre-multiplying the original estimates with this matrix and multiplying the result by a scale factor. The scale factor is a function of the root mean square error (RMSE) and the number of rows. It is defined as follows:

\[ \text{RMSE} / \sqrt{\text{NRows}} \]

The transformation matrix can be obtained using the Cholesky decomposition. Express \( X'X \) as \( LL' \), where \( L \) is the lower triangular matrix in the Cholesky decomposition. Then the transformation matrix is given by \( L' \).
This transformation orthonormalizes each regressor with respect to the regressors that precede it in the ordering of model terms. The transformation produces a diagonal covariance matrix with equal diagonal elements. The coded estimates are a result of this iterative process.

**Note:** The orthogonally coded estimates depend on the order of terms in the model. Each effect’s contribution is estimated only after it is made orthogonal to previously entered effects. Consider entering main effects first, followed by two-way interactions, then three-way interactions, and so on.

## Normal Plot Report

Below the Normal Plot report title, select either a normal plot or a half-normal plot (Daniel 1959). Both plots are predicated on the principle of effect sparsity, namely, the idea that relatively few effects are active. Those effects that are inactive represent random noise. Their estimates can be assumed to have a normal distribution with mean 0 and variance $\sigma^2$, where $\sigma^2$ represents the residual error variance. It follows that, on a normal probability plot, estimates representing inactive effects fall close to a line with slope $\sigma$.

### Normal Plot

If no transformation is required, the vertical coordinate of the normal plot represents the value of the estimate and the horizontal coordinate represents its normal quantile. Points that represent inactive effects should follow a line with slope of $\sigma$. Lenth’s PSE is used to estimate $\sigma$ and a blue line with this slope is shown on the plot.

If a transformation to orthogonality has been applied, the vertical axis represents the Normalized Estimates. These are the Orthog $t$-Ratio values found in the Parameter Estimate Population report. (The Orthog $t$-Ratio values are the Orthog Coded estimates divided by the Coded Scale Lenth PSE.)

Because the estimates are normalized by an estimate of $\sigma$, the points corresponding to inactive effects should fall along a line of slope 1. A red line with slope 1 is shown on the plot, as well as a blue line with slope equal to the t-Test Scale Lenth PSE.

In all cases, estimates that deviate from normality at the 0.20 level, based on the $p$-values in the Parameter Estimate Population report, are labeled on the plot.

### Half-Normal Plot

The half normal plot shows the absolute values of effects. The construction of the axes and the lines displayed mirror those aspects of normal plot.
Figure 3.44 shows the Normal Plot report for the Bicycle.jmp sample data table. No transformation is needed for this model, so the plot shows the raw estimates plotted against their normal quantiles. A line with slope equal to Lenth’s PSE is shown on the plot. The plot suggests that Gear, Dynamo, and Seat are active factors.

**Example of a Normal Plot**

1. Select Help > Sample Data Library and open Bicycle.jmp.
2. Select Analyze > Fit Model.
3. Select Y and click Y.
4. Select HBars through Brkfast and click Add.
5. Click Run.
6. Click the Response Y red triangle and select Effect Screening > Normal Plot.

The following Normal Plot appears.

**Bayes Plot Report**

The Bayes Plot report gives another approach to determining which effects are active. This report helps you compute posterior probabilities using a Bayesian approach. This method, due to Box and Meyer (1986), assumes that the estimates are a mixture from two distributions. The majority of the estimates, corresponding to inactive effects, are assumed to be pure random normal noise with variance $\sigma^2$. The remaining estimates, the active ones, are assumed to come from a contaminating distribution that has a variance $K$ times larger than $\sigma^2$.

**Term**  
Gives the model term corresponding to the parameter estimate.
**Estimate**  Gives the parameter estimate. The Bayes plot is constructed with respect to estimates that have estimated standard deviation equal to 1. If the estimates are not correlated, the t-Ratio is used. If the estimates are correlated, the Orthog t-Ratio is used.

**Prior Prob**  Enables you to specify a probability that the estimate is nonzero (equivalently, that the estimate is in the contaminating distribution). Prior probabilities for estimates are usually set to equal values. The commonly recommended value of 0.2 appears initially, though you can change it.

**K Contam**  The value of the contamination coefficient, representing the ratio of the contaminating distribution variance to the error variance. $K$ is commonly set to 10, which is the default value.

**Std Err Scale**  If there are degrees of freedom for an estimate of standard error, this value is set to 1. JMP uses this value because the estimates used in the report are transformed and scaled to unit variance. The value is set to 0 for a saturated model with no estimate of error. If you specify a different value, think of it in terms of a scale factor of the RMSE estimate.

**DFE**  Gives the error degrees of freedom.

The specifications window, showing default settings for a Bayes Plot for the Bicycle.jmp sample data table, is shown in Figure 3.45. Clicking Go in this window updates the report to show Posterior probabilities for each of the terms and a bar chart (Figure 3.46).

**Example of a Bayes Plot**

1. Select **Help > Sample Data Library** and open Bicycle.jmp.
2. Select **Analyze > Fit Model**.
3. Select **Y** and click **Y**.
4. Select **HBars** through **Brkfast** and click **Add**.
5. Click **Run**.
6. Click the Response Y red triangle and select **Effect Screening > Bayes Plot**.

**Figure 3.45**  Bayes Plot Specifications

7. Click **Go** to calculate the posterior probabilities.
Figure 3.46  Bayes Plot Report

![Bayes Plot](image)

The note beneath the plot in the Bayes Plot report gives the Posterior Prob that the sample is uncontaminated. Posterior Prob is the probability, based on the priors and the data, that there are no active effects whatsoever. The probability is small, 0.0144, indicating that it is likely that there are active effects. The Posterior probability column suggests that at least Dynamo and Gear are active effects.

Pareto Plot Report

The Pareto Plot report presents a Pareto chart of the absolute values of the estimates. Figure 3.47 shows a Pareto Plot report for the Bicycle.jmp sample data table.

- If the original estimates have equal variances and are not correlated, the original estimates are plotted.
- If the original estimates have unequal variances and are not correlated, the $t$ ratios are plotted.
- If the original estimates have unequal variances and are correlated, the Orthog Coded estimates are plotted.

The cumulative sum line in the plot sums the absolute values of the estimates. Keep in mind that the orthogonal estimates depend on the order of entry of terms into the model.

**Note:** The estimates that appear in the plot are standardized to have equal variances and are transformed to be orthogonal. You have the option of undoing these transformations. See “Transformations” on page 155.

Figure 3.47  Pareto Plot
Factor Profiling

The Factor Profiling menu helps you explore and visualize your estimated model. You can explore the shape of the response surface, find optimum settings, simulate response data based on your specified noise assumptions, and transform the response if needed.

The Profiler, Contour Profiler, Mixture Profiler, and Surface Profiler are extremely versatile tools whose use extends beyond standard least squares models. For more information about their interpretation and use, see Profilers.

If the response column in your model contains an invertible transformation of one variable, the profilers and Interaction Plots show the response on the untransformed scale.

The following Factor Profiling options are available:

**Note:** If your model contains an expression or vector as an effect, most of these options are not available.

**Profiler**  Shows prediction traces for each X variable. Enables you to find optimum settings for one or more responses and to explore response distributions using simulation. See “Profiler” on page 164 and Profilers.

**Interaction Plots**  Shows a matrix of interaction plots, when there are interaction effects in the model. See “Interaction Plots” on page 165.

**Contour Profiler**  Provides an interactive contour profiler, which is useful for optimizing response surfaces graphically. See “Contour Profiler” on page 166 and Profilers.

**Mixture Profiler**  Shows response contours of mixture experiment models on a ternary plot. See “Mixture Profiler” on page 167 and Profilers.

**Note:** This option appears only if you apply the Mixture Effect attribute to three or more effects or the Mixture property to three or more columns.

**Cube Plots**  Shows predicted values for the extremes of the factor ranges laid out on the vertices of cubes. See “Cube Plots” on page 168.

**Box Cox Y Transformation**  Finds a Box-Cox power transformation of the response that is best in terms of satisfying the normality and homogeneity of variance assumptions. See “Box Cox Y Transformation” on page 169.

**Surface Profiler**  Shows a three-dimensional surface plot of the response surface. See “Surface Profiler” on page 171 and Profilers.
Profiler

Note: For more information about the profiler, see Profilers.

The **Profiler** (or Prediction Profiler) shows prediction traces for each X variable.

Figure 3.48 illustrates part of the profiler for the Reactor.jmp sample data table. The vertical dotted line for each X variable shows its current value or current setting. Use the Profiler to change one variable at a time in order to examine the effect on the predicted response.

Figure 3.48 Illustration of Prediction Traces

The factors F and Ct in Figure 3.48 are continuous. If the factor is nominal, the levels are displayed on the horizontal axis.

For each X variable, the value above the factor name is its current value. You change the current value by clicking in the graph or by dragging the dotted line where you want the new current value to be.

- The horizontal dotted line shows the current predicted value of each Y variable for the current values of the X variables.
- The black lines within the plots show how the predicted value changes when you change the current value of an individual X variable. The 95% confidence interval for the predicted values is shown by a dotted curve surrounding the prediction trace (for continuous variables) or an error bar (for categorical variables).
Interaction Plots

When there are interaction effects in the model, the Interaction Plots option shows a matrix of interaction plots. Each cell of the matrix contains a plot whose horizontal axis is scaled for the effect displayed in the column in which the plot appears. Line segments are plotted for the interaction of that effect with the effect displayed in the corresponding row. So, an interaction plot shows the interaction of the row effect with the column effect.

A line segment is plotted for each level of the row effect. Response values predicted by the model are joined by line segments. Non-parallel line segments give visual evidence of possible interactions. However, the $p$-value for such a suggested interaction should be checked before concluding that it exists. Figure 3.49 gives an interaction plot matrix for the Reactor.jmp sample data table.

Example of Interaction Plots

1. Select Help > Sample Data Library and open Reactor.jmp.
2. Select Analyze > Fit Model.
3. Select Y and click Y.
4. Make sure that the Degree box has a 2 in it.
5. Select Ct, A, T, and Cn and click Macros > Factorial to Degree.
6. Click Run.
7. Click the Response Y red triangle and select Factor Profiling > Interaction Plots.

Figure 3.49 Interaction Plots
The plot corresponding to the $T^*Cn$ interaction is the third plot in the bottom row of plots or equivalently, the third plot in the last column of plots. Either plot shows that the effect of $Cn$ on $Y$ is fairly constant at the low level of $T$, whether $Cn$ is set at a high or low level. However, at the high level of $T$, the effect of $Cn$ on $Y$ differs based on its level. $Cn$ at –1 leads to a higher predicted $Y$ than $Cn$ at 1. Note that this interaction is significant with a $p$-value < 0.0001.

In certain designs, two-way interactions are aliased with other two-way interactions. When this aliasing occurs, cells in the Interaction Profiles plot corresponding to these interactions are dimmed.

**Contour Profiler**

**Note:** For more information about the contour profiler, see *Profiler*.

Use the interactive Contour Profiler for optimizing response surfaces graphically. The Contour Profiler shows contours for the fitted model for two factors at a time. The report also includes a surface plot.

Figure 3.50 shows a contour profiler view for the Tiretread.jmp sample data table. Run the data table script **RSM for 4 Responses** and select **Profiler > Contour Profiler** from the Least Squares Fit report menu.
Figure 3.50 Contour Profiler

Mixture Profiler

Note: This option appears only if you specify the Macros > Mixture Response Surface option for an effect. For more information about the mixture profiler, see Profilers.

The Mixture Profiler shows response contours of mixture experiment models on a ternary plot. Use the Mixture Profiler when three or more factors in your experiment are components in a mixture. The Mixture Profiler helps you visualize and optimize the response surfaces of your experiment.
Figure 3.51 shows the Mixture Profiler for the model in the Plasticizer.jmp sample data table. Run the Model data table script and then select Factor Profiling > Mixture Profiler from the report’s red triangle menu. You modify plot axes for the factors by selecting different radio buttons at the top left of the plot. The Lo and Hi Limit columns at the upper right of the plot let you enter constraints for both the factors and the response.

Figure 3.51 Mixture Profiler

Cube Plots

The Cube Plots option displays predicted values for the extremes of the factor ranges. These values appear on the vertices of cubes (Figure 3.52). The vertices are defined by the smallest and largest observed values of the factor. When you have multiple responses, the multiple responses are shown stacked at each vertex.
Example of Cube Plots

1. Select Help > Sample Data Library and open Reactor.jmp.
2. Select Analyze > Fit Model.
3. Select Y and click Y.
4. Make sure that the Degree box has a 2 in it.
5. Select Ct, A, T, and Cn and click Macros > Factorial to Degree.
6. Click Run.
7. Click the Response Y red triangle and select Factor Profiling > Cube Plots.

Figure 3.52 Cube Plots

Note that there is one cube for Cn = –1 and one for Cn = 1. To change the layout so that the factors are mapped to different cube coordinates, click a factor name in the first cube. Drag it to cover the factor name for the desired axis. For example, in Figure 3.52, if you click T and drag it over Ct, then T and Ct (and their corresponding coordinates) exchange places. To see the levels of Cn in a single cube, exchange it with another factor in the first cube by dragging it over that factor.

Box Cox Y Transformation

A Box-Cox power transformation is used to transform the response so that the usual regression assumptions of normality and homogeneity of variance are more closely satisfied. The transformed response can then be fit using a regression model. However, you can also use the Box-Cox power transformation to transform a variable for other reasons. This transformation is appropriate only when the response, Y, is strictly positive.
A commonly used transformation raises the response to some power. Box and Cox (1964) formalized and described this family of power transformations. The formula for the transformation is constructed to provide a continuous definition in terms of the parameter $\lambda$, and so that the error sums of squares are comparable. Specifically, the following equation provides the family of transformations:

$$Y_{\lambda} = \begin{cases} 
\frac{y^{\lambda} - 1}{\lambda y^{\lambda - 1}} & \text{if } \lambda \neq 0 \\
\hat{y} \ln(y) & \text{if } \lambda = 0
\end{cases}$$

Here, $\hat{y}$ denotes the geometric mean.

The Box Cox Y Transformation option fits transformations from $\lambda = -2$ to 2 in increments of 0.2. To choose a value of $\lambda$, the likelihood function for each of these transformations is computed. They are computed under the assumption that the errors are independent and normal with mean zero and variance $\sigma^2$. The value of $\lambda$ that maximizes the likelihood is selected. This value also minimizes the SSE over the values of $\lambda$. The value of $\lambda$ that minimizes the SSE is found using a quadratic interpolation between the two incremental grid points surrounding the grid point with the smallest SSE. If this interpolation results in a negative SSE value, then the grid value of $\lambda$ that minimizes the SSE is reported as the best $\lambda$.

The Box-Cox Transformations report displays a plot showing the sum of squared errors (SSE) values against the values of $\lambda$. The horizontal red line on the plot represents a one-sided 95% confidence interval for $\lambda$. This confidence interval is based on the confidence region defined in Box and Cox (1964, p. 216). The confidence region is defined by the following inequality:

$$\text{SSE}(\lambda) < \text{SSE}(\lambda_{\text{best}}) \times \exp(\text{ChiSquareQuantile}(0.95,1) / \text{dfe})$$

where

- $\text{SSE}(\lambda_{\text{best}})$ is the SSE calculated using the reported Best $\lambda$.
- $\text{ChiSquareQuantile}(0.95,1)$ is the $0.95^{\text{th}}$ quantile of a $\chi^2$ distribution with 1 degree of freedom.
- $\text{dfe}$ is the error degrees of freedom in the Analysis of Variance table for the regression model.

The Box Cox Transformations report provides the following options:

**Refit with Transform**  Enables you to specify a value for lambda to define a transformed Y variable and then provides a least squares fit to the transformed variable.

**Replace with Transform**  Enables you to specify a value for lambda to define a transformed Y variable and then replaces the existing least squares fit with a fit to the transformed variable. If you have multiple responses, Replace with Transform replaces only the report for the response that you are transforming.
Save Best Transformation  Creates a new column in the data table and saves the formula for the best transformation.

Save Specific Transformation  Enables you to specify a value for lambda and creates a column in the data table with the formula for your specified transformation.

Table of Estimates  Creates a new data table containing parameter estimates and SSE values for all $\lambda$ from –2 to 2, in increments of 0.2.

Example of Box-Cox Y Transformation
1. Select Help > Sample Data Library and open Reactor.jmp.
2. Select Analyze > Fit Model.
3. Select Y and click Y.
4. Make sure that the Degree box has a 2 in it.
5. Select F, Ct, A, T, and Cn and click Macros > Factorial to Degree.
6. Click Run.
7. Click the Response Y red triangle and select Factor Profiling > Box Cox Y Transformation.

Figure 3.53  Box Cox Y Transformation

The plot shows that the best values of $\lambda$ are between 0.1 and 2.0. The value that JMP selects, using interpolation between the best two values in the 0.2-unit grid of $\lambda$ values, is 1.124.

8. (Optional) To see the SSE values used to construct the graph, select Table of Estimates.

Surface Profiler

Note: For more information about the surface profiler, see Profilers.

The Surface Profiler shows a three-dimensional surface plot of the response surface.
Figure 3.54 shows the Surface Profiler for the model in the Odor.jmp sample data table. Run the Model data table script and then select Factor Profiling > Surface Profiler from the report’s red triangle menu. You can change the variables on the axes using the radio buttons under Independent Variables. Also, you can plot points by clicking Actual under Appearance.

**Figure 3.54 Surface Plot**

---

**Row Diagnostics**

The row diagnostics menu addresses issues specific to rows, or observations.

**Plot Regression**  Shows a Regression Plot report, displaying a scatterplot of the data and regression lines for each level of the categorical effect.

This option appears only if there is exactly one continuous effect and no more than one categorical effect in the model. In that case, the Regression Plot report is provided by default.

**Plot Actual by Predicted**  Shows an Actual by Predicted plot, which plots the observed values of Y against the predicted values of Y. This plot is the leverage plot for the whole model. See “Leverage Plots” on page 174.

**Note:** The Actual by Predicted Plot is shown by default when Effect Leverage or Effect Screening is selected as the Emphasis in the Fit Model launch window and the RSquare value is less than 0.999.

**Plot Effect Leverage**  Shows a Leverage Plot report for each effect in the model. The plot shows how observations influence the test for that effect and gives insight on multicollinearity. See “Leverage Plots” on page 174.
Note: Effect Leverage Plots are shown by default when Effect Leverage is selected as the Emphasis in the Fit Model launch window and the RSquare value is less than 0.999. They appear to the right of the Whole Model report. When another Emphasis is selected, the Effect Leverage Plots appear in the Effect Details report. In all cases, the option Regression Reports > Effect Details must be selected in order for Effect Leverage plots to display.

Plot Residual by Predicted  Shows a Residual by Predicted Plot report. The plot shows the residuals plotted against the predicted values of Y. You typically want to see the residual values scattered randomly about zero.

Note: The Residual by Predicted Plot is shown by default when Effect Leverage or Effect Screening is selected as the Emphasis in the Fit Model launch window and the RSquare value is less than 0.999.

Plot Residual by Row  Shows a Residual by Row Plot report. The residual values are plotted against the row numbers. This plot can help you detect patterns that result from the row ordering of the observations.

Plot Studentized Residuals  Shows a Studentized Residuals plot. Each point on the plot is computed using an estimate of its standard deviation obtained with the current observation deleted. These residuals are also called \( R_{\text{Student}} \) or externally Studentized residuals.

The plot contains two sets of limits:

- The outer limits that appear in red on the plot are 95% Bonferroni limits. These limits are placed at \( \pm t_{\text{Quantile}(0.025/n, n-p-1)} \), where \( n \) is the number of observations and \( p \) is the number of predictors.

- The inner limits that appear in green on the plot are 95% individual \( t \) distribution limits. These limits are placed at \( \pm t_{\text{Quantile}(0.025, n-p-1)} \), where \( n \) is the number of observations and \( p \) is the number of predictors.

Points that fall outside the red limits should be treated as probable outliers. Points that fall outside the green limits but within the red limits should be treated as possible outliers, but with less certainty. The confidence level of 95% for these limits is not affected by your selection in the Set Alpha Level option in the Model Specification window.

Caution: The residuals saved using Save Columns > Studentized Residuals are not externally Studentized.

Note: If the model contains random effects and REML is the specified Method in the launch window, the Studentized Residuals plot does not contain limits and the points that are plotted are not externally Studentized.
Plot Residual by Normal Quantiles  (Not available when REML is the specified Method in the launch window.) Shows a Residual Normal Quantile Plot. The residual values are plotted against quantiles of the normal distribution. This plot can help you assess the assumption of normality of the residuals.

Press  Shows a Press Report giving the Press statistic and its root mean square error (RMSE). The Press statistic is useful when comparing multiple models. Models with lower Press statistics are favored. (See “Press” on page 178.)

Durbin-Watson Test  (Not available when you specify a Frequency column.) Shows the Durbin-Watson report, which gives a statistic to test whether the residuals have first-order autocorrelation. The report also displays the autocorrelation of the residuals and Prob<DW, which is the exact probability associated with the statistic. This option is appropriate only for time series data and assumes that your observations are in time order.

Leverage Plots

An effect leverage plot for X is useful in the following ways:

- You can see which points might be exerting influence on the hypothesis test for X.
- You can spot unusual patterns and violations of the model assumptions.
- You can spot multicollinearity issues.

Construction

A leverage plot for an effect shows the impact of adding this effect to the model, given the other effects already in the model. For illustration, consider the construction of an effect leverage plot for a single continuous effect X. See “Horizontal Axis Scaling” on page 176 for information about the scaling of the horizontal axis in more general situations.

The response Y is regressed on all the predictors except X, and the residuals are obtained. Call these residuals the Y-residuals. Then X is regressed on all the other predictors in the model and the residuals are computed. Call these residuals the X-residuals. The X-residuals might contain information beyond what is present in the Y-residuals, which were obtained without X in the model.

The effect leverage plot for X is essentially a scatterplot of the X-residuals against the Y-residuals (Figure 3.57). To help interpretation and comparison with other plots that you might construct, JMP adds the mean of Y to the Y-residuals and the mean of X to the X-residuals. The translated Y-residuals are called the Y Leverage Residuals and the translated X-residuals are called X Leverage values. The points on the Effect Leverage plots are these X Leverage and Y Leverage Residual pairs.
JMP fits a least squares line to these points as well as confidence bands for the mean; the line of fit is solid red and the confidence bands are shaded red. The slope of the least squares line is precisely the estimate of the coefficient on X in the model where Y is regressed on X and the other predictors. The dashed horizontal blue line is set at the mean of the Y Leverage Residuals. This line describes a situation where the X residuals are not linearly related to the Y residuals. If the line of fit has nonzero slope, then adding X to the model can be useful in terms of explaining variation.

Figure 3.55 shows how residuals are depicted in the leverage plot. The distance from a point to the line of fit is the residual for a model that includes the effect. The distance from the point to the horizontal line is what the residual error would be without the effect in the model. In other words, the mean line in the leverage plot represents the model where the hypothesized value of the parameter (effect) is constrained to zero.

**Figure 3.55** Illustration of a Generic Leverage Plot

Confidence curves for the line of fit are shown on leverage plots. These curves provide a visual indication of whether the test of interest is significant at the 5% level (or at the Set Alpha Level that you specified in the Fit Model launch window). If the confidence region between the curves contains the horizontal line representing the hypothesis, then the effect is not significant. If the curves cross the line, the effect is significant. See the examples in Figure 3.56.
Horizontal Axis Scaling

If the modeling type of a predictor X is continuous, then the horizontal axis is scaled in terms of the units of the X. The horizontal axis range mirrors the range of X values. The slope of the line of fit in the leverage plot is the parameter estimate for X. See the left illustration in Figure 3.57.

If the effect is nominal or ordinal, or if the effect is a complex effect such as an interaction, then the horizontal axis cannot represent the values of the effect directly. In this case the horizontal axis is scaled in units of the response, and the line of fit is a diagonal with a slope of 1. The Whole Model leverage plot, where the hypothesis of interest is that all parameter values are zero, uses this scaling. (See “Leverage Plot Details” on page 205.) For this plot, the horizontal axis is scaled in terms of predicted response values for the whole model, as illustrated by the right-hand plot in Figure 3.57.

The leverage plot for the linear effect in a simple regression is the same as the traditional plot of actual response values against the predictor.

Leverage

The term leverage is used because these plots help you visualize the influence of points on the test for including the effect in the model. A point that is horizontally distant from the center of the plot exerts more influence on the effect test than does a point that is close to the center. Recall that the test for an effect involves comparing the sum of squared residuals to the sum of squared residuals of the model with that effect removed. At the extremes, the differences of the residuals before and after being constrained by the hypothesis tend to be comparatively larger. Therefore, these residuals tend to have larger contributions to the sums of squares for that effect’s hypothesis test.
Multicollinearity

Multicollinearity is a condition where two or more predictors are highly related, or more technically, involved in a nearly linear dependent relationship. When multicollinearity is present, standard errors can be inflated and parameters estimates can be unstable. If an effect is collinear with other predictors, the horizontal values of the points tend to cluster toward the middle of the plot. This situation indicates that the slope of the line of fit is unstable.

The Whole Model Actual by Predicted Plot

The Plot Effect Leverage option produces a leverage plot for each effect in the model. In addition, the Actual by Predicted plot can be considered to be a leverage plot. This plot lets you visualize the test that all the parameters in the model (except the intercept) are zero. The same test is conducted analytically in the Analysis of Variance report. (See “Leverage Plot Details” on page 205 for more information about this plot.)

Example of a Leverage Plot for a Linear Effect

1. Select Help > Sample Data Library and open Big Class.jmp.
2. Select Analyze > Fit Model.
3. Select weight and click Y.
4. Select height, age, and sex, and click Add.
5. Click Run.

The Whole Model Actual by Predicted Plot and the effect Leverage Plot for height are shown in Figure 3.57. The Whole Model plot, on the left, tests for all effects. You can infer that the model is significant because the confidence curves cross the horizontal line at the mean of the response, height. The Leverage Plot for height, on the right, also shows that height is significant, even with age and sex in the model. Neither plot suggests concerns relative to influential points or multicollinearity.
Press

The Press, or prediction error sum of squares, statistic is an estimate of prediction error computed using leave-one-out cross validation. In leave-one-out cross validation, each observation, in turn, is removed. Consider a specific observation. The model is fit with that observation withheld and then a predicted value is obtained for that observation. The residual for that observation is computed. This procedure is applied to all observations and the residuals are squared and summed to give the Press value.

Specifically, the Press statistic is given by the following:

$$\text{Press} = \sum_{i=1}^{n} (\hat{y}_{(i)} - y_i)^2$$

where \(n\) is the number of observations, \(y_i\) is the observed response value for the \(i^{th}\) observation, and \(\hat{y}_{(i)}\) is the predicted response value for the \(i^{th}\) observation. These values are based on a model fit without including that observation.

The Press RMSE is defined as \(\sqrt{\text{Press}/n}\).

The Press RSquare is defined as \(1 - \text{Press}/\text{SS}_{\text{Total}}\).
Each Save Columns option adds one or more new columns to the current data table. Additional Save Columns options appear when the fitting method is REML. These are detailed in “REML Save Columns Options” on page 196.

Note the following:

- When formulas are created, they are entered as Formula column properties.
- For many of the new columns, a Notes column property is added describing the column and indicating that Fit Least Squares created it.
- For the Predicted Formula and Predicted Values options, a Predicting column property is added. This property is used internally by JMP in conducting model comparisons (Analyze > Predictive Modeling > Model Comparison). When you fit many models, it is also useful to you because it documents the origin of the column.

The following Save Columns options are available:

**Prediction Formula**  Creates a new column called Pred Formula <colname> that contains both the formula and the predicted values. A Predicting column property is added, noting the source of the prediction.

**Note:** Pred Formula <colname> inherits certain properties from <colname>. These include Response Limits, Spec Limits, and Control Limits. If you change these properties for <colname> after saving Pred Formula <colname>, they will not update in Pred Formula <colname>.

See “Prediction Formula” on page 182.

**Predicted Values**  Creates a new column called Predicted <colname> that contains the predicted values computed by the specified model. Both a Notes and a Predicting column property are added, noting the source of the prediction.

**Note:** Predicted <colname> inherits certain properties from <colname>. These include Response Limits, Spec Limits, and Control Limits. If you change these properties for <colname> after saving Predicted <colname>, they will not update in Predicted <colname>.

**Residuals**  Creates a new column called Residual <colname> that contains the observed response values minus their predicted values.

**Mean Confidence Interval**  Creates two new columns called Lower 95% Mean <colname> and Upper 95% Mean <colname>. These columns contain the lower and upper 95% confidence limits for the mean response.
Save Columns Fitting Linear Models

**Note:** If you press Shift while selecting the option, you are prompted to enter an $\alpha$ level for the computations.

**Indiv Confidence Interval**  Creates two new columns called Lower 95% Indiv <colname> and Upper 95% Indiv <colname>. These columns contain lower and upper 95% confidence limits for individual response values.  

**Note:** If you press Shift while selecting the option, you are prompted to enter an $\alpha$ level for the computations.

**Studentized Residuals**  Creates a new column called Studentized Resid <colname> that contains the residuals divided by their standard errors.

**Externally Studentized Residuals**  (Not available when the fitting method is REML.) Creates a new column called Externally Studentized Residuals <colname> that contains the residuals divided by standard error estimates that exclude the current row. See “Plot Studentized Residuals” on page 173.

**Hats**  Creates a new column called $h <colname>$. The column values are the diagonal values of the matrix $X(X'X)^{-1}X'$, sometimes called hat values.

**Std Error of Predicted**  Creates a new column called StdErr Pred <colname> that contains the standard errors of the predicted mean response.

**Std Error of Residual**  Creates a new column called StdErr Resid <colname> that contains the standard errors of the residual values.

**Std Error of Individual**  Creates a new column called StdErr Indiv <colname> that contains the standard errors of the individual predicted response values.

**Effect Leverage Pairs**  Creates a set of new columns that contain the X Leverage values and Y Leverage Residuals for each leverage plot. For each effect in the model, two columns are added. If the response column name is $R$ and the effect is $X$, the new column names are:

- X Leverage of $X$ for $R$
- Y Leverage of $X$ for $R$

In the columns panel, these columns are organized in a columns group called Leverage.

**Cook’s D Influence**  Creates a new column called Cook’s D Influence <colname>, which contains values of the Cook’s D influence statistic.

**StdErr Pred Formula**  Creates a new column called PredSE <colname> that contains both the formula and the values for the standard error of the predicted values.
Note: The saved formula can be large. If you do not need the formula, use the Std Error of Predicted option.

Mean Confidence Limit Formula  Creates two new columns called
Lower 95% Mean <colname> and Upper 95% Mean <colname>. These columns contain both the formulas and the values for lower and upper 95% confidence limits for the mean response.

Note: If you press Shift while selecting the option, you are prompted to enter an α level for the computations.

Indiv Confidence Limit Formula  Creates two new columns called
Lower 95% Indiv <colname> and Upper 95% Indiv <colname>. These columns contain both the formulas and the values for lower and upper 95% confidence limits for individual response values.

Note: If you press Shift while selecting the option, you are prompted to enter an α level for the computations.

Save Coding Table  Creates a new data table whose first columns show the JMP coding for all model parameters. The last column gives the values of the response. If you entered more than one response column, all of these columns appear as the last columns in the coding table.

Note: The coding data table contains a table variable called Original Data that gives the name of the data table that was used for the analysis. In the case where a By variable is specified, the Original Data table variable gives the By variable and its level.

Publish Prediction Formula  Creates a prediction formula and saves it as a formula column script in the Formula Depot platform. If a Formula Depot report is not open, this option creates a Formula Depot report. See Predictive and Specialized Modeling.

Publish Standard Error Formula  Creates a standard error formula and saves it as a formula column script in the Formula Depot platform. If a Formula Depot report is not open, this option creates a Formula Depot report. See Predictive and Specialized Modeling.

Publish Mean Confid Limit Formula  Creates confidence limit formulas for the mean response and saves them as formula column scripts in the Formula Depot platform. If a Formula Depot report is not open, this option creates a Formula Depot report. See Predictive and Specialized Modeling.

Publish Indiv Confid Formula  Creates confidence formulas for individual response values and saves them as formula column scripts in the Formula Depot platform. If a
Formula Depot report is not open, this option creates a Formula Depot report. See *Predictive and Specialized Modeling*.

**Prediction Formula**

Pred Formula <colname> differs from Predicted <colname> in that it contains the prediction formula. Right-click in the Pred Formula <colname> column heading and select **Formula** to see the prediction formula. The prediction formula can require considerable space if the model is large. If you do not need the formula with the column of predicted values, use the **Save Columns > Predicted Values** option. For information about formulas, see *Using JMP*.

The Prediction Formula option is useful for predicting values in new rows or for use with the profilers. The profilers are available in the Fit Least Squares report (Factor Profiling). However, when your data table includes formula columns, you can also use the profilers provided in the **Graph** menu. When you are analyzing multiple responses, accessing the profilers from the **Graph** menu can be useful.

**Note:** If you select **Graph > Profiler** to access the profilers, first save the formula columns to the data table using Prediction Formula and StdErr Pred Formula. Then place both of these formulas into the Y, Prediction Formula role in the Profiler window. After you click **OK**, specify whether you want to use PredSE <colname> to construct confidence intervals for Pred Formula <colname>. Otherwise, JMP creates a separate profiler plot for PredSE <colname>.

**Effect Summary Report**

The Effect Summary option shows an interactive report. It gives a plot of the LogWorth (or FDR LogWorth) values for the effects in the model. The report also provides controls that enable you to add or remove effects from the model. The model fit report updates automatically based on the changes made in the Effects Summary report.

The Effect Summary report is available in the following personalities:

- Standard Least Squares
- Nominal Logistic
- Ordinal Logistic
- Proportional Hazard
- Parametric Survival
- Generalized Linear Model
Figure 3.58 shows the initial view of the Effect Summary report for the Fitness.jmp data table. The check box labeled FDR controls the columns that appear in the summary table.

**Figure 3.58  Effect Summary Report**

![Effect Summary Table](image)

**Effect Summary Table Columns**

The Effect Summary table contains the following columns:

- **Source** Lists the model effects, sorted by ascending $p$-values.
- **LogWorth** Shows the LogWorth for each model effect, defined as $-\log_{10}(p\text{-value})$. This transformation adjusts $p$-values to provide an appropriate scale for graphing. A value that exceeds 2 is significant at the 0.01 level (because $-\log_{10}(0.01) = 2$).
- **FDR LogWorth** Shows the False Discovery Rate LogWorth for each model effect, defined as $-\log_{10}(\text{FDR PValue})$. This is the best statistic for plotting and assessing significance. However, it is highly dependent on the ordering of the significances, is conservative for positively correlated tests, and does not give experimentwise protection at the alpha level. Select the FDR check box to replace the LogWorth column with the **FDR LogWorth** column.
- **Bar Graph** Shows a bar graph of the LogWorth (or FDR LogWorth) values. The graph has dashed vertical lines at integer values and a blue reference line at 2.
- **PValue** Shows the $p$-value for each model effect. This is generally the $p$-value corresponding to the significance test displayed in the Effect Tests table or Effect Likelihood Ratio Tests table of the model report.
- **FDR PValue** Shows the False Discovery Rate $p$-value for each model effect calculated using the Benjamini-Hochberg technique. This technique adjusts the $p$-values to control the false discovery rate for multiple tests. Select the FDR check box to replace the PValue column with the **FDR PValue** column.

For more information about the FDR correction, see Benjamini and Hochberg (1995). For more information about the false discovery rate, see *Predictive and Specialized Modeling* or Westfall et al. (2011).
**Effect Heredity Column** Identifies lower-order effects that are components of more significant higher-order effects. The lower-order effects are identified with a caret. See “Effect Heredity” on page 185.

**Effect Summary Table Options**

The options below the summary table enable you to add and remove effects:

- **Remove** Removes the selected effects from the model. To remove one or more effects, select the rows corresponding to the effects and click the **Remove** button.

- **Add** Opens a panel that contains a list of all columns in the data table. Select columns that you want to add to the model, and then click **Add** below the column selection list to add the columns to the model. Click **Close** to close the panel. Figure 3.59 shows the Add Columns panel.

**Figure 3.59 Effect Summary Add Columns Panel**

**Edit** Opens the Edit Model panel, which contains a Select Columns list and an Effects specification panel. The Effects panel resembles the Construct Model Effects panel in the Fit Model launch window. The Edit Model panel enables you to add individual, crossed, nested, and transformed effects. You can also add multiple effects using the Macros menu. For more information about how to construct effects using Add, Cross, Nest, Macros, and Transform, see “Construct Model Effects” on page 39.

The following options are available to the right of the Effects panel:

- **Commit** applies your updates to the model.
Close closes the panel without making changes to the model.

Remove removes one or more selected effects from the Effects list.

Figure 3.60 shows the Edit Model panel.

**Tip:** The Edit button gives you the greatest degree of control over updates to your model. It includes the functionality of the Remove and Add buttons and enables you to construct effects to add to your model.

Undo Enables you to undo changes to the effects in the model.

**Effect Heredity**

When a model contains significant higher-order effects, you might want to retain some or all of their lower-order components, even though these are not significant. The principle of *strong effect heredity* states that, if a higher-order effect is included in the model, all of its lower-order components should be included as well. The principle of *weak effect heredity* indicates that a chain of components should be included.

When a lower-order component of a higher-order effect appears in the Effect Summary table below the higher-order effect, a caret appears in the right-most column. The caret indicates that the containing higher-order effect is more significant than the lower-order effect. If all higher-order effects that contain a lower-order effect are less significant than the lower-order effect, no caret appears in the row for the lower-order effect.
If you remove an effect marked with a caret, you can choose one of two approaches for removing effects. Choose **Remove all selected effects** to remove all the selected effects, including the ones marked with a caret. Choose **Remove only non-contained effects** to remove only the selected effects that do not have a higher-order effect that still remains in the model.

Figure 3.61 show an example of an Effect Summary table where three lower-order effects appear below higher-order effects that contain the lower-order effects. For example, **Stir Rate(100,120)** appears below **Stir Rate*Temperature**.

**Figure 3.61** Effect Summary Table with Effect Heredity for Reactor 32 Runs.jmp

### Multiple Responses

In the case of multiple responses, each effect appears in each response model, but only one Effect Summary report appears. For each effect, the table shows the minimum $p$-value among the $p$-values for that effect. Adding or removing an effect applies to the models for all of the responses.
Mixed and Random Effect Model Reports and Options

Mixed and random effect models can be specified in the Fit Model launch window. The Standard Least Squares personality fits the variance component covariance structure. Two methods, REML and EMS, are provided for fitting such models.

Note: JMP Pro users are encouraged to use the Mixed Model personality in the Fit Model window. The Mixed Model personality offers a broader set of covariance structures than does Standard Least Squares.

- “Mixed Models and Random Effect Models”
- “Restricted Maximum Likelihood (REML) Method”
- “EMS (Traditional) Model Fit Reports”

Mixed Models and Random Effect Models

A random effect model is a model all of whose factors represent random effects. (See “Random Effects” on page 187.) Such models are also called variance component models. Random effect models are often hierarchical models. A model that contains both fixed and random effects is called a mixed model. Repeated measures and split-plot models are special cases of mixed models. Often the term mixed model is used to subsume random effect models.

To fit a mixed model, you must specify the random effects in the Fit Model launch window. However, if all of your model effects are random, you can also fit your model in the Variability / Attribute Gauge Chart platform. Only certain models can be fit in this platform. Note that the fitting methods used in the Variability / Attribute Gauge Chart platform do not allow variance component estimates to be negative. For more information about how the Variability / Attribute Gauge Chart platform fits variance components models, see Quality and Process Methods.

Random Effects

A random effect is a factor whose levels are considered a random sample from some population. Often, the precise levels of the random effect are not of interest, rather it is the variation reflected by the levels that is of interest (the variance components). However, there are also situations where you want to predict the response for a given level of the random effect. Technically, a random effect is considered to have a normal distribution with mean zero and nonzero variance.
Suppose that you are interested in whether two specific ovens differ in their effect on mold shrinkage. An oven can process only one batch of 50 molds at a time. You design a study where three randomly selected batches of 50 molds are consecutively placed in each of the two ovens. Once the batches are processed, shrinkage is measured for five parts randomly selected from each batch.

Note that Batch is a factor with six levels, once for each batch. So, in your model, you include two factors, Oven and Batch. Because you are specifically interested in comparing the effect of each oven on shrinkage, Oven is a fixed effect. But you are not interested in the effect of these specific six batches on the mean shrinkage. These batches are representative of a whole population of batches that could have been chosen for this experiment and to which the results of the analysis must generalize. Batch is considered a random effect. In this experiment, the Batch factor is of interest in terms of the variation in shrinkage among all possible batches. Your interest is in estimating the amount of variation in shrinkage that it explains. (Note that Batch is also nested within Oven, because only one batch can be processed once in one oven.)

Now suppose that you are interested in the weight of eggs for hens subjected to two feed regimes. Ten hens are randomly assigned to feed regimes: Five are given Feed regime A and five are given Feed regime B. However, these ten hens have some genetic differences that are not accounted for in the design of the study. In this case, you are interested the predicted weight of the eggs from certain specific hens as well as in the variance of the weights of eggs among hens.

### The Classical Linear Mixed Model

JMP fits the classical linear mixed effects model:

\[
Y = X\beta + Z\gamma + \varepsilon \\
\gamma \sim N(0, G) \\
\varepsilon \sim N(0, \sigma^2 I_n)
\]

Here,
- \( Y \) is an \( n \times 1 \) vector of responses
- \( X \) is the \( n \times p \) design matrix for the fixed effects
- \( \beta \) is a \( p \times 1 \) vector of unknown fixed effects with design matrix \( X \)
- \( Z \) is the \( n \times s \) design matrix for the random effects
- \( \gamma \) is an \( s \times 1 \) vector of unknown random effects with design matrix \( Z \)
- \( \varepsilon \) is an \( n \times 1 \) vector of unknown random errors
- \( G \) is an \( s \times s \) diagonal matrix with identical entries for each level of the random effect
- \( I_n \) is an \( n \times n \) identity matrix
• $\gamma$ and $\varepsilon$ are independent

The diagonal elements of $G$, as well as $\sigma^2$, are called variance components. These variance components, together with the vector of fixed effects $\beta$ and the vector of random effects $\gamma$, are the model parameters that must be estimated.

The covariance structure for this model is sometimes called the variance component structure (SAS Institute Inc. 2020d, ch. 83). This covariance structure is the only one available in the Standard Least Squares personality.

The Mixed Model personality fits a variety of covariance structures, including Residual, First-order Autoregressive (or $AR(1)$), Unstructured, and Spatial. See “Repeated Structure Tab” on page 368 in the “Mixed Models” chapter.

**REML versus EMS for Fitting Models with Random Effects**

JMP provides two methods for fitting models with random effects:

• REML, which stands for restricted maximum likelihood (always the recommended method)
• EMS, which stands for expected mean squares (use only for teaching from old textbooks)

The REML method is now the mainstream fitting methodology, replacing the traditional EMS method. REML is considerably more general in terms of applicability than the EMS method. The REML approach was pioneered by Patterson and Thompson (1974). See also Wolfinger et al. (1994) and Searle et al. (1992).

The EMS method, also called the method of moments, was developed before the availability of powerful computers. Researchers restricted themselves to balanced situations and used the EMS methodology, which provided computational shortcuts to compute estimates for random effect and mixed models. Because many textbooks still in use today use the EMS method to introduce models containing random effects, JMP provides an option for EMS. (See, for example, McCulloch et al., 2008; Poduri, 1997; Searle et al., 1992.)

The REML methodology performs maximum likelihood estimation of a restricted likelihood function that does not depend on the fixed-effect parameters. This yields estimates of the variance components that are then used to obtain estimates of the fixed effects. Estimates of precision are based on estimates of the covariance matrix for the parameters. Even when the data are unbalanced, REML provides useful estimates, tests, and confidence intervals.

The EMS methodology solves for estimates of the variance components by equating observed mean squares to expected mean squares. For balanced designs, a complex set of rules specifies how estimates are obtained. There are problems in applying this technique to unbalanced data.

For balanced data, REML estimates are identical to EMS estimates. But, unlike EMS, REML performs well with unbalanced data.
Specifying Random Effects and Fitting Method

Models with random effects are specified in the Fit Model launch window. To specify a random effect, highlight it in the Construct Model Effects list and select Attributes > Random Effect. This appends &Random to the effect name in the model effect list. (For a definition of random effects, see “Random Effects” on page 187.) Random effects can also be specified in a separate effects tab. (See “Construct Model Effects Tabs” on page 44 in the “Model Specification” chapter.)

In the Fit Model launch window, once the &Random attribute has been appended to an effect, you are given a choice of fitting Method: REML (Recommended) or EMS (Traditional).

**Caution:** You must declare crossed and nested relationships explicitly. For example, a subject ID might also identify the group that contains the subject, as when each subject is in only one group. In such a situation, subject ID must still be declared as nested within group. Take care to be explicit in defining the design structure.

Unrestricted Parameterization for Variance Components

There are two different approaches to parameterizing the variance components: the unrestricted and the restricted approaches. The issue arises when there are mixed effects in the model, such as the interaction of a fixed effect with a random effect. Such an interaction term is considered to be a random effect.

In the restricted approach, for each level of the random effect, the sum of the interaction effects across the levels of the fixed effect is assumed to be zero. In the unrestricted approach, the mixed terms are simply assumed to be independent random realizations of a normal distribution with mean 0 and common variance. (This assumption is analogous to the assumption typically applied to residual error.)

JMP and SAS use the unrestricted approach. This distinction is important because many statistics textbooks use the restricted approach. Both approaches have been widely taught for 60 years. For a discussion of both approaches, see Cobb (1998, Section 13.3).

Negative Variances

Though variances are always positive, it is possible to have a situation where the unbiased estimate of the variance is negative. Negative estimates can occur in experiments when an effect is very weak or when there are very few levels corresponding to a variance component. By chance, the observed data can result in an estimate that is negative.
Unbounded Variance Components

JMP can produce negative estimates for both REML and EMS. For REML, there are two options in the Fit Model launch window: Unbounded Variance Components and Estimate Only Variance Components. The Unbounded Variance Components option is selected by default. Deselecting this option constrains variance component estimates to be nonnegative. You should leave the Unbounded Variance Components option selected if you are interested in fixed effects. Constraining the variance estimates to be nonnegative leads to bias in the tests for the fixed effects.

Estimate Only Variance Components

Select this option if you want to see only the REML Variance Component Estimates report. If you are interested only in variance components, you might want to constrain variance components to be nonnegative. Deselecting the Unbounded Variance Components option and selecting the Estimate Only Variance Components option might be appropriate.

Restricted Maximum Likelihood (REML) Method

Based on the fitting method selected, the Fit Least Squares report provides different analysis results and provide additional menu options for Save Columns and Profiler. In particular, the analysis of variance report is not shown because variances and degrees of freedom do not partition in the usual way. You can obtain the residual variance estimate from the REML Variance Component Estimates report. (See “REML Variance Component Estimates” on page 193.) The Effect Tests report is replaced by the Fixed Effect Tests report where fixed effects are tested. Additional reports give predicted values for the random effects and details about the variance components.

Figure 3.62 shows the report obtained for a fit to the Investment Castings.jmp sample data using the REML method. Run the script Model - REML, and then fit the model. Note that Casting is a random effect and is nested within Temperature.
Random Effect Predictions

For each term in the model, this report gives an empirical estimate of its best linear unbiased predictor (BLUP) and a test for whether the corresponding coefficient is zero.

**Note:** The Regression Reports > Parameter Estimates option must be selected for the Random Effect Predictions report to appear.

- **Term**  The terms in the model that correspond to random effects.
- **BLUP**  The empirical estimate of the best linear unbiased predictor (BLUP) for each random effect. See “Best Linear Unbiased Predictors” on page 193.
- **Std Error**  The standard error of the BLUP.
- **DFDen**  The denominator degrees of freedom for a test that the effect is zero. In most cases, the degrees of freedom for the \( t \) test is fractional.
- **t Ratio**  The \( t \) ratio for testing that the effect is zero. The \( t \) ratio is obtained by dividing the BLUP by its standard error.
- **Prob>|t|**  The \( p \)-value for the test.
Lower 95% The lower 95% confidence limit for the BLUP. This column appears only if you have the Regression Reports > Show All Confidence Intervals option selected or if you right-click in the report and select Columns > Lower 95%.

Upper 95% The upper 95% confidence limit for the BLUP. This column appears only if you have the Regression Reports > Show All Confidence Intervals option selected or if you right-click in the report and select Columns > Upper 95%.

Best Linear Unbiased Predictors

The term *best linear unbiased predictor* (BLUP) refers to an estimator of a random effect. Specifically, it is an estimator that, among all unbiased estimators, minimizes mean square prediction error. The Random Effect Predictions report gives estimates of the BLUPs, or *empirical* BLUPs. These are empirical because the BLUPs depend on the values of the variance components, which are unknown. The estimated values of the variance components are substituted into the formulas for the BLUPs, resulting in the estimates shown in the report.

REML Variance Component Estimates

When REML is selected as the fitting method in the Fit Model launch window, the REML Variance Component Estimates report is provided. This report contains the following columns:

Random Effect The random effects in the model.

Var Ratio The ratio of the variance component for the effect to the variance component for the residual. It compares the effect’s estimated variance to the model’s estimated error variance.

Var Component The estimated variance component for the effect. Note that the variance component for the Total is the sum of the positive variance components only. The sum of all variance components is given beneath the table.

Std Error The standard error for the variance component estimate.

95% Lower The lower 95% confidence limit for the variance component. See “Confidence Intervals for Variance Components” on page 194.

95% Upper The upper 95% confidence limit for the variance component. See “Confidence Intervals for Variance Components” on page 194.

Wald p-Value The $p$-value for the test that the covariance parameter is equal to zero. This column appears only when you have selected Unbounded Variance Components in the Fit Model launch window.

Pct of Total The ratio of the variance component for the effect to the variance component for the total as a percentage.
**Sqrt Variance Component**  The square root of the corresponding variance component. It is an estimate of the standard deviation for the effect. This column appears only if you right-click in the report and select Columns > Sqrt Variance Component.

**CV**  The coefficient of variation for the variance component. It is 100 times the square root of the variance component, divided by the mean response. This column appears only if you right-click in the report and select Columns > CV.

**Norm KHC**  The Kackar-Harville correction. See “Kackar-Harville Correction” on page 194. This column appears only if you right-click in the report and select Columns > Norm KHC.

### Confidence Intervals for Variance Components

The method used to calculate the confidence limits depends on whether you have selected Unbounded Variance Components in the Fit Model launch window. Note that Unbounded Variance Components is selected by default.

- If Unbounded Variance Components is selected, Wald-based confidence intervals are computed. These are valid asymptotically but note that they can be unreliable with small samples.
- If Unbounded Variance Components is not selected, meaning that parameters have a lower boundary constraint of zero, a Satterthwaite approximation is used (Satterthwaite 1946).

**Kackar-Harville Correction**

In the REML method, the standard errors of the fixed effects are estimated using estimates of the variance components. However, if variability in these estimates is not taken into account, the standard error is underestimated. To account for the increased variability, the covariance matrix of the fixed effects is adjusted using the Kackar-Harville correction (Kackar and Harville 1984; Kenward and Roger 1997). All calculations that involve the covariance matrix of the fixed effects use this correction. These include least squares means, fixed effect tests, confidence intervals, and prediction variances. For statistical details, see “The Kackar-Harville Correction” on page 208.

Norm KHC is the Frobenius (matrix) norm of the Kackar-Harville correction. In cases where the design is fairly well balanced, Norm KHC tends to be small.

**Covariance Matrix of Variance Components Estimates**

This report gives an estimate of the asymptotic covariance matrix for the variance components. It is the inverse of the observed Fisher information matrix.
Chapter 3
Fitting Linear Models

Standard Least Squares Models

Mixed and Random Effect Model Reports and Options

---

**Iterations**

The estimates of $\sigma^2$ and the variance components in $G$ are obtained by maximizing a residual log-likelihood function that depends on only these parameters. An iterative procedure attempts to maximize the residual log-likelihood function, or equivalently, to minimize twice the negative of the residual log-likelihood ($-2\text{LogLike}$). The Iterations report provides details about this procedure.

- **Iter**  Iteration number.
- **-2LogLike**  Twice the negative log-likelihood. It is the objective function. See “Likelihood, AICc, and BIC” on page 559 in the “Statistical Details” appendix.
- **Norm Gradient**  The norm of the gradient (first derivative) of the objective function
- **Parameters**  The column labeled Parameters and the remaining columns each correspond to a random effect. The order of the columns follows the order in which random effects are listed in the REML Variance Component Estimates report. At each iteration, the value in the column is the estimate of the variance component at that point.

The convergence criterion is based on the gradient, with a default tolerance of $10^{-8}$. You can change the criterion in the Fit Model launch window by selecting the option Convergence Settings > Convergence Limit and specifying the desired tolerance.

---

**Fixed Effect Tests**

When REML is used, the Effect Tests report provides tests for the fixed effects. This report contains the following columns:

- **Source**  The fixed effects in the model.
- **Nparm**  The number of parameters associated with the effect.
- **DF**  The degrees of freedom associated with the effect.
- **DFDen**  The denominator degrees of freedom. These are based on an approximation to the distribution of the statistic obtained when the covariance matrix is adjusted using the Kenward-Roger correction. See “Kackar-Harville Correction” on page 194 and “Random Effects” on page 81.
- **FRatio**  The computed $F$ ratio.
- **Prob > F**  The $p$-value for the effect test.

---

---
REML Save Columns Options

When you use the REML method, six additional options appear in the Save Columns menu. These option names start with the adjective Conditional. This prefix indicates that the calculations for these columns use the predicted values for the terms associated with the random effects, rather than their expected values of zero.

**Conditional Pred Formula**  Saves the prediction formula to a new column in the data table.

**Conditional Pred Values**  Saves the predicted values to a new column in the data table.

**Conditional Residuals**  Saves the residuals to a new column in the data table.

**Conditional Mean CI**  Saves the confidence interval for the mean.

**Conditional Indiv CI**  Saves the confidence interval for individuals.

Publish Conditional Formula  Creates a conditional prediction formula and saves it as a formula column script in the Formula Depot platform. If a Formula Depot report is not open, this option creates a Formula Depot report. See Predictive and Specialized Modeling.

REML Profiler Option

When you use the REML method and select Factor Profiling > Profiler, a new option, Conditional Predictions, appears on the red triangle menu next to Prediction Profiler. Note that the conditional values use the predicted values for the random effects, rather than their zero expected values.

**Note:** The profiler displays conditional predicted values and conditional mean confidence intervals for all combinations of factors levels. Some of these combinations might not be meaningful due to nesting.

EMS (Traditional) Model Fit Reports

**Caution:** The use of EMS is not recommended. REML is the recommended method.

When EMS is selected as the fitting method, four new reports are displayed. The Effect Tests report is not shown, as tests for both fixed and random effects are conducted in the Tests wrt Random Effects report.
Expected Mean Squares

The expected mean square for a model effect is a linear combination of variance components and fixed effect values, including the residual error variance. This table gives the coefficients that define each model effect’s expected mean square. The rows of the matrix correspond to the effects, listed on the left. The columns correspond to the variance components, identified across the top. Each expected mean square includes the residual variance with a coefficient of one. This information is given beneath the table.

Figure 3.63 shows the Expected Mean Squares report for the Investment Castings.jmp sample data table. Run the Model - EMS script and then run the model.

Figure 3.63  Expected Mean Squares Report

As indicated by the table, the expected mean square for Casting[Temperature] is

$$4\sigma^2_{\text{Casting}[\text{Temperature}]} + \sigma^2_{\text{Error}}$$

Variance Component Estimates

Estimates of the variance components are obtained by equating the expected mean squares to the corresponding observed mean squares and solving. The Variance Component Estimates report gives the estimated variance components.

**Component**  Lists the random effects.

**Var Comp Est**  Gives the estimate of the variance component.

**Percent of Total**  Gives the ratio of the variance component to the sum of the variance components.

**CV**  Gives the coefficient of variation for the variance component. It is 100 times the square root of the variance component, divided by the mean response.

**Note:** Appears only if you right-click in the report and select Columns > CV.
Test Denominator Synthesis

For each effect to be tested, an F statistic is constructed. The denominator for this statistic is the mean square whose expectation is that of the numerator mean square under the null hypothesis. This denominator is constructed, or synthesized, from variance components and values associated with fixed effects.

- **Source**: Shows the effect to be tested.
- **MS Den**: Gives the estimated mean square for the denominator of the F test.
- **DF Den**: Gives the degrees of freedom for the synthesized denominator. These are constructed using Satterthwaite’s method (Satterthwaite 1946).
- **Denom MS Synthesis**: Gives the variance components used in the denominator synthesis. The residual error variance is always part of this synthesis.

Tests wrt Random Effects

Tests for fixed and random effects are presented in this report.

- **Source**: Lists the effects to be tested. These include fixed and random effects.
- **SS**: Gives the sum of squares for the effect.
- **MS Num**: Gives the numerator mean square.
- **DF Num**: Gives the numerator degrees of freedom.
- **F Ratio**: Gives the F ratio for the test. It is the ratio of the numerator mean square to the denominator mean square. The denominator mean square can be obtained from the Test Denominator Synthesis report.
- **Prob > F**: Gives the p-value for the effect test.

**Caution**: Standard errors for least squares means and denominators for contrast F tests use the synthesized denominator. In certain situations, such as tests involving crossed effects compared at common levels, these tests might not be appropriate. Custom tests are conducted using residual error, and leverage plots are constructed using the residual error, so these also might not be appropriate.
EMS Profiler

When you use the EMS method and select Factor Profiling > Profiler, the profiler gives predictions and conditional mean confidence intervals based on the fixed-effects model. These values are not based on the predicted values for the random effects.

Models with Linear Dependencies among Model Terms

When there are linear dependencies among the columns of the matrix of predictors, several standard least squares reports are affected.

- “Singularity Details”
- “Parameter Estimates Report”
- “Effect Tests Report”
- “Examples”

Singularity Details

The linear regression model is formulated as $Y = X\beta + \epsilon$. Here $X$ is a matrix whose first column consists of $1$s, and whose remaining columns are the values of the non-intercept terms in the model. If the model consists of $p$ terms, including the intercept, then $X$ is an $n$ by $p$ matrix, where $n$ is the number of observations. The parameter estimates, denoted by the vector $b$, are typically given by the formula:

$$b = (X'X)^{-1}X'Y$$

However, this formula presumes that $X'X^{-1}$ exists, in other words, that the $p \times p$ matrix $X'X$ is invertible, or equivalently, of full rank. Situations often arise when $X'X$ is not invertible because there are linear dependencies among the columns of $X$.

In such cases, the matrix $X'X$ is singular, and the Fit Least Squares report contains the Singularity Details report. This report contains a table of expressions that describe the linear dependencies. The terms involved in these linear dependencies are aliased (confounded).

Figure 3.64 shows reports for the Reactor 8 Runs.jmp sample data table. To obtain these reports, fit a model with Percent Reacted as $Y$. Enter Feed Rate, Catalyst, Stir Rate, Temperature, Concentration, Catalyst*Stir Rate, Catalyst*Concentration, and Feed Rate*Catalyst as model effects.
Parameter Estimates Report

When $X'X$ is singular, a generalized inverse is used to obtain estimates. This approach permits some, but not all, of the parameters involved in a linear dependency to be estimated. Parameters are estimated based on the order of entry of their associated terms into the model, so that the last terms entered are the ones whose parameters are not estimated. Estimates are given in the Parameter Estimates report, and parameters that cannot be estimated are given estimates of 0.

However, estimates of parameters for terms involved in linear dependencies are not unique. Because the associated terms are aliased, there are infinitely many vectors of estimates that satisfy the least squares criterion. In these cases, “Biased” appears to the left of these estimates in the Parameter Estimates report. “Zeroed” appears to the left of the estimates of 0 in the Parameter Estimates report for terms involved in a linear dependency whose parameters cannot be estimated. For an example, see Figure 3.64.

If there are degrees of freedom available for an estimate of error, $t$ tests for parameters estimated using biased estimates are conducted. These tests should be interpreted with caution, though, given that the estimates are not unique.
Effect Tests Report

In a standard least squares fit, only as many parameters are estimable as there are model degrees of freedom. In conducting the tests in the Effect Tests report, each effect is considered to be the last effect entered into the model.

- If all the Model degrees of freedom are used by the other effects, an effect shows DF equal to 0. When DF equals 0, no sum of squares can be computed. Therefore, the effect cannot be tested.
- If not all Model degrees of freedom are used by the other effects, then that effect has nonzero DF. However, its DF might be less than its number of parameters (Nparm), indicating that only some of its associated parameters are testable.

An $F$ test is conducted if the degrees of freedom for an effect are nonzero, assuming that there are degrees of freedom for error. Whenever DF is less than Nparm, the description LostDFs is displayed to the far right in the row corresponding to the effect (Figure 3.64). These effects have the opportunity to explain only model sums of squares that have not been attributed to the aliased effects that have absorbed their lost degrees of freedom. It follows that the sum of squares given in the Effect Tests report most likely under represents the “true” sum of squares associated with the effect. If the test is significant, its significance is meaningful. But lack of significance should be interpreted with caution.

For statistical details, see the section “Statistical Background” in the “Introduction to Statistical Modeling with SAS/STAT Software” chapter in SAS Institute Inc. (2020c).

Examples

Open the Singularity.jmp sample data table. There is a response $Y$, four predictors $X_1$, $X_2$, $X_3$, and $A$, and five observations. The predictors are continuous except for $A$, which is nominal with four levels. Also note that there is a linear dependency among the continuous effects, namely, $X_3 = X_1 + X_2$.

Non-Uniqueness of Estimates

To see that estimates are not unique when there are linear dependencies:

1. Select Help > Sample Data Library and open Singularity.jmp.
2. Run the script Model 1. The script opens a Fit Model launch window where the effects are entered in the order $X_1$, $X_2$, $X_3$.
3. Click Run and leave the report window open.
4. Run the script Model 2. The script opens a Fit Model launch window where the effects are entered in the order $X_1$, $X_3$, $X_2$.
5. Click Run and leave the report window open.
Compare the two reports (Figure 3.65). The Singularity Details report at the top of both reports displays the linear dependency, indicating that $X_1 = X_3 - X_2$.

Now compare the Parameter Estimates reports for both models. Note, for example, that the estimate for $X_1$ for Model 1 is $-1.25$ while for Model 2 it is $2.75$. In both models, only two of the terms associated with effects are estimated, because there are only two model degrees of freedom. See the Analysis of Variance report. The estimates of the two terms that are estimated are labeled Biased while the remaining estimate is set to 0 and labeled Zeroed.

The Effect Tests report shows that no tests are conducted. Each row is labeled LostDFs. The reason this happens is that the effect test for any one of these effects requires it to be entered into the model last. However, the other two effects entirely account for the model sum of squares associated with the two model degrees of freedom. So there are no degrees of freedom or associated sum of squares left for the effect of interest.

**Figure 3.65** Fit Least Squares Reports for Model 1 (on left) and Model 2 (on right)

**LostDFs**

To gain more insight on LostDFs, follow the steps below or run the data table script Fit Model Report:

1. Select **Help > Sample Data Library** and open Singularity.jmp.
2. Click **Analyze > Fit Model**.
3. Select Y and click Y.
4. Select X1 and A and click Add.
5. Set the **Emphasis** to **Minimal Report**.
6. Click Run.
 Portions of the report are shown in (Figure 3.66). The Singularity Details report shows that there is a linear dependency involving X1 and the three terms associated with the effect A. (For more information about how a nominal effect is coded, see “Details of Custom Test Example” on page 204). The Analysis of Variance report shows that there are three model degrees of freedom. The Parameter Estimates report shows Biased estimates for the three terms X1, A[a], and A[b] and a Zeroed estimate for the fourth, A[c].

The Effect Tests report shows that X1 cannot be tested, because A must be entered first and A accounts for the three model degrees of freedom. However, A can be tested, but with only two degrees of freedom. (X1 must be entered first and it accounts for one of the model degrees of freedom.) The test for A is partial, so it must be interpreted with care.

**Figure 3.66** Fit Least Squares Report for Model with X1 and A

---

### Statistical Details for the Standard Least Squares Personality

- “Emphasis Rules”
- “Details of Custom Test Example”
- “Correlation of Estimates”
- “Leverage Plot Details”
- “The Kackar-Harville Correction”
- “Power Analysis”
Emphasis Rules

The default emphasis in the Fit Model launch window is based on the number of rows, \( n \), the number of effects (\( k \)) entered in the Construct Model Effects list, and the attributes applied to effects.

- If \( n > 1000 \), the Emphasis is set to Minimal Report.
- If \( n \leq 1000 \) and \( k \leq 4 \), the Emphasis is set to Effect Leverage.
- If \( n \leq 1000 \) and \( k \geq 10 \), the Emphasis is set to Effect Screening.
- If \( n \leq 1000 \) and \( 4 < k < 10 \) and \( n - k > 20 \), the Emphasis is set to Effect Leverage.
- If any effect has a Random Effect attribute, the Emphasis is set to Minimal Report.
- If none of these conditions hold, the Emphasis is set to Effect Screening.

Details of Custom Test Example

In “Example of a Custom Test” on page 125, you are interested in testing three contrasts using the Cholesterol.jmp sample data table. Specifically, you want to compare:

- the mean responses for treatments A and B,
- the mean response for treatments A and B combined to the mean response for the control group,
- the mean response for treatments A and B combined to the mean response for the combined control and placebo groups.

To derive the contrast coefficients that you enter into the Custom Test columns, do the following. Denote the theoretical effects for the four treatment groups as \( \alpha_A \), \( \alpha_B \), \( \alpha_{\text{Control}} \), and \( \alpha_{\text{Placebo}} \). These are the treatment effects, so they are constrained to sum to 0. Because the parameters associated with the indicator variables represent only the first three effects, you need to formulate your contrasts in terms of these first three effects. See “Details of Custom Test Example” on page 204 and “Interpretation of Parameters” on page 536 in the “Statistical Details” appendix.

The hypotheses that you want to test can be written in terms of model effects as follows:

- Compare treatment A to treatment B:
  \[ \alpha_A - \alpha_B = 0 \]
- Compare treatments A and B to the control group:
  \[ 0.5(\alpha_A + \alpha_B) - \alpha_{\text{Control}} = 0 \]
- Compare treatments A and B to the control and placebo groups:
  \[ 0.5(\alpha_A + \alpha_B) - 0.5(\alpha_{\text{Control}} + \alpha_{\text{Placebo}}) = \alpha_A + \alpha_B = 0 \]
To obtain contrast coefficients for this contrast, you need to write the placebo effect in terms of the model effects. Specifically, use the fact that \( \alpha_A + \alpha_B + \alpha_{Control} + \alpha_{Placebo} = 0 \). Then \( \alpha_{Placebo} = -\alpha_A - \alpha_B - \alpha_{Control} \). It follows that:

\[
0.5(\alpha_A + \alpha_B) - 0.5(\alpha_{Control} + \alpha_{Placebo}) = 0.5(\alpha_A + \alpha_B) - 0.5(\alpha_{Control} - \alpha_A - \alpha_B - \alpha_{Control})
\]
\[
= 0.5(\alpha_A + \alpha_B) - 0.5\alpha_{Control} + 0.5(\alpha_A + \alpha_B + \alpha_{Control})
\]
\[
= \alpha_A + \alpha_B
\]
\[
= 0
\]

**Correlation of Estimates**

Consider a data set with \( n \) observations and \( p - 1 \) predictors. Define the matrix \( X \) to be the design matrix. That is, \( X \) is the \( n \) by \( p \) matrix whose first column consists of 1s and whose remaining \( p - 1 \) columns consist of the \( p - 1 \) predictor values. (Nominal columns are coded in terms of indicator predictors. Each of these is a column in the matrix \( X \).)

The estimate of the vector of regression coefficients is

\[
\hat{\beta} = (X'X)^{-1}X'Y
\]

where \( Y \) represents the vector of response values.

Under the usual regression assumptions, the covariance matrix of \( \hat{\beta} \) is

\[
Cov(\hat{\beta}) = \sigma^2(X'X)^{-1}
\]

where \( \sigma^2 \) represents the variance of the response.

The correlation matrix for the estimates is obtained by dividing each entry in the covariance matrix by the product of the square roots of the diagonal entries. Define \( V \) to be the diagonal matrix whose entries are the square roots of the diagonal entries of the covariance matrix:

\[
V = \text{Sqrt}(\text{Diag}(Cov(\hat{\beta})))
\]

Then the correlation matrix for the parameter estimates is given by the following:

\[
\text{Corr}(\hat{\beta}) = \sigma^2 V^{-1}(X'X)^{-1} V^{-1}
\]

**Leverage Plot Details**

Effect leverage plots are also referred to as *partial-regression residual leverage plots* (Belsley et al. 1980) or *added variable plots* (Cook and Weisberg 1982). Sall (1990) generalized these plots to apply to any linear hypothesis.
JMP provides two types of leverage plots:

- Effect Leverage plots show observations relative to the hypothesis that the effect is not in the model, given that all other effects are in the model.
- The Whole Model leverage plot, given in the Actual by Predicted Plot report, shows the observations relative to the hypothesis of no factor effects.

In the Effect leverage plot, only one effect is hypothesized to be zero. However, in the Whole Model Actual by Predicted plot, all effects are hypothesized to be zero. Sall (1990) generalizes the idea of a leverage plot to arbitrary linear hypotheses, of which the Whole Model leverage plot is an example. The details from that paper, summarized in this section, specialize to the two types of plots found in JMP.

**Construction**

Suppose that the estimable hypothesis of interest is

\[ L\beta = 0 \]

The leverage plot characterizes this test by plotting points so that the distance of each point to the sloped regression line displays the unconstrained residual. The distance to the horizontal line at 0 displays the residual when the fit is constrained by the hypothesis. The difference between the sums of squares of these two sets of residuals is the sum of squares due to the hypothesis. This value becomes the main component of the \( F \) test.

The parameter estimates constrained by the hypothesis can be written

\[ b_0 = b - (X'X)^{-1}L\lambda \]

Here \( b \) is the least squares estimate

\[ b = (X'X)^{-1}X'y \]

and \( \lambda \) is the Lagrangian multiplier for the hypothesis constraint, calculated by

\[ \lambda = (L(X'X)^{-1}L')^{-1}Lb \]

The unconstrained and hypothesis-constrained residuals are, respectively,

\[ r = y - Xb \]
\[ r_0 = r + X(X'X)^{-1}L\lambda \]

For each observation, consider the point with horizontal axis value \( v_x \) and vertical axis value \( v_y \), where:

- \( v_x \) is the constrained residual minus the unconstrained residual, \( r_0 - r \), reflecting information left over once the constraint is applied.
• \( v_y \) is the horizontal axis value plus the unconstrained residual

Thus, these points have \( x \) and \( y \) coordinates

\[
 vx = X(X'X)^{-1}L'\lambda \quad \text{and} \quad vy = r + vx
\]

These points form the basis for the leverage plot. This construction is illustrated in Figure 3.67, where the response mean is 0 and slope of the solid line is 1.

Leverage plots in JMP have a dotted horizontal line at the mean of the response, \( \bar{y} \). The plotted points are given by \((vx + \bar{y}, vy)\).

**Figure 3.67  Construction of Leverage Plot**

---

**Superimposing a Test on the Leverage Plot**

In simple linear regression, you can plot the confidence limits for the expected value of the response as a smooth function of the predictor variable \( x \)

Upper \((x) = x \bar{b} + t_{\alpha/2}s_\epsilon \sqrt{x(X'X)^{-1}x'}\)

Lower \((x) = x \bar{b} - t_{\alpha/2}s_\epsilon \sqrt{x(X'X)^{-1}x'}\)

where \( x = [1 \ x] \) is the 2-vector of predictors.

These confidence curves give a visual assessment of the significance of the corresponding hypothesis test, illustrated in Figure 3.56:

• Significant: If the slope parameter is significantly different from zero, the confidence curves cross the horizontal line at the response mean.

• Borderline: If the \( t \) test for the slope parameter is sitting right on the margin of significance, the confidence curve is asymptotic to the horizontal line at the response mean.

• Not Significant: If the slope parameter is not significantly different from zero, the confidence curve does not cross the horizontal line at the response mean.
Leverage plots mirror this thinking by displaying confidence curves. These are adjusted so that the plots are suitably centered. Denote a point on the horizontal axis by \( z \). Define the functions

\[
Upper(z) = z + \sqrt{\frac{2}{n} \left( \frac{1}{\alpha} \right) \bar{h}} + \left( \frac{F_{\alpha}}{F} \right) z^2
\]

and

\[
Lower(z) = z - \sqrt{\frac{2}{n} \left( \frac{1}{\alpha} \right) \bar{h}} + \left( \frac{F_{\alpha}}{F} \right) z^2
\]

where \( F \) is the \( F \) statistic for the hypothesis and \( F_{\alpha} \) is the reference value for significance level \( \alpha \).

And \( \bar{h} = \bar{x} (X'X)^{-1} X' \), where \( \bar{x} \) is a row vector consisting of suitable middle values for the predictors, such as their means.

These functions behave in the same fashion as do the confidence curves for simple linear regression:

- If the \( F \) statistic is greater than the reference value, the confidence functions cross the horizontal axis.
- If the \( F \) statistic is equal to the reference value, the confidence functions have the horizontal axis as an asymptote.
- If the \( F \) statistic is less than the reference value, the confidence functions do not cross.

Also, it is important that \( Upper(z) - Lower(z) \) is a valid confidence interval for the predicted value at \( z \).

**The Kackar-Harville Correction**

The variance matrix of the fixed effects is always modified to include a Kackar-Harville correction. The variance matrix of the BLUPs, and the covariances between the BLUPs and the fixed effects, are not Kackar-Harville corrected. The rationale for this approach is that corrections for BLUPs can be computationally and memory intensive when the random effects have many levels.

In SAS, the Kackar-Harville correction is done for both fixed effects and BLUPs only when the `DDFM=KENWARDROGER` is set.

- Standard errors for linear combinations involving only fixed effects parameters match `PROC MIXED DDFM=KENWARDROGER`. This case assumes that one has taken care to transform between the different parameterizations used by `PROC MIXED` and JMP.
- Standard errors for linear combinations involving only BLUP parameters match `PROC MIXED DDFM=SATTERTHWAITE`. 
• Standard errors for linear combinations involving both fixed effects and BLUPS do not match PROC MIXED for any DDFM option if the data are unbalanced. However, these standard errors are between what you get with the DDFM=SATTERTHWAITE and DDFM=KENWARDROGER options. If the data are balanced, JMP matches SAS for balanced data, regardless of the DDFM option, because the Kackar-Harville correction is null.

Degrees of Freedom

The degrees of freedom for tests involving only linear combinations of fixed effect parameters are calculated using the Kenward and Roger correction. Therefore, the JMP results for these tests match PROC MIXED using the DDFM=KENWARDROGER option. If there are BLUPs in the linear combination, JMP uses a Satterthwaite approximation to get the degrees of freedom. The results then follow a pattern similar to what is described for standard errors in the preceding paragraph.

For more information about the Kackar-Harville correction and the Kenward-Roger DF approach, see Kenward and Roger (1997). The Satterthwaite method is described in detail in the MIXED Procedure chapter in SAS Institute Inc. (2020d, ch. 83).

Power Analysis

Options relating to power calculations are available only for continuous-response models. These are the contexts in which power and related test details are available:

Parameter Estimate

To obtain retrospective test details for each parameter estimate, select Estimates > Parameter Power from the report’s red triangle menu. This option displays the least significant value, the least significant number, and the adjusted power for the 0.05 significance level test for each parameter based on current study data.

Effect or Effect Details

To obtain either prospective or retrospective details for the $F$ test of a specific effect, select Power Analysis from the effect’s red triangle menu. Keep in mind that, for the Effect Screening and Minimal Report personalities, the report for each effect is found under Effect Details. For the Effect Leverage personality, the report for an effect is found to the right of the first (Whole Model) column in the report.

LS Means Contrast

To obtain either prospective or retrospective details for a test of one or more contrasts, select LSMeans Contrast from the effect’s red triangle menu. Define the contrasts of interest and click Done. From the Contrast red triangle menu, select Power Analysis.
Custom Test

To obtain either prospective or retrospective details for a custom test, select Estimates > Custom Test from the response’s red triangle menu. Define the contrasts of interest and click Done. From the Custom Test red triangle menu, select Power Analysis.

In all cases except the first, selecting Power Analysis opens the Power Details window. You then enter information in the Power Details window to modify the calculations according to your needs.

Effect Size

The effect size, denoted by \( \delta \), is a measure of the difference between the null hypothesis and the true values of the parameters involved. The null hypothesis might be formulated in terms of a single linear contrast that is set equal to zero, or of several such contrasts. The value of \( \delta \) reflects the difference between the true values of the contrasts and their hypothesized values of 0.

In general terms, the effect size is given by:

\[
\delta = \sqrt{\frac{SS_{Hyp(Pop)}}{n}}
\]

where \( SS_{Hyp(Pop)} \) is the sum of squares for the hypothesis being tested given in terms of population parameters and \( n \) is the total number of observations.

When observations are available, the estimated effect size is calculated by substituting the calculated sum of squares for the hypothesis into the formula for \( \delta \).

Balanced One-Way Layout

For example, in the special case of a balanced one-way layout with \( k \) levels where the \( i^{th} \) group has mean response \( \alpha_i \)

\[
\delta^2 = \frac{\sum (\alpha_i - \bar{\alpha})^2}{k}
\]

Recall that JMP codes parameters so that, for \( i = 1, 2, ..., k-1 \)

\[
\beta_i = (\alpha_i - \bar{\alpha})
\]

and

\[
\beta_k = - \sum_{m=1}^{k-1} \alpha_m
\]
So, in terms of these parameters, \( \delta \) for a two-level balanced layout is given by:

\[
\delta^2 = \frac{\beta_1^2 + (-\beta_1)^2}{2} = \beta_1^2
\]

or \( \delta = |\beta_1| \)

### Unbalanced One-Way Layout

In the case of an unbalanced one-way layout with \( k \) levels, and where the \( i^{th} \) group has mean response \( \alpha_i \) and \( n_i \) observations, and where \( n = \sum n_i \):

\[
\delta^2 = \sum \frac{n_i}{n} (\alpha_i - \bar{\alpha})^2
\]

### Effect Size and Power

The power is the probability that the \( F \) test of a hypothesis is significant at the \( \alpha \) significance level, when the true effect size is a specified value. If the true effect size equals \( \delta \), then the test statistic has a noncentral \( F \) distribution with noncentrality parameter

\[
\lambda = (n\delta^2)/\sigma^2
\]

When the null hypothesis is true (that is, when the effect size is zero), the noncentrality parameter is zero and the test statistic has a central \( F \) distribution.

The power of the test increases with \( \lambda \). In particular, the power increases with sample size \( n \) and effect size \( \delta \), and decreases with error variance \( \sigma^2 \).

Some books, such as Cohen (1977), use a standardized effect size, \( \Delta = \delta/\sigma \), rather than the raw effect size used by JMP. For the standardized effect size, the noncentrality parameter equals \( \lambda = n\Delta^2 \).

In the Power Details window, \( \delta \) is initially set to \( \sqrt{SS_{Hyp}/n} \). \( SS_{Hyp} \) is the sum of squares for the hypothesis, and \( n \) is the number of observations in the current study. \( SS_{Hyp} \) is an estimate of \( \delta \) computed from the data, but such estimates are biased (Wright and O’Brien 1988). To calculate power using a sample estimate for \( \delta \), you might want to use the Adjusted Power and Confidence Interval calculation rather than the Solve for Power calculation. The adjusted power calculation uses an estimate of \( \delta \) that is partially corrected for bias. See “Computations for the Adjusted Power” on page 563 in the “Statistical Details” appendix.
Plot of Power by Sample Size

To see a plot of power by sample size, select the Power Plot option from the red triangle menu at the bottom of the Power report. JMP plots the Power and Number columns from the Power table. The plot shown in Figure 3.68 results from plotting the Power table obtained in “Example of Retrospective Power Analysis” on page 214.

Figure 3.68  Plot of Power by Sample Size

The Least Significant Number (LSN)

The least significant number (LSN) is the smallest number of observations that leads to a significant test result, given the specified values of delta, sigma, and alpha. Recall that delta, sigma, and alpha represent, respectively, the effect size, the error standard deviation, and the significance level.

Note: LSN is not a recommendation of how large a sample to take because it does not take into account the probability of significance. It is computed based on specified values of delta and sigma.

The LSN has these characteristics:

- If the LSN is less than the actual sample size $n$, then the effect is significant.
- If the LSN is greater than $n$, the effect is not significant. If you believe that more data will show essentially the same structural results as does the current sample, the LSN suggests how much data you would need to achieve significance.
- If the LSN is equal to $n$, then the $p$-value is equal to the significance level alpha. The test is on the border of significance.
- The power of the test for the effect size, calculated when $n = \text{LSN}$, is always greater than or equal to 0.5. Note, however, that the power can be close to 0.5, which is considered low for planning purposes.
The Least Significant Value (LSV)

The LSV, or least significant value, is computed for single-degree-of-freedom hypothesis tests. These include tests for the significance of individual model parameters, as well as more general linear contrasts. The LSV is the smallest effect size, in absolute value, that would be significant at level alpha. The LSV gives a measure of the sensitivity of the test on the scale of the parameter, rather than on a probability scale.

The LSV has these characteristics:

- If the absolute value of the parameter estimate or contrast is greater than or equal to the LSV, then the \( p \)-value of the significance test is less than or equal to alpha.
- The absolute value of the parameter estimate or contrast is equal to the LSV if and only if its significance test has \( p \)-value equal to alpha.
- The LSV is the radius of a \( 1 - \alpha \) confidence interval for the parameter or linear combination of parameters. The \( 1 - \alpha \) confidence interval is centered at the estimate of the parameter or contrast.

Power

The power of a test is the probability that the test gives a significant result. The power is a function of the effect size \( \delta \), the significance level \( \alpha \), the error standard deviation \( \sigma \), and the sample size \( n \). The power is the probability that you will detect a specified effect size at a given significance level. In general, you would like to design studies that have high power of detecting differences that are of practical or scientific importance.

Power has these characteristics:

- If the true value of the parameter is in fact the hypothesized value, the power equals the significance level of the test. The significance level is usually a small value, such as 0.05. The small value is appropriate, because you want a low probability of seeing a significant result when the postulated hypothesis is true.
- If the true value of the parameter is not the hypothesized value, in general, you want the power to be as large as possible.
- Power increases as: sample size increases; error variance decreases; the difference between the true parameter value and the hypothesized value increases.

The Adjusted Power and Confidence Intervals

In retrospective power analysis, you typically substitute sample estimates for the population parameters involved in power calculations. This substitution causes the noncentrality parameter estimate to have a positive bias (Wright and O’Brien 1988). The adjusted power calculation is based on a form of the estimated noncentrality parameter that is partially corrected for this bias.
You can also construct a confidence interval for the adjusted power. Such confidence intervals tend to be wide. See Wright and O’Brien (1988).

Note that the adjusted power and confidence interval calculations are relevant only for the value of \( \delta \) estimated from the data (the value provided by default). For other values of delta, the adjusted power and confidence interval are not provided.

See “Computations for the Adjusted Power” on page 563 in the “Statistical Details” appendix.

**Example of Retrospective Power Analysis**

This example illustrates a retrospective power analysis using the Big Class.jmp sample data table. The Power Details window (Figure 3.69) permits exploration of various quantities over ranges of values for \( \alpha \), \( \sigma \), \( \delta \), and Number, or study size. Clicking Done replaces the window with the results of the calculations.

1. Select Help > Sample Data Library and open Big Class.jmp.
2. Select Analyze > Fit Model.
3. Select weight and click Y.
4. Add age, sex, and height as the effects.
5. Click Run.
6. Click the age red triangle and select Power Analysis.

**Figure 3.69** Power Details Window for Age

7. Replace the \( \delta \) value in the From box with 3, and enter 6 and 1 in the To and By boxes as shown in Figure 3.69.
8. Replace the Number value in the From box with 20, and enter 60 and 10 in the To and By boxes as shown in Figure 3.69.
9. Select Solve for Power and Solve for Least Significant Number.
10. Click Done.
11. The Power Details window is replaced by the Power Details report.
This analysis is a retrospective power analysis because the calculations assume a study with a structure identical to that of the Big Class.jmp sample data table. For example, the calculation of power in this example depends on the effects entered into the model and the number of participants in each age and sex grouping. Also, the value of $\sigma$ was derived from the current study, though you could have replaced it with a value that would be representative of a future study.

For more information about the power results shown in Figure 3.70, see “Power” on page 213. For more information about the least significant number (LSN), see “The Least Significant Number (LSN)” on page 212.

**Prospective Power Analysis**

Prospective analysis helps you answer the question, “If differences of a specified size exist, will I detect them given my proposed sample size, alpha level, and estimate of error variance?” In a prospective power analysis, you must provide estimates of the group means and sample sizes in a data table. You must also provide an estimate of the error standard deviation $\sigma$ in the Power Details window.
Equal Group Sizes

Consider a situation where you are comparing the means of three independent groups. To obtain sample sizes to achieve a given power, select DOE > Sample Size and Power and then select k Sample Means. Next to Std Dev, enter your estimate of the error standard deviation. In the Prospective Means list, enter means that reflect the smallest differences that you want to detect. If, for example, you want to detect a difference of 8 units between any two means, enter the extreme values of the means (for example, 40, 40, and 48). Because the power is based on deviations from the grand mean, you can enter only values that reflect the desired differences (for example, 0, 0, and 8).

If you click Continue, you obtain a graph of power versus sample size. If instead you specify either power or sample size in the Sample Size window, the other quantity is computed and displayed in the Sample Size window. In particular, if you specify power, the sample size that is provided is the total required sample size. The k Sample Means calculation assumes equal group sizes. For three groups, you would divide the sample size by 3 to obtain the individual group sizes. For more information about k Sample Means, see the Design of Experiments Guide.

Unequal Group Sizes

Suppose that you want to design a study that uses groups of different sizes. You need to plan an experiment to study two treatments that reportedly reduce bacterial counts. You want to compare the effect of these treatments with results from a control group that receives no treatment. You also want to detect a difference of at least 8 units between the means of each treatment group and the control group. But the control group must be twice as large as either treatment group. The two treatment groups also must be equal in size. Previous studies suggest that the error standard deviation is on the order of 5 or 6.

To obtain a prospective power analysis for this situation, create a data table containing some basic information, as shown in the Bacteria.jmp sample data table.

Figure 3.71 Bacteria.jmp Data Table

<table>
<thead>
<tr>
<th></th>
<th>Group</th>
<th>Group Means</th>
<th>Relative Sizes</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>Control</td>
<td>40</td>
<td>2</td>
</tr>
<tr>
<td>2</td>
<td>Treatment A</td>
<td>40</td>
<td>1</td>
</tr>
<tr>
<td>3</td>
<td>Treatment B</td>
<td>48</td>
<td>1</td>
</tr>
</tbody>
</table>

- The Group column identifies the groups.
- The Means column reflects the smallest difference among the columns that it is important to detect. Here, it is assumed that the control group has a mean of about 40. You want the test to be significant if either treatment group has a mean that is at least 8 units higher than the mean of the control group. For this reason, you assign a mean of 48 to one of the two treatment groups. Set the mean of the other treatment group equal to that of the control group. (Alternatively, you could assign the control group and one of the treatment groups
means of 0 and the remaining treatment group a mean of 8.) Note that the differences in the group means are population values.

- The Relative Sizes column shows the desired relative sizes of the treatment groups. This column indicates that the control group needs to be twice as large as each of the treatment groups. (Alternatively, you could start out with an initial guess for the treatment sizes that respects the relative size criterion.)

**Note:** The Relative Sizes column must be assigned the role of a Freq (frequency). See the symbol to the right of the column name in the Columns panel.

Next, use Fit Model to fit a one-way analysis of variance model (Figure 3.72). Note that Relative Sizes is declared as Freq in the launch window. Also, the Minimal Report emphasis option is selected.

**Figure 3.72** Fit Model Launch Window for Bacteria Study

Click **Run** to obtain the Fit Least Squares report. The report shows Root Mean Square Error and Sum of Squares for Error as 0.0, because you specified a data table with no error variation within the groups. You must enter a proposed range of values for the error variation to obtain the power analysis. Specifically, you have information that the error variation will be about 5 but might be as large as 6.

1. Click the disclosure icon next to Effect Details to open this report.
2. Click the Group red triangle and select **Power Analysis**.
3. To explore the range of error variation suspected by the scientist, under $\sigma$, enter 5 in the first box and 6 in the second box (Figure 3.73).
4. Note that $\delta$ is entered as 3.464102. This is the effect size that corresponds to the specified difference in the group means. The data table contains three hidden columns that illustrate the calculation of the effect size. (See “Unbalanced One-Way Layout” on page 211.)

5. To explore power over a range of study sizes, under **Number**, enter 16 in the first box, 64 in the second box, and an increment of 4 in the third box (Figure 3.73).

6. Select **Solve for Power**.

7. Click **Done**.

**Figure 3.73**  Power Details Window for Bacteria Study

The Power Details report, shown in Figure 3.74, replaces the Power Details window. This report gives power calculations for $\alpha = 0.05$, for all combinations of $\sigma = 5$ and 6, and sample sizes of 16 to 64 in increments of size 4. When $\sigma$ is 5, to obtain about 90% power, you need a total sample size of about 32. You need 16 participants in the control group and 8 in each of the treatment groups. On the other hand, if $\sigma$ is 6, then a total of 44 participants is required.
Click the arrow at the bottom of the table in the Power Details report to obtain a plot of power versus sample size for the two values of $\sigma$, shown in Figure 3.75. Here, the red markers correspond to $\sigma = 5$ and the green correspond to $\sigma = 6$.

Figure 3.75  Power Plot for Bacteria Study
Chapter 4

Standard Least Squares Examples
Analyze Common Classes of Models

This chapter provides examples with instructional material for several standard least squares topics. These include analysis of variance, analysis of covariance, a response surface model, a split plot design, estimation of random effect parameters, a knotted spline fit, and the identification of active factors using a script that provides a Bayesian approach.

One-Way Analysis of Variance Example

In a one-way analysis of variance, a different mean is fit to each of the different groups, as identified by a nominal variable. To specify the model for JMP, select a continuous response column and a nominal effect column. This example uses the data in Drug.jmp.

1. Select Help > Sample Data Library and open Drug.jmp.
2. Select Analyze > Fit Model.
3. Select y and click Y.
4. Select Drug and click Add.
5. Click Run.

In this example, Drug has three levels, a, d, and f. The standard least squares fitting method translates this specification into a linear model: The nominal variables define a sequence of indicator variables, which assume only the values 1, 0, and –1. The linear model is specified as follows:

\[ y_i = \beta_0 + \beta_1 x_{1i} + \beta_2 x_{2i} + \epsilon_i \]

where:
- \( y_i \) is the observed response for the \( i^{th} \) observation
- \( x_{1i} \) is the value of the first indicator variable for the \( i^{th} \) observation
- \( x_{2i} \) is the value of the second indicator variable for the \( i^{th} \) observation
- \( \beta_0, \beta_1, \) and \( \beta_2 \) are parameters for the intercept, the first indicator variable, and the second indicator variable, respectively
- \( \epsilon_i \) are the independent and normally distributed error terms

The first indicator variable, \( x_{1i} \), is defined as follows. Note that Drug = a contributes a value 1, Drug = d contributes a value 0, and Drug = f contributes a value –1 to the indicator variable:

\[ x_{1i} = \begin{cases} 1, & \text{if Drug = a} \\ 0, & \text{if Drug = d} \\ -1, & \text{if Drug = f} \end{cases} \]

The second indicator variable, \( x_{2i} \), is given the following values:

\[ x_{2i} = \begin{cases} 0, & \text{if Drug = a} \\ 1, & \text{if Drug = d} \\ -1, & \text{if Drug = f} \end{cases} \]
The estimates of the means for the three levels in terms of this parameterization are defined as follows:

\[
\begin{align*}
\mu_a &= \beta_0 + \beta_1 \\
\mu_d &= \beta_0 + \beta_2 \\
\mu_f &= \beta_0 - \beta_1 - \beta_2
\end{align*}
\]

Solving for \( \beta_i \) yields the following:

\[
\begin{align*}
\beta_0 &= \frac{\left( \mu_a + \mu_d + \mu_f \right)}{3} = \mu \quad \text{(the average over levels)} \\
\beta_1 &= \mu_a - \mu \\
\beta_2 &= \mu_d - \mu
\end{align*}
\]

Therefore, if regressor variables are coded as indicators for each level minus the indicator for the last level, then the parameter for a level is interpreted as the difference between that level’s response and the average response across all levels. See the appendix “Statistical Details” on page 529 for additional information about the interpretation of the parameters for nominal factors.

Figure 4.1 shows the Leverage Plot and the LS Means Table for the Drug effect. Figure 4.2 shows the Parameter Estimates and the Effect Tests reports for the one-way analysis of the drug data.

**Figure 4.1** Leverage Plot and LS Means Table for Drug
Figure 4.2  Parameter Estimates and Effect Tests for Drug.jmp

The Drug effect can be studied in more detail by using a contrast of the least squares means:

1. Click the Drug red triangle and select **LSMeans Contrast**.
2. Click the + boxes for drugs a and d, and the - box for drug f to define the contrast that compares the average of drugs a and d to f (shown in Figure 4.3).
3. Click **Done**.

Figure 4.3  Contrast Example for the Drug Experiment

The Contrast report shows that the LSMean for drug f is significantly different from the average of the LSMeans of the other two drugs.
Analysis of Covariance with Equal Slopes Example

An analysis of variance model with a continuous regressor term is called an analysis of covariance. In the Drug.jmp sample data table, the column x is a covariate.

The covariate adds an additional term, \( x_3i \) to the model equation. The model analysis of covariance model is written this way:

\[
y_i = \beta_0 + \beta_1 x_{1i} + \beta_2 x_{2i} + \beta_3 x_{3i} + \varepsilon_i
\]

There are two model effects: one is a nominal main effect involving two parameters, and the other is continuous covariate associated with one parameter.

1. Select Help > Sample Data Library and open Drug.jmp.
2. Select Analyze > Fit Model.
3. Select \( y \) and click Y.
4. Select both Drug and x and click Add.
5. Click Run.

The Regression Plot in the report shows that you have fit a model with equal slopes (Figure 4.4). Compared to the main effects model (Drug effect only), RSquare increases from 22.8% to 67.6%. The Root Mean Square Error decreases from 6.07 to 4.0. As shown in Figure 4.4, the \( F \) test significance probability for the whole model decreases from 0.03 to less than 0.0001.
The drug data table contains replicated observations. For example, rows 1 and 9 both have Drug = a and x = 11. When fitting models, replicated observations can be used to construct a pure error estimate of variation. Another estimate of error can be constructed for unspecified functional forms of covariates, or interactions of nominal effects. These estimates form the basis for a lack of fit test. If the lack of fit error is significant, this indicates that there is some effect in your data not explained by your model.

The Lack of Fit report shows the results of this test for the drug data. The lack of fit error is not significant, as seen by the Prob > F value of 0.7507.
The covariate, \( x \), accounts for much of the variation in the response previously accounted for by the Drug variable. Thus, even though the model is fit with much less error, the Drug effect is no longer significant. The significance of Drug observed in the main effects model appears to be explained by the covariate.

The least squares means in the covariance model differ from the ordinary means. This is because they are adjusted for the effect of \( x \), the covariate, on the response, \( y \). The least squares means are values predicted for each of the three levels of Drug, when the covariate, \( x \), is held at some neutral value. The neutral value is chosen to be the mean of the covariate, which is 10.7333.

The least squares means are calculated using the parameter estimates given in the Parameter Estimates report:

**Prediction Expression:** \[-2.696 - 1.185*\text{Drug}[a] - 1.0761*\text{Drug}[d] + 0.98718*x\]

For a: \[-2.696 - 1.185*(1) - 1.0761*(0) + 0.98718*(10.7333) = 6.71\]

For d: \[-2.696 - 1.185*(0) - 1.0761*(1) + 0.98718*(10.7333) = 6.82\]

For f: \[-2.696 - 1.185*(-1) - 1.0761*(-1) + 0.98718*(10.7333) = 10.16\]

Figure 4.5 shows a leverage plot for each effect. Because the covariate is significant, the leverage values for Drug are dispersed somewhat from their least squares means.

**Figure 4.5** Comparison of Leverage Plots for Drug Test Data
Analysis of Covariance with Unequal Slopes Example

Continuing with the Drug jmp sample data table, this example fits a model where the slope for the covariate depends on the level of Drug. After fitting the model, the example compares the least square means for the levels of Drug at a specific value of the covariate x.

1. Select Help > Sample Data Library and open Drug jmp.
2. Select Analyze > Fit Model.
3. Select y and click Y.
4. Select both Drug and x and click Macros > Factorial to Degree.
   This adds terms up to the degree specified in the Degree box to the model. The default value for Degree is 2. Thus, the main effects of Drug and x, and their interaction, Drug*x, are added to the model effects list.
5. Click Run.

This specification adds two columns to the linear model (call them $x_4$ and $x_5$) that allow the slopes for the covariate to differ by Drug level. The new variables are formed by multiplying the indicator variables for Drug by the covariate values, giving the following formula:

$$y_i = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 + \beta_4 x_4 + \beta_5 x_5 + \varepsilon_i$$

Table 4.1 shows the coding for this model. The mean of $X$ is 10.7333. It is used in centering continuous terms.

</tbody>
</table>

A portion of the report is shown in Figure 4.6. The Regression Plot shows fitted lines with different slopes. The Effect Tests report gives a $p$-value for the interaction of 0.56. This is not significant, indicating the model does not need to include different slopes.
Perform a Spotlight Analysis

You now want to compare the least square means for the levels of Drug at a specific value of the covariate x. This type of comparison in an analysis of covariance model is sometimes referred to as *spotlight analysis*. For more information about spotlight analysis, see Spiller et al. (2013).

1. Click the Response y red triangle and select **Estimates > Multiple Comparisons**.
2. In the Multiple Comparisons window, select **User-Defined Estimates**.
3. Select all three values below **Choose Drug Levels**.
4. In the first box below x, enter 12.5.
5. Click **Add Estimates**.
   This adds comparisons of the three levels of Drug at x = 12.5.
6. Click **OK**.
   The User-Defined Estimates report shows least square means estimates for each level of Drug with the covariate x set to 12.5. The red triangle next to Multiple Comparisons for User-Defined Estimates contains options that enable you to test for differences among the estimates.
Fitting Linear Models Response Surface Model Example

7. Click the red triangle next to Multiple Comparisons for User-Defined Estimates and select **Comparisons with Overall Average**.

**Figure 4.8** Comparisons with Overall Average Decision Chart

The Comparisons with Overall Average option creates an analysis of means (ANOM) chart for differences between the average and the three least squares means. From the ANOM chart, you conclude that there is not a significant effect of Drug on the response at x = 12.5.

Response Surface Model Example

This example fits a response surface model. Your objective is to minimize the response.

- “Fit the Full Response Surface Model”
- “Reduce the Model”
- “Examine the Response Surface Report”
- “Find the Critical Point Using the Prediction Profiler”
- “View the Surface Using the Contour Profiler”
Fit the Full Response Surface Model

1. Select Help > Sample Data Library and open Design Experiment/Custom RSM.jmp.
2. Select Analyze > Fit Model.

Because the data table contains a Model script, the Model Specification window is filled out as specified in the Model script. Note the following:

- Main effects appear in the Construct Model Effects list with a &RS suffix, indicating that the Response Surface macro has been applied.
- The effects are those for a full response surface in the three predictors $X_1$, $X_2$, and $X_3$.
- Because the model contains terms with the &RS suffix, the analysis results will include a Response Surface report.

**Figure 4.9 Fit Model Launch Window for the Response Surface Analysis**

3. Click Run.
Reduce the Model

The Actual by Predicted Plot shows that the model is significant. There is no evidence of lack of fit.

**Figure 4.10** Actual by Predicted Plot for Full Model

The Effect Summary report suggests that a number of effects are not significant. In particular, $X_2 \times X_3$ is the least significant effect with a PValue of 0.99563. Next, you will systematically reduce the model using the Effect Summary report interactively.

**Figure 4.11** Effect Summary Report

1. In the Effect Summary report, click $X_2 \times X_3$ and click **Remove**.
   The model updates.
   The PValue column in the Effect Summary report indicates that $X_1 \times X_3$ is not significant.
2. Click $X_1 \times X_3$ and click **Remove**.
   The PValue for $X_3 \times X_3$ indicates that it is not significant.
3. Click $X_3 \times X_3$ and click **Remove**.
4. Click $X_1 \times X_2$ and click **Remove**.
Notice that $X_3$ is not significant. It is not contained in any higher-order effects, so you can remove it without violating the Effect Heredity principle. See “Effect Heredity” on page 185 in the “Standard Least Squares Models” chapter.

5. Click $X_3$ and click **Remove**.

**Figure 4.12** Effect Summary Report After Reducing Model

All remaining effects are significant.

**Examine the Response Surface Report**

1. Click the Response Y red triangle and select **Estimates > Show Prediction Expression**.

**Figure 4.13** Prediction Expression

<table>
<thead>
<tr>
<th>Prediction Expression</th>
</tr>
</thead>
<tbody>
<tr>
<td>$55.721136364$</td>
</tr>
<tr>
<td>$+ 2.349 \cdot X_1$</td>
</tr>
<tr>
<td>$+ 5.003 \cdot X_2$</td>
</tr>
<tr>
<td>$+ X_1 \cdot (X_1 \cdot 4.4365909091)$</td>
</tr>
<tr>
<td>$+ X_2 \cdot (X_2 \cdot 5.0765909091)$</td>
</tr>
</tbody>
</table>

**Tip:** The Prediction Expression is the prediction formula. You can also obtain this formula by selecting **Save Columns > Prediction Formula**.

In the following steps, you can refer to the prediction expression to see the model coefficients.

2. Open the Response Surface report and then the Canonical Curvature report.
The first table gives the second-order model coefficients in matrix form. The coefficient of $X_1^2$ is 4.4365909, the coefficient of $X_2^2$ is 5.0765909, and the coefficient of $X_1X_2$ is 0. The coefficients of the linear effects, 2.349 for $X_1$ and 5.003 for $X_2$, are given in the column labeled $Y$.

The Solution report shows the critical values. These are the values where a maximum, a minimum, or a saddle point occur. In this example, the Solution report indicates that the response surface achieves a minimum of 54.18 at the critical value, where $X_1 = -0.265$ and $X_2 = -0.493$.

The Canonical Curvature report shows the eigenstructure of the matrix of second-order parameter estimates. The eigenstructure is useful for identifying the shape and orientation of the curvature. See “Canonical Curvature Report” on page 86 in the “Standard Least Squares Models” chapter.

In this example, both eigenvalues are positive, which indicates that the surface achieves a minimum. The direction of greatest curvature corresponds to the largest eigenvalue (5.0766). That direction is defined by the corresponding eigenvector components. For the first direction, $X_2$, with an eigenvector value of 1.00, determines the direction. The second direction is determined by $X_1$, also with an eigenvector value of 1.00.

**Find the Critical Point Using the Prediction Profiler**

The Prediction Profiler report shows the quadratic behavior of the response surface along traces for $X_1$ and $X_2$. Because the Response Limits column property is set for $Y$, the profiler also shows desirability functions.
The goal for the Response Limits column property is set to Match Target. For this example, you are interested in minimizing $Y$, not matching a target. Therefore, you must change the setting:

1. Press Ctrl and click in the top right cell of the Prediction Profiler.
2. In the Response Goal dialog, select **Minimize** from the list of options.
3. Click **OK**.
   The desirability function now reflects your goal of minimizing $Y$.
4. Click the Prediction Profiler red triangle and select **Optimization and Desirability > Maximize Desirability**.

Settings within the design region that minimize $Y$ appear under the profiler. Note that these are precisely the Critical Values given in the Solution report.
View the Surface Using the Contour Profiler

The Contour Profiler shows contours of the response surface. It gives an alternate profiler visualization of the predicted response in the area of the critical point.

1. Click the Response Y red triangle and select Factor Profiling > Contour Profiler.
2. Click the Contour Profiler red triangle and select Contour Grid.
3. For Increment, type 1.
4. Click OK.

The contours are plotted at one unit intervals. See Figure 4.17.

5. Click the Prediction Profiler red triangle and select Factor Settings > Link Profilers.

Figure 4.17 Contour Profiler with Crosshairs at Critical Point

Linking the Contour Profiler to the Prediction Profiler links the Current X values in the Contour Profiler to the X values shown in the Prediction Profiler. The X values in the Prediction Profiler give the critical point where Y is minimized. The crosshairs in the Contour Profiler show the critical point. Notice that the Current Y value is 54.177592, the predicted minimum value according to the Prediction Profiler.

Often, it is not possible to set your process factors to exactly the values that optimize the response. The Contour Profiler can help you identify alternate settings of the process factors. In the next steps, suppose that you can set your process to X1 and X2 values with
only one decimal place precision, and that your process settings can vary by one decimal place in either direction of those settings.

6. In the Contour Profiler report, under **Current X**, type -0.3 next to X1 and -0.5 next to X2.

**Figure 4.18** Contour Profiler Showing X1 = -0.3 and X2 = -0.5

The crosshairs are well within the innermost contour and the Current Y (the predict Y value at the Current X settings) is 54.183377, only slightly different from the predicted minimum of 54.177592.

7. In the Contour Profiler, click and drag the crosshairs to explore Current X values within a 0.1 unit radius of X1 = -0.3 and X2 = -0.5.

The predicted Y values are all below 54.4. In fact, if the settings wander to any point within the innermost contour, the predicted Y is less than the contour value of 55.17.
Levels of random effects are randomly selected from a larger population of levels. For the purpose of inference, the distribution of a random effect is assumed to be normal, with mean zero and some variance (called a variance component).

In a sense, every model has at least one random effect, which is the effect that makes up the residual error. The individual observations are assumed to be randomly selected from a much larger population, and the error term is assumed to have a mean of zero and variance $\sigma^2$.

The most common random effects model is the repeated measures or split plot model. Table 4.2 lists the types of effects in a split plot model. In these models, the experiment has two layers. Some effects are applied on the whole plots or subjects of the experiment. Then these plots are divided or the subjects are measured at different times and other effects are applied within those subunits. The effects describing the whole plots or subjects are whole plot effects, and the subplots or repeated measures are subplot effects. Usually, the subunit effect is omitted from the model and absorbed as residual error.

### Table 4.2 Types of Effects in a Split Plot Model

<table>
<thead>
<tr>
<th>Split Plot Model</th>
<th>Type of Effect</th>
<th>Repeated Measures Model</th>
</tr>
</thead>
<tbody>

<td>within subject treatment</td>
</tr>
<tr>
<td>subplot ID</td>
<td>random effect</td>
<td>repeated measures ID</td>
</tr>
</tbody>
</table>

Each of these cases can be treated as a layered model, and there are several traditional ways to fit them in a fair way. The situation is treated as two different experiments:

1. The whole plot experiment has whole plot or subjects as the experimental unit to form its error term.
2. Subplot treatment has individual measurements for the experimental units to form its error term (left as residual error).

The older, traditional way to test whole plots is to do any one of the following:

- Take means across the measurements and fit these means to the whole plot effects.
- Form an $F$-ratio by dividing the whole plot mean squares by the whole plot ID mean squares.
These approaches work if the structure is simple and the data are complete and balanced. However, there is a more general model that works for any structure of random effects. This more generalized model is called the mixed model, because it has both fixed and random effects.

The most common type of layered design is a balanced split plot, often in the form of repeated measures across time. One experimental unit for some of the effects is subdivided (sometimes by time period) and other effects are applied to these subunits.

Consider the data in the Animals.jmp sample data table (the data are fictional). The study collected information about differences in the seasonal hunting habits of foxes and coyotes. Each season for one year, three foxes and three coyotes were marked and observed periodically. The average number of miles that they wandered from their dens during different seasons of the year was recorded (rounded to the nearest mile). The model is defined by the following aspects:

- The continuous response variable called miles
- The species effect with values fox or coyote
- The season effect with values fall, winter, spring, and summer
- An animal identification code called subject, with nominal values 1, 2, and 3 for both foxes and coyotes

There are two layers to the model:

1. The top layer is the between-subject layer, in which the effect of being a fox or coyote (species effect) is tested with respect to the variation from subject to subject.
2. The bottom layer is the within-subject layer, in which the repeated-measures factor for the four seasons (season effect) is tested with respect to the variation from season to season within a subject. The within-subject variability is reflected in the residual error.

The season effect can use the residual error for the denominator of its $F$ statistics. However, the between-subject variability is not measured by residual error and must be captured with the subject within species (subject[species]) effect in the model. The $F$ statistic for the between-subject effect species uses this nested effect instead of residual error for its $F$ ratio denominator.

**Note:** JMP Pro users can construct this model using the Mixed Model personality.

To specify the split plot model for this data, follow these steps:

1. Select Help > Sample Data Library and open Animals.jmp.
2. Select Analyze > Fit Model.
3. Select miles and click Y.
4. Select species and subject and click Add.
5. In the Select Columns list, select species.
6. In the Construct Model Effects list, select subject.
7. Click Nest.
   This adds the subject within species (subject[species]) effect to the model.
8. Select the nested effect subject[species].
9. Select Attributes > Random Effect.
   This nested effect is now identified as an error term for the species effect and appears as subject[species]&Random.
10. In the Select Columns list, select season and click Add.
    When you define an effect as random using the Attributes menu, the Method options (REML and EMS) appear at the top right of the dialog. The REML option is selected as the default. The completed launch window is shown in Figure 4.19.

Figure 4.19  Fit Model Dialog

11. Click Run.
    The report is shown in Figure 4.20. Both fixed effects, species and season, are significant. The REML Variance Component Estimates report gives estimates of the subject within species and residual variances.
Random effects have a dual character. In one characterization, they represent residual error, such as the error associated with a whole-plot experimental unit. In another characterization, they are like fixed effects, associating a parameter with each level of the random effect. As parameters, you have extra information about them—they are derived from a normal distribution with mean zero and the variance estimated by the variance component. The effect of this extra information is that the estimates of the parameters are shrunken toward zero.

The parameter estimates associated with random effects are called BLUPs (Best Linear Unbiased Predictors). Some researchers consider these BLUPs as parameters of interest, and others consider them uninteresting by-products of the methodology.
BLUP parameter estimates are used to estimate random-effect least squares means, which are therefore also shrunken toward the grand mean. The degree of shrinkage depends on the variance of the effect and the number of observations per level in the effect. With large variance estimates, there is little shrinkage. If the variance component is small, then more shrinkage takes place. If the variance component is zero, the effect levels are shrunk to exactly zero. It is even possible to obtain highly negative variance components where the shrinkage is reversed. You can consider fixed effects as a special case of random effects where the variance component is very large.

The REML method balances the information about each individual level with the information about the variances across levels. If the number of observations per level is large, the estimates shrink less. If there are very few observations per level, the estimates shrink more. If there are infinitely many observations, there is no shrinkage and the estimates are identical to fixed effects.

Suppose that you have batting averages for different baseball players. The variance component for the batting performance across players describes how much variation is typical between players in their batting averages. Suppose that the player plays only a few times and that the batting average is unusually small or large. Then you tend not to trust that estimate, because it is based on only a few at-bats. But if you mix that estimate with the grand mean, that is, shrink the estimate toward the grand mean, you would trust the estimate more. For players who have a long batting record, you would shrink much less than those with a short record.

You can explore this behavior yourself.

1. Select Help > Sample Data Library and open Baseball.jmp.
2. Select Analyze > Fit Model.
3. Select Batting and click Y, Response.
4. Select Player and click Add.
5. Select Player in the Construct Model Effects box, and select Random Effect from the Attributes list.
6. Click Run.

Table 4.3 shows the Least Squares Means from the Player report for a REML (Recommended) fit. Also shown are the Method of Moment estimates, obtained using the EMS Method. The Method of Moment estimates are the ordinary Player means. Note that the REML estimate for Suarez, who has only three at-bats, is shrunk more toward the grand mean than estimates for other players with more at-bats.
Knotted Spline Effect Example

Use the Knotted Spline Effect option to fit a segmentation of smooth polynomials to a specified effect. When you select this attribute, a window appears, enabling you to specify the number of knot points. (Knotted splines are implemented only for main-effect continuous terms.)

JMP follows the advice in the literature in positioning the points. The knotted spline is also referred to as a Stone spline or a Stone-Koo spline. See Stone and Koo (1985). If there are 100 or fewer points, the first and last knots are the fifth point inside the minimum and maximum, respectively. Otherwise, the first and last knots are placed at the 0.05 and 0.95 quantiles if there are 5 or fewer knots, or the 0.025 and 0.975 quantiles for more than 5 knots. The default number of knots is 5 unless there are 30 or fewer points. In that case, the default is 3 knots.

Knotted splines have the following properties in contrast to smoothing splines:

- Knotted splines work inside general models with many terms, whereas smoothing splines are for bivariate regressions.
- The regression basis is not a function of the response.
- Knotted splines are parsimonious, adding only \( k - 2 \) terms for curvature for \( k \) knot points.
- Knotted splines are conservative compared to pure polynomials in the sense that the extrapolation outside the range of the data is a straight line, rather than a polynomial.
- There is an easy test for curvature.

Table 4.3  Comparison of Estimates between Method of Moments and REML

Least Squares Means

- same as ordinary means
- shrunken from means
Example Using the Knotted Spline Effect to Test for Curvature

To test for curvature, follow these steps:

1. Select Help > Sample Data Library and open Growth.jmp.
2. Select Analyze > Fit Model.
3. Select the ratio column and click Y.
4. Select the age column and click Add.
5. Select age in the Effects pane and select Attributes > Knotted Spline Effect.
6. For the number of knots, type 5 and click OK.

Figure 4.21 Fit Model Launch Window

7. Click Run.
8. Click the Response ratio red triangle and select Estimates > Custom Test.
   In the Custom Test report, notice that there is only one column. You want three columns.
9. Click the Add Column button twice to produce a total of three columns.
10. In the first column, type 1 for age&Knotted@4.5.
11. In the second column, type 1 for age&Knotted@20.25.
12. In the third column, type 1 for age&Knotted@36.
Suppose that you conduct an experimental design and want to determine which factors are active. You can address this in several ways using JMP. This example illustrates a script that can be used to identify active factors using a Bayesian approach.

1. Select **Help > Sample Data Library** and open **Reactor.jmp**.
2. In the Samples > Scripts folder, open the **BayesPlotforFactors.jsl** sample script.
3. Select **Edit > Run Script**.
4. Select **Y** and click **Y, Response**.
5. Select **F**, **Ct**, **A**, **T**, and **Cn** and click **X, Factor**.
6. Click **OK**.
Figure 4.24  Bayes Plot for Factor Activity

The Model Complexity indicates that the highest order interaction to consider is two. Therefore, all possible models that include up to second-order interactions are constructed. Based on the value assigned to Prior Probability, a posterior probability is computed for each of the possible models. The probability for a factor is the sum of the probabilities for each of the models where it was involved.

This approach identifies \(C_t\), \(T\), and \(C_n\) as active factors, and \(A\) and \(F\) as inactive.

If the ridge parameter were zero (not allowed), all the models would be fit by least squares. As the ridge parameter increases, the parameter estimates for any model shrink toward zero. For more information on the ridge parameter, and why it cannot be zero, see Box and Meyer (1993).
Stepwise regression models

Stepwise regression is an approach to selecting a subset of effects for a regression model. It can be useful in the following situations:

- There is little theory to guide the selection of terms for a model.
- You want to interactively explore which predictors seem to provide a good fit.
- You want to improve a model’s prediction performance by reducing the variance caused by estimating unnecessary terms.

For categorical predictors, you can do the following:

- Choose from among various rules to determine how associated terms enter the model.
- Enforce effect heredity.

The Stepwise platform also enables you to explore all possible models and to conduct model averaging.

Overview of Stepwise Regression

In JMP, stepwise regression is a personality of the Fit Model platform. The Stepwise feature computes estimates that are the same as those of other least squares platforms, but it facilitates searching and selecting among many models.

The approach has side effects of which you need to be aware. The significance levels on the statistics for selected models violate the standard statistical assumptions because the model has been selected rather than tested within a fixed model. On the positive side, the approach has been helpful for 30 years in reducing the number of terms. The book *Subset Selection in Regression* (Miller 1990) brings statistical sense to model selection statistics.

This chapter uses the term *significance probability* in a mechanical way to represent that the calculation would be valid in a fixed model, recognizing that the true significance probability could be nowhere near the reported one.

Example Using Stepwise Regression

The Fitness.jmp data table contains the results of an aerobic fitness study. Aerobic fitness can be evaluated using a special test that measures the oxygen uptake of a person running on a treadmill for a prescribed distance. However, it would be more economical to find a formula that uses simpler measurements that evaluate fitness and predict oxygen uptake. To identify such an equation, measurements of age, weight, run time, and pulse were taken for 31 participants who ran 1.5 miles.

*Note:* For purposes of illustration, certain values of MaxPulse and RunPulse have been changed from data reported by Rawlings (1988, p.105).

1. Select Help > Sample Data Library and open Fitness.jmp.
2. Select Analyze > Fit Model.
3. Select Oxy and click Y.
4. Select Weight, Runtime, RunPulse, RstPulse, MaxPulse, and click Add.
5. For Personality, select Stepwise.
To find a good oxygen uptake prediction equation, you need to compare many different regression models. Use the options in the Stepwise report window to search through models with combinations of effects and choose the model that you want.
The Stepwise Report

The Stepwise report window contains the following elements:

Platform options  The Stepwise Fit red triangle menu contains options that affect all of the variables. See “Stepwise Platform Options” on page 253.

Stepwise Regression Control  Controls that limit regressor effect probabilities, determine the method of selecting effects, start or stop the selection process, and create a model. See “Stepwise Regression Control Panel” on page 254.

Current Estimates  A report that enables you to add, remove, and lock in model effects. See “Current Estimates Report” on page 261.

Step History  A report that records the effect of adding a term to the model. See “Step History Report” on page 262.

Stepwise Platform Options

The Stepwise Fit red triangle menu contains the following options:

K-Fold Crossvalidation  (Available only for continuous responses.) Performs K-Fold cross validation in the selection process. When selected, this option enables the Max K-Fold RSquare stopping rule (“Stepwise Regression Control Panel” on page 254). For more information about validation, see “Validation Options in Stepwise Regression” on page 278.

All Possible Models  (Available only for continuous responses.) Fits all possible models up to specified limits and shows the best models for each number of terms. Enter values for the maximum number of terms to fit in any one model. Also enter values for the maximum number of best model results to show for each number of terms in the model. Categorical variables are represented using indicator variables. See “Models with Nominal and Ordinal Effects” on page 265. You can restrict the models that appear to those that satisfy strong effect heredity. See “The All Possible Models Option” on page 275.

Model Averaging  (Available only for continuous responses.) Enables you to average the fits for a number of models, instead of selecting a single best model. See “The Model Averaging Option” on page 277.

Plot Criterion History  Creates a plot of AICc and BIC versus the number of parameters. The Criterion History plot contains two shaded zones. Define the minimum AICc value as $V^{\text{best}}$. The green zone is defined by the range $[V^{\text{best}}, V^{\text{best}}+4]$. The yellow zone is defined by the range $(V^{\text{best}}+4, V^{\text{best}}+10]$. 
**Plot RSquare History**  (Available only for continuous responses.) Creates a plot of training and validation R-square versus the number of parameters.

**Clear History**  Clears and resets the step history.

**Export Model with Validation**  (Available only when you have entered a Validation column in the Stepwise launch window.) Adds the Validation column to the Model Specification window when you select Make Model. Runs the model with the Validation column when you select Run Model.

This option is selected by default.

**Model Dialog**  Shows the completed Fit Model launch window for the current model.

---

**Stepwise Regression Control Panel**

Use the Stepwise Regression Control panel to limit regressor effect probabilities, determine the method of selecting effects, begin or stop the selection process, and run a model. A note appears beneath the Go button to indicate whether you have excluded or missing rows.

**Figure 5.3**  Stepwise Regression Control Panel

---

**Stopping Rule**

The Stopping Rule determines which model is selected. For all stopping rules other than P-value Threshold, only the Forward and Backward directions are allowed. The only stopping rules that use validation are Max Validation RSquare and Max K-Fold RSquare. See “Validation Options in Stepwise Regression” on page 278.

**P-value Threshold**  Uses $p$-values (significance levels) to enter and remove effects from the model. Two other options appear when you choose P-value Threshold:

**Prob to Enter**  Specifies the maximum $p$-value that an effect must have to be entered into the model during a forward step.

**Prob to Leave**  Specifies the minimum $p$-value that an effect must have to be removed from the model during a backward step.
Minimum AICc  Uses the minimum corrected Akaike Information Criterion to choose the best model. For more details, see “Likelihood, AICc, and BIC” on page 559 in the “Statistical Details” appendix.

Minimum BIC  Uses the minimum Bayesian Information Criterion to choose the best model. For more details, see “Likelihood, AICc, and BIC” on page 559 in the “Statistical Details” appendix.

Max Validation RSquare  Uses the maximum R-square from the validation set to choose the best model. This is available only when you use a validation column with two or three distinct values. For more information about validation, see “Validation Set with Two or Three Values in Stepwise Regression” on page 278.

Max K-Fold RSquare  Uses the maximum RSquare from K-fold cross validation to choose the best model. You can access the Max K-Fold RSquare stopping rule by selecting this option from the Stepwise red triangle menu. JMP Pro users can access the option by using a validation set with four or more values. When you select this option, you are asked to specify the number of folds. For more information about validation, see “K-Fold Cross Validation in Stepwise Regression” on page 281.

Direction

The Direction you choose controls how effects enter and leave the model. Select one of the following options:

Forward  Enters the term with the smallest $p$-value. If the P-value Threshold stopping rule is selected, that term must be significant at the level specified by Prob to Enter. See “Forward Selection Example” on page 259.

Backward  Removes the term with the largest $p$-value. If the P-value Threshold stopping rule is selected, that term must not be significant at the level specified in Prob to Leave. See “Backward Selection Example” on page 259.

Note: When Backward is selected as the Direction, you must click Enter All before clicking Go or Step.

Mixed  Available only when the P-value Stopping Rule is selected. It alternates the forward and backward steps. It includes the most significant term that satisfies Prob to Enter and removes the least significant term satisfying Prob to Leave. It continues removing terms until the remaining terms are significant and then it changes to the forward direction.

Go, Stop, Step Buttons

The Go, Stop, and Step buttons enable you to control how terms are entered or removed from the model.
**Note:** All Stopping Rules consider only models defined by $p$-value entry (Forward direction) or removal (Backward direction). Stopping rules do not consider all possible models.

**Go**  
Automates the process of entering (Forward direction) or removing (Backward direction) terms. Among the fitted models, the model that is considered best based on the selected Stopping Rule is listed last. Except for the P-value Threshold stopping rule, the model selected as Best is one that overlooks local dips in the behavior of the stopping rule statistic. The button to the right the Best model selects it for the Make Model and Run Model options, but you are free to change this selection.

- For P-value Threshold, the best model is based on the Prob to Enter and Prob to Leave criteria. See “P-value Threshold” on page 254.
- For Min AICc and Min BIC, the automatic fits continue until a Best model is found. The Best model is one with a minimum AICc or BIC that can be followed by as many as ten models with larger values of AICc or BIC, respectively. This model is designated by the terms Best in the Parameter column and Specific in the Action column.
- For Max Validation RSquare (JMP Pro only) and Max K-Fold RSquare, the automatic fits continue until a Best model is found. The Best model is one with an RSquare Validation or RSquare K-Fold value that can be followed by as many as ten models with smaller values of RSquare Validation or RSquare K-Fold, respectively. This model is designated by the terms Best in the Parameter column and Specific in the Action column.

**Stop**  
Stops the automatic selection process started by the Go button.

**Step**  
Enters terms one-by-one in the Forward direction or removes them one-by one in the Backward direction. At any point, you can select a model by clicking its button on the right in the Step History report. The selection of model terms is updated in the Current Estimates report. This is the model that is used once you click Make Model or Run Model.

**Rules**

**Note:** Appears only if your model contains related terms. When you have a nominal or ordinal variable, related terms are constructed and appear in the Current Estimates table.

Use Rules to change the rules that are applied when there is a hierarchy of terms in the model. A hierarchy can occur in the following ways:

- A hierarchy results when a variable is a component of another variable. For example, if your model contains variables A, B, and A*B, then A and B are *precedent* terms to A*B in the hierarchy.
• A hierarchy also results when you include nominal or ordinal variables. A term that is above another term in the tree structure is a **precedent** term. See “Construction of Hierarchical Terms” on page 265.

Select one of the following options:

**Combine**  Calculates *p*-values for two separate tests when considering entry for a term that has precedents. The first *p*-value, *p₁*, is calculated by grouping the term with its precedent terms and testing the group’s significance probability for entry as a joint *F* test. The second *p*-value, *p₂*, is the result of testing the term’s significance probability for entry after the precedent terms have already entered into the model. The final significance probability for entry for the term that has precedents is max(*p₁*, *p₂*).

**Tip:** The Combine rule avoids including non-significant interaction terms, whose precedent terms can have particularly strong effects. In this scenario, the strong main effects might make the group’s significance probability for entry, *p₁*, very small. However, the second test finds that the interaction by itself is not significant. As a result, *p₂* is large and is used as the final significance probability for entry.

**Caution:** The degrees of freedom value for a term that has precedents depends on which of the two significance probabilities for entry is larger. The test used for the final significance probability for entry determines the degrees of freedom, nDF, in the Current Estimates table. Therefore, if *p₁* is used, nDF equals the number of terms in the group for the joint test, and if *p₂* is used, nDF equals 1.

The Combine option is the default rule. See “Models with Crossed, Interaction, or Polynomial Terms” on page 263.

**Restrict**  Restricts the terms that have precedents so that they cannot be entered until their precedents are entered. See “Models with Nominal and Ordinal Effects” on page 265 and “Example of the Restrict Rule for Hierarchical Terms” on page 271.

**No Rules**  Gives the selection routine complete freedom to choose terms, regardless of whether the routine breaks a hierarchy or not.

**Whole Effects**  Enters only whole effects, when terms involving that effect are significant. This rule applies only when categorical variables with more than two levels are entered as possible model effects. See “Rules” on page 270.

**Buttons**

The Stepwise Control Panel contains the following buttons:

**Go**  Automates the selection process to completion.

**Stop**  Stops the selection process.
**Stepwise Regression Models**

**Chapter 5**

**The Stepwise Report**

**Fitting Linear Models**

**Step**  Increments the selection process one step at a time.

**Arrow buttons**  ▶ ◀  Step forward and backward one step in the selection process.

**Enter All**  Enters all unlocked terms into the model.

**Remove All**  Removes all unlocked terms from the model.

**Make Model**  Creates a model for the Fit Model window from the model currently showing in the Current Estimates table. In cases where there are nominal or ordinal terms, **Make Model** creates temporary transform columns that contain terms that are needed for the model.

**Run Model**  Runs the model currently showing in the Current Estimates table. In cases where there are nominal or ordinal terms, **Run Model** creates temporary transform columns that contain terms that are needed for the model.

**Statistics**

The following statistics appear below the Stepwise Regression Control panel.

**SSE**  Sum of squared errors for the current model.

**DFE**  Error degrees of freedom for the current model.

**RMSE**  Root mean square error (residual) for the current model.

**RSquare**  Proportion of the variation in the response that can be attributed to terms in the model rather than to random error.

**RSquare Adj**  Adjusts $R^2$ to make it more comparable over models with different numbers of parameters by using the degrees of freedom in its computation. The adjusted $R^2$ is useful in stepwise procedure because you are looking at many different models and want to adjust for the number of terms in the model.

**Cp**  Mallow’s $C_p$ criterion for selecting a model. It is an alternative measure of total squared error and can be defined as follows:

$$C_p = \left( \frac{SSE_p}{s^2} \right) - (N - 2p)$$

where $s^2$ is the MSE for the full model and $SSE_p$ is the sum-of-squares error for a model with $p$ variables, including the intercept. Note that $p$ is the number of $x$-variables+1. If $C_p$ is graphed with $p$, Mallows (1973) recommends choosing the model where $C_p$ first approaches $p$.

**p**  Number of parameters in the model, including the intercept.
**AICc** Corrected Akaike’s Information Criterion. For more details, see “Likelihood, AICc, and BIC” on page 559 in the “Statistical Details” appendix.

**BIC** Bayesian Information Criterion. For more details, see “Likelihood, AICc, and BIC” on page 559 in the “Statistical Details” appendix.

**Forward Selection Example**

In forward selection, terms are entered into the model and most significant terms are added until all of the terms are significant.

1. Complete the steps in “Example Using Stepwise Regression” on page 251.
   
   Notice that the default selection for **Direction** is Forward.

2. Click **Step**.

   In Figure 5.4, you can see that after one step, the most significant term, Runtime, is entered into the model.

3. Click **Go**.

   In Figure 5.5 you can see that all of the terms have been added, except RstPulse and Weight.

**Figure 5.4** Current Estimates Table for Forward Selection after One Step

**Figure 5.5** Current Estimates Table for Forward Selection after Three Steps

**Backward Selection Example**

In backward selection, all terms are entered into the model and then the least significant terms are removed until all of the remaining terms are significant.

1. Complete the steps in “Example Using Stepwise Regression” on page 251.

2. Click **Enter All**.
3. For **Direction**, select Backward.

4. Click **Step** two times.

   The first backward step removes **RstPulse** and the second backward step removes **Weight**.

**Figure 5.7** Current Estimates with Terms Removed and Step History Table

The Current Estimates and Step History tables shown in Figure 5.7 summarize the backward stepwise selection process. Note the BIC value of 156.362 for the third step in the Step History table. If you click Step again to remove another parameter from the model, the BIC value increases to 159.984. For this reason, you choose the step 3 model. This is also the model that the Go button produces.
Current Estimates Report

Use the Current Estimates report to enter, remove, and lock in model effects. (The intercept is permanently locked into the model.) This report contains the following columns:

Figure 5.8 Current Estimates Table

<p>| | | | | | | | | | | |</p>

<td>197.5412</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

**Lock**  Locks a term in or out of the model. A checked term cannot be entered or removed from the model.

**Entered** Indicates whether a term is currently in the model. You can click a term’s check box to manually bring an effect in or out of the model.

**Parameter** The effect names.

**Estimate** The current parameter estimate, which is zero if the effect is not currently in the model.

**nDF** The number of degrees of freedom for a term. A term has more than one degree of freedom if its entry into a model also forces other terms into the model.

**Wald/Score ChiSq** (Shown only when response is categorical.) The test statistic for each term in the model. For terms not already included in the model, the test statistic is based on a score test of including the term in the model. For terms that are already included in the model, the test statistic is based on a Wald test of removing the term from the model.

**“Sig Prob”** (Shown only when response is categorical.) The p-value associated with the Wald/Score ChiSq test statistic based on nDF degrees of freedom. The “Sig Prob” is used to determine the next term to be included in the model.

**SS** (Shown only when response is continuous.) The reduction in the error (residual) sum of squares (SS) if the term is entered into the model or the increase in the error SS if the term is removed from the model. If a term is restricted in some fashion, it could have a reported SS of zero.

**“F Ratio”** (Shown only when response is continuous.) The traditional test statistic to test that the term effect is zero. It is the square of a t-ratio. It is in quotation marks because it does not have an F-distribution for testing the term because the model was selected as it was fit.
“Prob>F” (Shown only when response is continuous.) The \( p \)-value associated with the \( F \) statistic. Like the “F Ratio,” it is in quotation marks because it is not to be trusted as a real significance probability.

\[ R \] The multiple correlation with the other effects in the model. This column appears only if you right-click in the report and select Columns > R.

**Step History Report**

As each step is taken, the Step History report records the effect of adding a term to the model. For example, the Step History report for the Fitness.jmp example shows the order in which the terms entered the model and shows the statistics for each model. See “Example Using Stepwise Regression” on page 251.

Use the radio buttons on the right to choose a model.

**Step History for Categorical Responses**

The Step History report for models with a categorical response contains four additional columns: L-R ChiSquare, “Sig Prob”, Entry ChiSquare, and Entry “Sig Prob”.

The L-R ChiSquare and “Sig Prob” columns contain the full-versus-reduced likelihood ratio test statistic and \( p \)-value. Here, the full model is the one that contains the specified term and the reduced model does not contain the specified term.

The Entry ChiSquare and Entry “Sig Prob” columns contain the Wald/Score ChiSquare and “Sig Prob” values that were used to choose the most recent term to include in the model.

**Figure 5.10 Step History for a Categorical Response before First Step**
Models with Crossed, Interaction, or Polynomial Terms

Some models, especially those associated with experimental designs, involve interaction terms. For continuous factors, these are products of the columns representing the effects. For nominal and ordinal factors, interactions are defined by model terms that involve products of terms representing the categorical levels.

When there are interaction terms, you often want to impose a restriction on the model selection process so that lower-order components of higher-order effects are included in the model. This is suggested by the principle of Effect Heredity. See the Design of Experiments Guide. For example, if a two-way interaction is included in a model, its component main effects (precedents) should be included as well.

Example of the Combine Rule

1. Select Help > Sample Data Library and open Reactor.jmp.
2. Select Analyze > Fit Model.
3. Select Y and click Y.
4. In the Degree box, type 2.
5. Select F, Ct, A, T, and Cn and click Macros > Factorial to Degree.
6. For Personality, select Stepwise.
7. Click Run.
Figure 5.12 Initial Current Estimates Report Using Combine Rule

The model in Figure 5.12 contains all terms for up to two-factor interactions for the five continuous factors. The Combine, Restrict, and Whole Effects rules described in “Rules” on page 256 enable you to control entry of interaction terms.

The Combine rule determines the entry of interaction terms based on two tests. See “Combine” on page 257. You can determine which of the two tests was used for the \( p \)-value based on the degrees of freedom, \( nDF \). For example, the interaction term \( F^*A \) has an \( nDF \) value of 3. This means that \( F^*A \) is grouped with its precedent terms \( F \) and \( A \), and is considered for entry based on the 3 degree of freedom joint \( F \) test. In contrast, the interaction term \( Ct^*T \) has an \( nDF \) value of 1. This means that \( Ct^*T \) is considered for entry based on the 1 degree of freedom \( F \) test that tests the significance of \( Ct^*T \) after its precedent terms, \( Ct \) and \( T \), are already included in the model. Click Step once to see that \( Ct \) is entered by itself.

8. Click Step again to see that \( Ct^*T \) is entered, along with \( T \) (\( Ct \) is already in the model).

Figure 5.13 Current Estimates Report Using Combine Rule, One Step
When there are significant interaction terms, several terms can enter at the same step. If the **Step** button is clicked twice, \( C_1 T \) is entered along with its two contained effects \( C_1 \) and \( T \). However, a step back is not symmetric because a crossed term can be removed without removing its two component terms. Notice that \( C_1 \) and \( T \) now each have 2 degrees of freedom. This is because if Stepwise removes \( C_1 \) or \( T \), it must also remove \( C_1 T \). If you change the Direction to **Backward** and click **Step**, \( C_1 T \) is removed and the degrees of freedom for \( C_1 \) and \( T \) change to 1.

---

## Models with Nominal and Ordinal Effects

Traditionally, stepwise regression has not addressed the situation where there are categorical effects in the model. Note the following:

- When a regression model contains nominal or ordinal effects, those effects are represented by sets of indicator columns.
- When a categorical effect has only two levels, that effect is represented by a single column.
- When a categorical effect has \( k \) levels, where \( k > 2 \), then it must be represented by \( k-1 \) columns.

The convention in JMP for standard platforms is to represent nominal variables by terms whose parameter estimates average to zero across all the levels.

In the Stepwise platform, categorical variables (nominal and ordinal) are coded in a hierarchical fashion. This differs from coding in other least squares fitting platforms. In hierarchical coding, the levels of the categorical variable are successively split into groups of levels that most separate the means of the response. The splitting process achieves the goal of representing a \( k \)-level categorical variable by \( k - 1 \) terms.

**Note:** In hierarchical coding, the initial terms that are constructed represent the groups responsible for the greatest separation. The advantage of this coding scheme is that these informative terms have the potential to enter the model early.

## Construction of Hierarchical Terms

Hierarchical terms are constructed using a tree structure that is analogous to a Partition analysis. However, the criterion that is maximized is the sum of squares between groups (SSB).
For a nominal variable with \( k \) levels, the \( k \) levels are split into two groups of levels that have maximum SSB. Call these two groups of levels A1 and A2, where A1 has the smaller mean and A2 has the larger mean. The two groups of levels in A1 and A2 are used to define an indicator variable with values of 1 for the levels in A1 and -1 for the levels in A2. This variable is the first hierarchical term for the nominal variable.

For the levels within each of the initial two groups A1 and A2, the split into two groups of levels with the maximum SSB is identified. Suppose that the groups of levels with maximum SSB are among the levels in A1. Call the two groups B1 and B2, where B1 has the smaller mean and B2 has the larger mean. The two groups of levels in B1 and B2 are used to define a hierarchical variable with values of 1 for the levels in B1, -1 for the levels in B2, and 0 for the levels in A2. To construct the next variable, splits of the levels in B1, B2, and A2 are considered. The split that maximizes SSB defines the next hierarchical variable. The process continues until \( k-1 \) hierarchical terms are constructed.

For an ordinal variable, the groups of levels considered in splitting contain only levels that are contiguous in the ordering. This ensures that the constructed terms respect the level ordering.

**Rules and Hierarchical Terms**

When you use the Combine rule or the Restrict rule, a term cannot enter the model unless all the terms above it in the hierarchy have been entered. When you use the Whole Effects rule and enter a term for a categorical variable, all of its associated terms are entered. For an example, see “Construction of Hierarchical Terms in Example” on page 269.

**Example of a Model with a Nominal Term**

This example uses data on movies that were released in 2011. You are particularly interested in the World Gross values, which represent the gross receipts. Your potential predictors are Rotten Tomatoes Score, Audience Score, and Genre. The two score variables are continuous, but Genre is nominal. Before you attempt to reduce your model using Stepwise, you want to explore the variables of interest.

2. Select Analyze > Distribution.
4. Click OK.
Note that Genre has nine levels, so it is represented by eight model terms. Further data exploration will reveal that, because of missing data, only eight levels are considered by Stepwise.

5. In the data table’s Columns panel, select the columns of interest: Rotten Tomatoes Score, Audience Score, and World Gross.

6. Select Analyze > Screening > Explore Missing Values.

7. Click Y, Columns and click OK.

Figure 5.15 Missing Columns Report
Note that Rotten Tomatoes Score is missing in 2 rows, Audience Score is missing in 1 row, and World Gross is missing in 2 rows.

8. In the Missing Columns report, select the three columns listed under **Column**.

9. Click **Select Rows**.

In the data table’s Rows panel, you can see that three rows are selected. Because these three rows contain missing data on the predictors or response, they are automatically excluded from the Stepwise analysis. Note that row 128 is the only entry in the Adventure category, which means that category is entirely removed from the analysis. For the purposes of the Stepwise analysis, it follows that **Genre** has only eight categories. Now that you have seen the effect of the missing data, you will conduct the Stepwise analysis.

10. Select **Analyze > Fit Model**.

11. Select Rotten Tomatoes Score, Audience Score, and **Genre** and click **Add**.

If you fit a standard least squares model to World Gross using Rotten Tomatoes Score, Audience Score, and **Genre** as predictors, the residuals are highly heteroscedastic. (This is typical of financial data.) Use a log transformation to better satisfy the regression assumption of equal variance.

12. Right-click **World Gross** in the Select Columns list and select **Transform > Log**.

The transformed variable **Log[World Gross]** appears at the bottom of the Select Columns list.

13. Select **Log[World Gross]** and click **Y**.

14. Select **Stepwise** from the Personality list.

15. Click **Run**.

</table>

In the Current Estimates table, note that **Genre** is represented by 7 terms. You will construct a model using two of these to see how these terms are defined.

16. Check the boxes under **Entered** next to the first two terms for **Genre**:

- Genre[Drama&Horror&Thriller&Fantasy&Romance&Comedy-Action&Animation]
- Genre[Drama&Horror&Thriller-Fantasy&Romance&Comedy]
17. Click **Make Model**.

Notice that the two terms are added as temporary transform columns to the Model Effects list in the Model Specification window. These columns are discussed in the next section.

**Construction of Hierarchical Terms in Example**

Recall that because of missing values, **Genre** is a nominal variable with eight levels. In the Current Estimates table, **Genre** is represented by seven terms. This is appropriate, because **Genre** has eight levels. The first two terms that represent **Genre** are described below. Subsequent terms are defined in a similar fashion.

**First Term**

The first term that appears is 
**Genre**\{Drama&Horror&Thriller&Fantasy&Romance&Comedy-Action&Animation\}. This variable has the form **Genre**\{A1 - A2\}, where A1 and A2 are separated by a minus sign. The notation indicates that the maximum separation in terms of sum of squares between groups occurs between the following two sets of levels:

- Drama, Horror, Thriller, Fantasy, Romance, and Comedy (represented by A1)
- Action and Animation (represented by A2)

If you include the term 
**Genre**\{Drama&Horror&Thriller&Fantasy&Romance&Comedy-Action&Animation\} in a model, a temporary transform column representing that term is used in the model. The column contains the following values:

- 1 for Drama, Horror, Thriller, Fantasy, Romance, and Comedy
- -1 for Action and Animation

**Second Term**

The second term that appears is 
**Genre**\{Drama&Horror&Thriller-Fantasy&Romance&Comedy\}. This set of levels is entirely contained in the first split for the first term (A1). The notation contrasts the levels:

- Drama, Horror, and Thriller
- Fantasy, Romance, and Comedy

Among all the splits of the levels of Drama, Horror, Thriller, Fantasy, Romance, and Comedy (A1) and of the levels of Action and Animation (A2), the algorithm determines that this split has the largest sum of squares between groups.
If you include this term in a model, a temporary transform column representing that term is used in the model. The column contains the following values:

- 1 for Drama, Horror, and Thriller
- -1 for Fantasy, Romance, and Comedy
- 0 for Action and Animation

**Hierarchy of Terms**

The splitting of terms continues, based on the sum of squares between groups criterion. The hierarchy that leads to the definition of the terms is illustrated in Figure 5.17.

**Figure 5.17** Tree Showing Splits Used in Hierarchical Coding

![Tree Diagram](image)

**Rules**

When you use the **Combine** rule or the **Restrict** rule, a term cannot enter the model unless all the terms above it in the hierarchy have been entered. For example, if you enter `Genre(Action-Animation)`, then JMP enters `Genre(Drama&Horror&Thriller&Fantasy&Romance&Comedy-Action&Animation)` as well.

When you use the **Whole Effects** rule and enter any one of the `Genre` terms, all of the `Genre` terms are entered.
Example of the Restrict Rule for Hierarchical Terms

If you have a model with nominal or ordinal terms, when you make or run the model, temporary transform columns containing the hierarchical terms involved in the model are used in the model fit. The model itself appears in a new Fit Model window. This example further illustrates how Stepwise constructs a model with hierarchical effects.

A simple model examines the cost per ounce ($/oz) of hot dogs as a function of the Type of hot dog (Meat, Beef, Poultry) and the Size of the hot dog (Jumbo, Regular, Hors d’oeuvre).

1. Select Help > Sample Data Library and open Hot Dogs2.jmp.
2. Select Analyze > Fit Model.
3. Select $/oz and click Y.
4. Select Type and Size and click Add.
5. For Personality, select Stepwise.
6. Click Run.
7. For Stopping Rule, select P-value Threshold.
8. For Rules, select Restrict.

Notice that when you change from the default Rule of Combine to Restrict, the F Ratio and Prob > F values for two terms are shown as missing. These are the terms Type{Poultry-Meat} and Size{Regular-Jumbo}. This is because these two terms cannot enter the model until their precedent terms enter.

9. Click Step.
The term \texttt{Type\{Poultry\&Meat-Beef\}} enters the model. This term has the smallest Prob>F value, and that value falls below the Prob to Enter threshold of 0.25.

**Figure 5.19** Stepwise Control Panel with One Term Entered

The F Ratio and Prob > F values for the term \texttt{Type\{Poultry-Meat\}} appear. Since its precedent term has entered the model, \texttt{Type\{Poultry-Meat\}} is now allowed to enter.

10. Click **Step**.

Since \texttt{Type\{Poultry-Meat\}} has the smallest Prob>F value among the remaining terms, and that value is below the Prob to Enter threshold, it is the next term to enter the model.

11. Click **Step**.

The term \texttt{Size\{Hors d’oeuvre-Regular\&Jumbo\}} enters the model, since its Prob>F value is 0.1577. Because its precedent term is now in the model, the term \texttt{Size\{Regular-Jumbo\}} is allowed to enter the model and its Prob>F value appears.

However, the Prob>F value for the term \texttt{Size\{Regular-Jumbo\}} is 0.7566, which exceeds the Prob to Enter value of 0.25. For this reason, if you click Step again, it is not entered into the model.

**Figure 5.20** Current Estimates Report for the Final Model

**Tip:** Use the Go button to run the entire stepwise process automatically. To see this in action, click **Remove All**. Then click **Go**.

12. Click **Make Model**.

After you click Make Model, a Fit Model launch window appears, containing only the three model effects that were selected in the stepwise process. In the launch window, temporary transform columns that define the three hierarchical effects entered into the model are included in the model.
Performing Binary and Ordinal Logistic Stepwise Regression

The Stepwise personality of Fit Model performs ordinal logistic stepwise regression when the response is ordinal or nominal. Nominal responses are treated as ordinal responses in the logistic stepwise regression fitting procedure. When a response has only two levels, ordinal logistic regression models are equivalent to nominal logistic regression models. To run a logistic stepwise regression, specify an ordinal or nominal response, add terms to the model as usual, and choose Stepwise from the Personality menu.

The Stepwise reports for a logistic model are similar to those provided when the response is continuous. The following elements are specific to logistic regression results:

- When the response is categorical, the overall fit of the model is given by its negative log-likelihood (-LogLikelihood). This value is calculated based on the full iterative maximum likelihood fit. See “Likelihood, AICc, and BIC” on page 559 in the “Statistical Details” appendix.

- The Current Estimates report shows chi-square statistics (Wald/Score ChiSq) and their p-values (Sig Prob). The test statistic column shows score statistics for parameters that are not in the current model and shows Wald statistics for parameters that are in the current model. The regression estimates (Estimate) are based on the full iterative maximum likelihood fit.

- The Step History report shows the L-R ChiSquare. This value is the test statistic for the likelihood ratio test of the hypothesis that the corresponding regression parameter is zero, given the other terms in the model. The Sig Prob is the p-value for this test.

Note: If the response is nominal, you can fit the current model using the Nominal Logistic personality of Fit Model by clicking the Make Model button. In the Fit Model launch window that appears, click Run.

Example Using Logistic Stepwise Regression

1. Select Help > Sample Data Library and open Fitness.jmp.
2. Select Analyze > Fit Model.
3. Select Sex and click Y.
4. Select Weight, Runtime, RunPulse, RstPulse, and MaxPulse and click Add.
5. For Personality, select Stepwise.
6. Click Run.
7. Click Go.
Figure 5.21 Logistic Stepwise Report

![Logistic Stepwise Report]

The two variables Weight and Runtime are entered into the model based on the Stopping Rule.

8. Click **Make Model**.

Figure 5.22 Model Specification Window for Reduced Model

![Model Specification Window]

A model specification window appears containing the two variables as model effects. Note that the Personality is Nominal Logistic. If the response had been ordinal, the Personality would be Ordinal Logistic.
The All Possible Models Option

Use the All Possible Models option to investigate all models that can be constructed using your predictors. This option is accessed from the Stepwise red triangle.

Note the following:

• This option is not practical for large problems, when the number of models is greater than 5 million.
• Categorical predictors are represented by indicator variables. See “Models with Nominal and Ordinal Effects” on page 265.

The following options restrict the number of models that appear:

**Maximum number of terms in a model** Enter a value for the maximum number of terms in a model.

**Number of best models to see** Enter the maximum number of models of each size to display. The best models according to RSquare value appear.

**Restrict to models where interactions imply lower order effects (Heredity Restriction)**

Shows only models that contain all lower-order effects when a higher-order effect is included. These models satisfy strong effect heredity. This option is useful when your predictors include interaction or polynomial terms.

Example Using the All Possible Models Option

1. Select Help > Sample Data Library and open Fitness.jmp.
2. Select Analyze > Fit Model.
3. Select Oxy and click Y.
4. Select Runtime, RunPulse, RstPulse, and MaxPulse and click Add.
5. For Personality, select Stepwise.
6. Click Run.
7. Click the Stepwise red triangle menu and select All Possible Models.
8. Enter 3 for the maximum number of terms, and enter 5 for the number of best models.

Figure 5.23  All Possible Models Pop-up Dialog
9. Click OK.

All possible models (up to three terms in a model) are fit.

**Figure 5.24** All Possible Models Report

The models are listed in increasing order of the number of parameters that they contain. The model with the highest $R^2$ for each number of parameters is highlighted. The radio button column at the right of the table enables you to select one model at a time and check the results.

**Note:** The recommended criterion for selecting a model is to choose the one corresponding to the smallest BIC or AICc value. Some analysts also want to see the $C_p$ statistic. Mallow’s $C_p$ statistic is computed, but initially hidden in the table. To make it visible, right-click in the table and select **Columns > Cp**.
The Model Averaging Option

The model averaging technique enables you to average the fits for several models, instead of selecting a single model. Often, the resulting average model has better prediction capability than each of the single models that were averaged. The Model Averaging feature is useful for avoiding a model that over fits your data. When many terms are selected into a model, the fit tends to inflate the parameter estimates. Model averaging tends to shrink the estimates on the weaker terms, which yields better predictions. The models are averaged with respect to the AICc Weight of each model, which is calculated as follows:

\[ \text{AICcWeight} = \exp\left[-0.5(\text{AICc} - \text{AICcBest})\right] \]

AICcBest is the smallest AICc value among the fitted models. The AICc Weight values are calculated for each model, sorted in decreasing order, and scaled to sum to 1. The scaled AICc Weight values that sum to less than one minus the specified Cumulative AICc Weight Cutoff value are set to zero. This eliminates the use of weak models in the averaged model. The parameters for the averaged model are the weighted averages of the parameter estimates across the models that have nonzero AICcWeights.

Example Using the Model Averaging Option

1. Select Help > Sample Data Library and open Fitness.jmp.
2. Select Analyze > Fit Model.
3. Select Oxy and click Y.
4. Select Runtime, RunPulse, RstPulse, and MaxPulse and click Add.
5. For Personality, select Stepwise.
6. Click Run.
7. Click the Stepwise red triangle menu and select Model Averaging.
8. Enter 3 for the Maximum number of terms in a model.
9. Keep 0.95 for the Cumulative AICc Weight Cutoff.

Figure 5.25  Model Averaging Window

10. Click OK.
Validation Options in Stepwise Regression

To perform cross validation for stepwise regression models in JMP, click the Stepwise Fit red triangle and select **K-Fold Crossvalidation**. See “K-Fold Cross Validation in Stepwise Regression” on page 281.

In JMP Pro, you can specify a Validation column in the Fit Model window. A validation column must have a numeric data type and should contain at least two distinct values.

- If the column contains two values, the smaller value defines the training set and the larger value defines the validation set.
- If the column contains three values, the values define the training, validation, and test sets in order of increasing size.
- If the column contains four or more distinct values and the response is continuous, these values define folds for k-fold validation.

For more information about using a Validation column, see “Validation Set with Two or Three Values in Stepwise Regression” on page 278.

Validation Set with Two or Three Values in Stepwise Regression

If you specify a Validation column with two or three values, Stepwise fits models based on the training set. Model fit statistics are reported for the validation and test sets. See “Validation and Test Set Statistic Definitions” on page 280 for details about how these statistics are defined.
If the response is continuous, the following statistics appear in the Stepwise Regression Control panel:

- RSquare Validation (also shown in the Step History report)
- RASE Validation
- RSquare Test (if there is a test set)
- RASE Test (if there is a test set)

If the response is binary nominal or ordinal, the following statistics appear in the Stepwise Regression Control panel:

- RSquare Validation (also shown in the Step History report)
- Avg Log Error Validation
- RSquare Test (if there is a test set)
- Avg Log Error Test (if there is a test set)

**Max Validation RSquare**

If you specify a validation column with two or three values in the Fit Model window, the Stopping Rule defaults to Max Validation RSquare. This rule attempts to find a model that maximizes the RSquare statistic for the validation set. The rule can be applied with the Direction set to Forward or Backward.

---

**Note:** Max Validation RSquare considers only the models defined by $p$-value entry (Forward direction) or removal (Backward direction). It does not consider all possible models.

You can use the Step button to enter terms one-by-one in the Forward direction or to remove them one-by one in the Backward direction. At any point, you can select a model by clicking the button to the right of RSquare Validation in the Step History report. The selection of model terms is updated in the Current Estimates report. This is the model that is used once you click Make Model or Run Model.

**Forward Direction**

In the Forward direction, Stepwise constructs successive models by adding terms based on the next smallest $p$-value.

If you click Go rather than Step, the process of entering terms proceeds automatically. Among the fitted models, the model that is considered best is listed last. This model is obtained by overlooking local dips in RSquare Validation. Specifically, it is the model with the largest RSquare Validation that can be followed by as many as ten models with lower RSquare Validation values. This model is designated by the terms Best in the Parameter column and Specific in the Action column. The button to the right of RSquare Validation selects this Best model, though you are free to change this selection.
Backward Direction

In the Backward direction, Stepwise constructs successive models by removing terms based on the next largest \( p \)-value.

To use the Backward direction, you must first click Enter All to enter all of the terms into the model. The Backward direction behaves in a similar fashion to the Forward direction. If you click Go rather than Step, the process of removing terms proceeds automatically. The model designated as Best is the one with the largest RSquare Validation that can be followed by as many as ten models with lower RSquare Validation values.

Validation and Test Set Statistic Definitions

RSquare Validation and RASE Validation are defined in this section. RSquare Test and RASE Test are computed for the test set in a completely analogous fashion.

Continuous Response

**RSquare Validation**  An RSquare measure for the validation set computed as follows:

- For each observation in the validation set, compute the prediction error. This is the difference between the actual response and the response predicted by the training set model.
- Square and sum the prediction errors to obtain \( \text{SSE}_{\text{Validation}} \).
- Square and sum the differences between the actual responses in the validation set and their mean. This is the \( \text{SST}_{\text{Validation}} \).
- RSquare Validation is:

\[
\text{RSquare Validation} = 1 - \frac{\text{SSE}_{\text{Validation}}}{\text{SST}_{\text{Validation}}}
\]

**Note:** It is possible for RSquare Validation to be negative.

**RASE Validation**  The square root of the mean squared prediction error for the validation set. This is computed as follows:

- For each observation in the validation set, compute the prediction error. This is the difference between the actual response and the response predicted by the training set model.
- Square and sum the prediction errors to obtain the \( \text{SSE}_{\text{Validation}} \).
- Denote the number of observations in the validation set by \( n_{\text{Validation}} \).
- RASE Validation is:
Binary Nominal or Ordinal Response

RSquare Validation  An Entropy RSquare measure (also known as McFadden’s $R^2$) for the validation set computed as follows:

- A model is fit using the training set.
- Predicted probabilities are obtained for all observations.
- Using the predicted probabilities based on the training set model, the likelihood for the model is computed for observations in the validation set. Call this quantity $\text{Likelihood}_{\text{FullValidation}}$.
- Using the data in the validation set, the likelihood of the reduced model (no predictors) is computed. Call this quantity $\text{Likelihood}_{\text{ReducedValidation}}$.
- RSquare Validation is:

$$\text{RSquare Validation} = 1 - \frac{\log(\text{Likelihood}_{\text{FullValidation}})}{\log(\text{Likelihood}_{\text{ReducedValidation}})}$$

**Note:** It is possible for RSquare Validation to be negative.

Avg Log Error Validation  The average log error for the validation set is computed as follows:

- For each observation in the validation set, compute the log of its predicted probability as determined by the model based on the training set.
- Sum these logs, divide by the number of observations in the validation set, and take the negative of the resulting value.

**Tip:** Smaller values of Avg Log Error Validation are desirable.

K-Fold Cross Validation in Stepwise Regression

K-fold cross validation randomly divides the data into $k$ subsets. In turn, each of the $k$ sets is used as a validation set while the remaining data are used as a training set to fit the model. In total, $k$ models are fit and $k$ validation statistics are obtained. The model giving the best validation statistic is chosen as the final model. This method is useful for small data sets, because it makes efficient use of limited amounts of data.

**Note:** K-fold cross validation is available only for continuous responses.
In JMP, click the Stepwise Fit red triangle and select **K-Fold Crossvalidation**.

In JMP Pro, you can access $k$-fold cross validation in two ways:

- Click the Stepwise Fit red triangle and select **K-Fold Crossvalidation**.
- Specify a validation column with four or more distinct values.

### RSquare K-Fold Statistic

If you conduct $k$-fold cross validation, the RSquare K-Fold statistic appears to the right of the other statistics in the Stepwise Regression Control panel. RSquare K-Fold is the average of the RSquare Validation values for the $k$ folds.

### Max K-Fold RSquare

When you use $k$-fold cross validation, the Stopping Rule defaults to Max K-Fold RSquare. This rule attempts to maximize the RSquare K-Fold statistic.

**Note:** Max K-Fold RSquare considers only the models defined by $p$-value entry (Forward direction) or removal (Backward direction). It does not consider all possible models.

The Max K-Fold RSquare stopping rule behaves in a fashion similar to the Max Validation RSquare stopping rule. See “**Max Validation RSquare**” on page 279. Replace references to RSquare Validation with RSquare K-Fold.
The Generalized Regression personality of the Fit Model platform is available only in JMP Pro.

In JMP Pro, the Fit Model platform’s Generalized Regression personality provides variable selection techniques, including shrinkage techniques, that specifically address modeling correlated and high-dimensional data. Two of these techniques, the Lasso and the Elastic Net, perform variable selection as part of the modeling procedure.

Large data sets that contain many variables typically exhibit multicollinearity issues. Modern data sets can include more variables than observations, requiring variable selection if traditional modeling techniques are to be used. The presence of multicollinearity and a profusion of predictors exposes the shortcomings of classical techniques.

Even for small data sets with little or no correlation, including designed experiments, the Lasso and Elastic Net are useful. They can be used to build predictive models or to select variables for model reduction or for future study.

The Generalized Regression personality is useful for many modeling situations. This personality enables you to specify a variety of distributions for your response variable. Use it when your response is continuous, binomial, a count, or zero-inflated. Use it when you are interested in variable selection or when you suspect collinearity in your predictors. More generally, use it to fit models that you compare to models obtained using other techniques.

Overview of the Generalized Regression Personality

The Generalized Regression personality features regularized, or penalized, regression techniques. Such techniques attempt to fit better models by shrinking the model coefficients toward zero. The resulting estimates are biased. This increase in bias can result in decreased prediction variance, thus lowering overall prediction error compared to non-penalized models. Two of these techniques, the Elastic Net and the Lasso, include variable selection as part of the modeling procedure.

Modeling techniques such as the Elastic Net and the Lasso are particularly useful for large data sets, where collinearity is typically a problem. In addition, modern data sets often include more variables than observations. This situation is sometimes referred to as the $p > n$ problem, where $n$ is the number of observations and $p$ is the number of predictors. Such data sets require variable selection if traditional modeling techniques are to be used.

The Elastic Net and Lasso can also be used for small data sets with little correlation, including designed experiments. They can be used to build predictive models or to select variables for model reduction or for future study.

The personality provides the following classes of modeling techniques:

- Maximum Likelihood
- Step-Based Estimation
- Penalized Regression

The Elastic Net and Lasso are relatively recent techniques (Tibshirani 1996; Zou and Hastie 2005). Both techniques penalize the size of the model coefficients, resulting in a continuous shrinkage. The amount of shrinkage is determined by a tuning parameter. An optimal level of shrinkage is determined by one of several validation methods. Both techniques have the ability to shrink coefficients to zero. In this way, variable selection is built into the modeling procedure. The Elastic Net model subsumes both the Lasso and ridge regression as special cases. See “Statistical Details for Estimation Methods” on page 334.

Details about Generalized Regression Modeling Techniques

- The Maximum Likelihood method is a classical approach. It provides a baseline to which you can compare the other techniques, and it is the most appropriate place for traditional inference techniques such as hypothesis testing.
- Forward Selection is a method of stepwise regression. In forward selection, terms are entered into the model. The most significant terms are added until all of the terms are in the model or there are no degrees of freedom left.
• The Lasso has two shortcomings. When several variables are highly correlated, it tends to select only one variable from that group. When the number of variables, \( p \), exceeds the number of observations, \( n \), the Lasso selects at most \( n \) predictors.

• The Elastic Net, on the other hand, tends to select all variables from a correlated group, fitting appropriate coefficients. It can also select more than \( n \) predictors when \( p > n \).

• Ridge regression was among the first of the penalized regression methods proposed (Hoerl 1962; Hoerl and Kennard 1970). Ridge regression does not shrink coefficients to zero, so it does not perform variable selection.

• The Double Lasso attempts to separate the selection and shrinkage steps by performing variable selection with an initial Lasso model. The variables selected in the initial model are then used as the input variables for a second Lasso model.

• Two-Stage Forward Selection performs two stages of forward stepwise regression. It performs variable selection on the main effects in the first stage. Then, higher-order effects are allowed to enter the model in the second stage.

The Generalized Regression personality also fits an adaptive version of the Lasso and the Elastic Net. These adaptive versions attempt to penalize variables in the true active set less than variables not contained in the true active set. The true active set refers to the set of terms in a model that have an actual effect on the response. The adaptive versions of the Lasso and Elastic Net were developed to ensure that the oracle property holds. The oracle property guarantees the following: Asymptotically, your estimates are what they would have been had you fit the model to the true active set of predictors. More specifically, your model correctly identifies the predictors that should have zero coefficients. Your estimates converge to those that would have been obtained had you started with only the true active set. See “Adaptive Methods” on page 336.

The Generalized Regression personality enables you to specify a variety of distributions for your response variable. The distributions fit include normal, Cauchy, Student’s \( t \), exponential, gamma, Weibull, lognormal, beta, binomial, beta binomial, Poisson, negative binomial, zero-inflated binomial, zero-inflated beta binomial, zero-inflated Poisson, zero-inflated negative binomial, and zero-inflated gamma. This flexibility enables you to fit categorical and count responses, as well as continuous responses, and specifically, right-skewed continuous responses. You can also fit quantile regression and Cox proportional hazards models. For some of the distributions, you can fit models to censored data. The personality provides a variety of validation criteria for model selection and supports training, validation, and test columns. See “Distribution” on page 292.
Example of Generalized Regression

The data in the Diabetes.jmp sample data table consist of measurements on 442 diabetics. The response of interest is Y, disease progression measured one year after a baseline measure was taken. Ten variables thought to be related to disease progression are also measured at baseline. This example shows how to develop a predictive model using generalized regression techniques.

1. Select Help > Sample Data Library and open Diabetes.jmp.
2. Select Analyze > Fit Model.
3. Select Y from the Select Columns list and click Y.
4. Select Age through Glucose and click Macros > Factorial to Degree.
   This adds all terms up to degree 2 (the default in the Degree box) to the model.
5. Select Validation from the Select Columns list and click Validation.
6. From the Personality list, select Generalized Regression.
7. Click Run.
   The Generalized Regression report that appears contains a Model Comparison report, a Model Launch control panel, and a Normal Standard Least Squares with Validation Column report.
   In the Model Launch control panel, note the following:
   – The Response Distribution is set to Normal because you specified Normal as the Distribution in the Fit Model launch window.
   – The default Estimation Method is the Lasso.
   – The Validation Method is set to Validation Column because you specified a validation column in the Fit Model window.
8. Click Go.
   A Normal Lasso with Validation Column report appears. The Solution Path report (Figure 6.2) shows plots of the parameter estimates and scaled negative log-likelihood. The shrinkage increases as the Magnitude of Scaled Parameter Estimates decreases. The estimates at the far right of the plot are the maximum likelihood estimates. A vertical red line indicates those parameter values selected by the validation criterion, in this case, the holdback sample defined by the column Validation.
9. Click the red triangle next to Normal Lasso with Validation Column and select Select Nonzero Terms.

This option highlights the nonzero terms in the Parameter Estimates for Original Predictors report (Figure 6.3) and their paths in the Solution Path Plot. The corresponding columns in the data table are also selected. Note that only 11 of the 55 parameter estimates are nonzero. The scale parameter for the normal distribution (sigma) is also estimated and shown in a separate table at the bottom of the Parameter Estimates for Original Data report. Note that not all of the 55 parameter estimates appear in Figure 6.3.
To save the prediction formula, click the red triangle next to Normal Lasso with Validation Column report and select **Save Columns > Save Prediction Formula.**
Launch the Generalized Regression Personality

Launch the Generalized Regression personality by selecting **Analyze > Fit Model**, entering one or more columns for **Y**, and selecting **Generalized Regression** from the **Personality** menu.

**Figure 6.4** Fit Model Launch Window with Generalized Regression Selected

For more information about aspects of the Fit Model window that are common to all personalities, see the “**Model Specification**” chapter on page 29. For more information about the options in the Select Columns red triangle menu, see *Using JMP*. Information specific to the Generalized Regression personality is presented here.

The parameterization of nominal variables used in the Generalized Regression personality differs from their parameterization using other Fit Model personalities. The Generalized Regression personality uses indicator function parameterization. In this parameterization, the estimate that corresponds to the indicator for a level of a nominal variable is an estimate of the difference between the mean response at that level and the mean response at the last level. The last level is the level with the highest value order coding; it is the level whose indicator function is not included in the model.

If your model effects have missing values, you can treat these missing values as informative categories. Select the Informative Missing option from the Model Specification red triangle menu.
To specify a model without an intercept term, select the No Intercept option in the Construct Model Effects panel of the Fit Model window. If you select this option, note the following:

- The predictors are not centered and scaled.
- Odds ratios, hazard ratios, and incidence rate ratios are not available in the report window.
- The No Intercept option is not available for the Ordinal Logistic Distribution.

**Caution:** Using the No Intercept option with the Lasso or Elastic Net is not recommended because the results are sensitive to the scale of the model effects. The adaptive versions of these estimation methods are recommended instead.

### Censoring

You can specify censoring for your response variable in one of the following ways:

- For interval-censored, right-censored, and left-censored responses, specify a column that contains a Detection Limits column property. The limits specified in the column property define the range of response values that are considered uncensored:
  - For interval-censored responses, specify a nonmissing value for both the Lower Detection Limit and the Upper Detection Limit in the Detection Limits column property.
  - For right-censored responses, specify a missing value for the Lower Detection Limit and a nonmissing value for the Upper Detection Limit in the Detection Limits column property.
  - For left-censored responses, specify a nonmissing value for the Lower Detection Limit and a missing value for the Upper Detection Limit in the Detection Limits column property.

- For right-censored responses, specify a column that contains indicators for right-censored observations as a Censor column in the launch window. Select the value in that column that designates right-censored observations from the Censor Code list.

- For interval-censored and left-censored responses, specify two columns that define the censoring interval in the Y column role:
  - For interval-censored responses, the first Y variable gives the lower limit.
  - For left-censored responses, the first Y variable contains a missing value.
  - For both interval-censored and left-censored responses, the second Y variable gives the upper limit for each response.

If you specify two columns for Y and a Distribution that supports censoring, an Alert appears that asks whether the columns represent censoring. If you choose No, the columns are treated as separate responses.
Note: You can specify the default behavior for two responses using the Treatment of Two Response Columns preference in Generalized Regression platform preferences.

Censoring is available when the specified Distribution is Normal, Exponential, Gamma, Weibull, Lognormal, or Cox Proportional Hazards.

Distribution

When you select Generalized Regression from the Personality menu, the Distribution option appears. Here you can specify a distribution for Y. The abbreviation ZI means zero-inflated. The distributions are separated into three categories based on their response: continuous, discrete, and zero-inflated. The options are described below.

Note: If you specify multiple Y variables in the Model Specification window, the same response distribution must be used for all of the specified Y variables. If you want to fit separate distributions to different response variables in the same Generalized Regression report, you must use a script.

Continuous

Normal  Y has a normal distribution with mean \( \mu \) and standard deviation \( \sigma \). The normal distribution is symmetric and with a large enough sample size, can approximate a large variety of other distributions using the Central Limit Theorem. The link function for \( \mu \) is the identity. That is, the mean of Y is expressed as a linear model.

Note: When the specified Distribution is Normal, Standard Least Squares replaces the Maximum Likelihood Estimation method.

The scale parameter for the normal distribution is \( \sigma \). When there is no penalty in the estimation method, the estimate of the scale parameter \( \sigma \) is the root mean square error (RMSE). The RMSE is the square root of the usual unbiased estimator of \( \sigma^2 \). The results shown are equivalent to a standard least squares fit unless censored observations are involved.

Note: The parameterization of nominal variables used in the Generalized Regression personality differs from their parameterization using the Standard Least Squares personality. Because of this difference, parameter estimates differ for models that contain nominal or ordinal effects.

See “Statistical Details for Distributions” on page 337.
Cauchy  Y has a Cauchy distribution with location parameter $\mu$ and scale parameter $\sigma$. The Cauchy distribution has an undefined mean and standard deviation. The median and mode are both $\mu$. Most data do not inherently follow a Cauchy distribution. However, it is useful for conducting a robust regression on data that contain a large proportion of outliers (up to 50%). The link function for $\mu$ is the identity. See “Statistical Details for Distributions” on page 337.

t(5)  Y has a Student’s $t$ distribution with 5 degrees of freedom, location parameter $\mu$ and scale parameter $\sigma$. The Student’s $t$ distribution is symmetric and is a robust option that spans the space between a normal distribution and a Cauchy distribution. As the degrees of freedom in the Student’s $t$ distribution approach infinity, the distribution is equivalent to the normal. When the degrees of freedom in the Student’s $t$ distribution equals 1, the distribution is equivalent to the Cauchy. The link function for $\mu$ is the identity. See “Statistical Details for Distributions” on page 337.

Exponential Y has an exponential distribution with mean parameter $\mu$. The exponential distribution is right-skewed and is often used to model lifetimes or the time between successive events. The link function for $\mu$ is the logarithm. See “Statistical Details for Distributions” on page 337.

Gamma Y has a gamma distribution with mean parameter $\mu$ and dispersion parameter $\sigma$. The gamma is a flexible distribution and contains a family of other widely used distributions. For example, the exponential distribution is a special case of the gamma distribution where $\sigma = \mu$. The chi-squared distribution can also be derived from the gamma distribution. The link function for $\mu$ is the logarithm. See “Statistical Details for Distributions” on page 337.

Weibull Y has a Weibull distribution with mean parameter $\mu$ and scale parameter $\sigma$. The Weibull distribution is a flexible distribution and is often used to model lifetimes or the time until an event. The link function for $\mu$ is the identity. See “Statistical Details for Distributions” on page 337.

LogNormal Y has a Lognormal distribution with mean parameter $\mu$ and scale parameter $\sigma$. The Lognormal distribution is right-skewed and is often used to model lifetimes or the time until an event. The link function for $\mu$ is the identity. See “Statistical Details for Distributions” on page 337.

Beta Y has a beta distribution with mean parameter $\mu$ and dispersion parameter $\sigma$. The response for the beta is between 0 and 1 (not inclusive) and is often used to model proportions or rates. The link function for $\mu$ is the logit. See “Statistical Details for Distributions” on page 337.

Quantile Regression  Quantile regression models a specified conditional quantile of the response. No assumption is made about the form of the underlying distribution. When
you select Quantile Regression, a Quantile box appears beneath the Distribution menu. Specify the desired quantile.

If you specify 0.5 (the default) for the Quantile on the Model Dialog window, quantile regression models the conditional median of the response. Quantile regression is particularly useful when the rate of change in the conditional quantile, expressed by the regression coefficients, depends on the quantile. An advantage of quantile regression over least squares regression is its flexibility for modeling data with heterogeneous conditional distributions.

Quantile Regression is fit by minimizing an objective function using an iterative approach. For more information about quantile regression, see Koenker and Hallock (2001) and Portnoy and Koenker (1997).

When you choose Quantile Regression, Maximum Likelihood is the only available Estimation Method, and None is the only available Validation Method.

**Note:** If a quantile regression fit is time intensive, a progress bar appears. The progress bar shows the relative change in the objective function. When you click Accept Current Estimates, the calculation stops and the reported parameter estimates correspond to the best model fit at that point.

**Cox Proportional Hazards** The Cox proportional hazards model is a regression model for time-to-event data with predictors. It is based on a multiplicative relationship between the predictors and the hazard function. It can be used to examine the effect of predictors on survival times. The model involves an arbitrary baseline hazard function that is scaled by the predictors to give a general hazard function. The proportional hazards model produces parameter estimates and standard errors for each predictor. The Cox proportional hazards model was first proposed by D. R. Cox (1972). For more information about proportional hazards models, see Kalbfleisch and Prentice (2002).

When you choose Cox Proportional Hazards, the only available Validation Methods are BIC and AICc. Also, the Ridge Estimation Method is not available.

**Note:** When there are ties in the response, the Efron likelihood is used. See Efron (1977). This is a different method for handling ties than is used in the Proportional Hazard personality of the Fit Model platform or in the Fit Proportional Hazards platform.

**Discrete**

**Binomial** Y has a binomial distribution with parameters p and n. The response, Y, indicates the total number of successes in n independent trials with a fixed probability, p, for all trials. This distribution allows for the use of a sample size column. If no column is listed, it is assumed that the sample size is one. The link function for p is the logit. When you select
a binary response variable that has a Nominal modeling type, Binomial is the only available response distribution. See “Statistical Details for Distributions” on page 337.

When you select Binomial as the Distribution, the response variable must be specified in one of the following ways.

- **Unsummarized:** If your data are not summarized as frequencies of events, specify a single binary column as the response. If this column has a modeling type of Nominal, you can designate one of the levels to be the Target Level. The default Target Level value is the higher of the two levels based on the order of the levels.

- **Summarized with Freq column:** If your data are summarized as frequencies of successes and failures, specify a single binary column as the response. If this column has a modeling type of Nominal, you can designate one of the levels to be the Target Level. The default Target Level value is the higher of the two levels based on the order of the levels. Assign the frequency column to the Freq role.

- **Summarized with sample size column entered as second Y:** If your data are summarized as frequencies of events (successes) and trials, specify two continuous columns as Y in this order: the count of the number of successes, and the count of the number of trials.

**Note:** When the specified Distribution is Binomial, Logistic Regression replaces the Maximum Likelihood Estimation method.

**Beta Binomial** Y has a beta binomial distribution with the probability of success, \( p \), the number of trials, \( n \), and overdispersion parameter, \( \delta \). This distribution is an overdispersed version of the binomial distribution.

Run demoBetaBinomial.jsl in the JMP Samples/Scripts folder to compare a beta binomial distribution with dispersion parameter \( \delta \) to a binomial distribution with parameters \( p \) and \( n = 20 \).

The beta binomial distribution requires a sample size greater than one for each observation. Thus, the user must specify a sample size column. To insert a sample size column, specify two continuous columns as Y in this order: the count of the number of successes, and the count of the number of trials. The link function for \( p \) is the logit. See “Statistical Details for Distributions” on page 337.

**Multinomial** Y has a multinomial distribution with three or more discrete levels. The response variable must have a nominal or ordinal modeling type. The model fits separate intercepts and effects parameters for each level of the response variable. If the response variable has \( k \) levels, the model contains \( k - 1 \) intercepts and effects parameters. The link function for the Multinomial distribution is the multinomial logit. See “Nominal Responses” on page 532 in the “Statistical Details” chapter.
**Ordinal Logistic**  
Y has a multinomial distribution with ordinal levels. The response variable must have an ordinal modeling type. The model fits an intercept for each level of the response variable. The effects parameters are common across all levels of the response variable. The link function for the Ordinal Logistic distribution is the ordered logit. See “Ordinal Responses” on page 533 in the “Statistical Details” chapter.

---

**Poisson**  
Y has a Poisson distribution with mean $\lambda$. The Poisson distribution typically models the number of events in a given interval and is often expressed as count data. The link function for $\lambda$ is the logarithm. Poisson regression is permitted even if Y assumes non-integer values. See “Statistical Details for Distributions” on page 337.

**Negative Binomial**  
Y has a negative binomial distribution with mean $\mu$ and dispersion parameter $\sigma$. The negative binomial distribution typically models the number of successes before a specified number of failures. The negative binomial distribution is also equivalent to the Gamma Poisson distribution under certain conditions. For more information about the connection between negative binomial and Gamma Poisson, see Basic Analysis.

Run demoGammaPoisson.jsl in the JMP Samples/Scripts folder to compare a Gamma Poisson distribution with mean $\lambda$ and dispersion parameter $\sigma$ to a Poisson distribution with mean $\lambda$.

The link function for $\mu$ is the logarithm. Negative binomial regression is permitted even if Y assumes non-integer values. See “Statistical Details for Distributions” on page 337.

---

**Zero-Inflated**

**ZI Binomial**  
Y has a zero-inflated binomial distribution with parameters $p$, $n$, and zero-inflation parameter $\pi$. The response, Y, indicates the total number of successes in $n$ independent trials with a fixed probability, $p$, for all trials. This distribution allows for the use of a sample size column. If no column is listed, it is assumed that the sample size is one. The link function for $p$ is the logit. See “Statistical Details for Distributions” on page 337.

**ZI Beta Binomial**  
Y has a beta binomial distribution with the probability of success, $p$, the number of trials, $n$, overdispersion parameter, $\delta$, and zero-inflation parameter $\pi$. This distribution is an overdispersed version of the ZI binomial distribution. The ZI beta binomial distribution requires a sample size greater than one for each observation. Thus, the user must specify a sample size column. To insert a sample size column, specify two
continuous columns as Y in this order: the count of the number of successes, and the count of the number of trials. The link function for $p$ is the logit. See “Statistical Details for Distributions” on page 337.

**ZI Poisson**  Y has a zero-inflated Poisson distribution with mean parameter $\lambda$ and zero-inflation parameter $\pi$. The parameter $\lambda$ is the conditional mean based on the observations coming from the Poisson distribution and not the inflating zeros. The link function for $\lambda$ is the logarithm. ZI Poisson regression is permitted even if Y assumes no observed zeros or non-integer values. See “Statistical Details for Distributions” on page 337.

**ZI Negative Binomial**  Y has a zero-inflated negative binomial with location parameter $\mu$, dispersion parameter $\sigma$, and zero-inflation parameter $\pi$. The parameter $\mu$ is the conditional mean based on the observations coming from the negative binomial distribution and not the inflating zeros. The link function for $\mu$ is the logarithm. ZI negative binomial regression is permitted even if Y assumes no observed zeros or non-integer values. See “Statistical Details for Distributions” on page 337.

**ZI Gamma**  Y has a zero-inflated gamma distribution with mean parameter $\mu$ and zero-inflation parameter $\pi$. Many times, we might believe that our nonzero responses are gamma distributed. This is true for insurance claims: claim values are approximately gamma distributed but there are also zeros in the data for policies that do not have any claims. The zero-inflated gamma could handle such data directly without having to split the data into zero and nonzero responses. The parameter $\mu$ is the conditional mean based on observations coming from the gamma distribution and not the inflating zeros. The link function for $\mu$ is the logarithm. See “Statistical Details for Distributions” on page 337.

Table 6.1 gives the Data Types, Modeling Types, and other requirements for Y variables assigned the various distributions.

After selecting an appropriate Distribution, click **Run**. The Generalized Regression report window appears.

### Generalized Regression Report Window

When you click **Run** in the Fit Model launch window, the Generalized Regression report window that appears contains the following items:

- A Model Comparison report that enables you to compare all of the models that have been fit in the report. Each time a new model is fit using the Model Launch control panel, it is added to the Model Comparison report. You can show or hide the reports for fitted models using the check boxes in the Show column. Other columns in the Model Comparison report contain information about each model that was fit, as well as fit statistics for each model. Click on the column headings to sort the models by any of the columns in the
Model Comparison report. The first click sorts in ascending order; click the column heading a second time to sort in descending order.

**Note:** The Model Comparison report appears when one or more models have been fit.

- A Model Launch control panel for fitting models. See “Model Launch Control Panel” on page 301. As you fit models, outlines are added with titles that describe the types of models that you have fit. See “Model Fit Reports” on page 312 and “Model Fit Options” on page 324.
  - If there are linear dependencies among the model terms, the Model Launch control panel contains a Singularity Details report that shows the linear functions that the model terms satisfy. See “Models with Linear Dependencies among Model Terms” on page 199 in the “Standard Least Squares Models” chapter.
- A Maximum Likelihood report that shows the results of a model that was fit using maximum likelihood estimation. See “Maximum Likelihood” on page 302. The Maximum Likelihood report appears only if the following conditions are met:
  - There are no linear dependencies among the predictors.
  - There are more observations than predictors.
  - There are no more than 250 predictors.

**Note:** When the specified Distribution is Normal, this report is labeled Standard Least Squares. When the specified Distribution is Binomial, this report is labeled Logistic Regression.

### Generalized Regression Report Options

**Model Dialog**  Shows the completed Fit Model launch window for the current analysis.

**Set Random Seed**  Sets the seed for the randomization process used for KFold and Holdback validation. This is useful if you want to reproduce an analysis. Set the seed to a positive value, save the script, and the seed is automatically saved in the script. Running the script always produces the same cross validation analysis.

**Save Coding Table**  Creates a new data table whose first columns show the JMP coding for all model parameters. The last column shows the values of the response variable. If you specified a sample size column for a binomial response, both the response and sample size columns are shown in the table. If you used two response columns to specify censoring, both response columns are shown in the table. If you used a response column that contains a Detection Limits column property to specify censoring, the response column in the coding table contains a Detection Limits column property.
Note: The coding data table contains a table variable called Original Data that gives the name of the data table that was used for the analysis. In the case where a By variable is specified, the Original Data table variable also gives the By variable and its level.

See *Using JMP* for more information about the following options:

**Local Data Filter**  Shows or hides the local data filter that enables you to filter the data used in a specific report.

**Redo**  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

**Save Script**  Contains options that enable you to save a script that reproduces the report to several destinations.

**Save By-Group Script**  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.

### Model Launch Control Panel

The Model Launch control panel provides options for the following:

- “Response Distribution” on page 301
- “Estimation Method Options” on page 302
- “Advanced Controls” on page 307
- “Validation Method Options” on page 310
- “Early Stopping” on page 311
- “Go” on page 312

### Response Distribution

The available response distributions in the control panel depend on attributes of the response variable specified in the Fit Model launch window. Appropriate response distributions are available in the Response Distribution option. See “*Distribution*” on page 292 for more information about the response distributions.
Estimation Method Options

The available estimation methods can be grouped into techniques with no selection and no penalty, step-based model selection techniques, and penalized regression techniques.

The Maximum Likelihood, Standard Least Squares, and Logistic Regression methods fit the entire model that is specified in the Fit Model launch window. No variable selection is performed. These models can serve as baselines for comparison to other methods.

**Note:** Only one of Maximum Likelihood, Standard Least Squares, and Logistic Regression is available for a given report. The name of this estimation method depends on the Distribution specified in the Fit Model launch window.

The Backward Elimination, Forward Selection, Pruned Forward Selection, Best Subset, and Two Stage Forward Selection methods are based on variables entering or leaving the model at each step. However, they do not impose a penalty on the regression coefficients.

The Dantzig Selector, Lasso, Elastic Net, Ridge, and Double Lasso methods are penalized regression techniques. They shrink the size of regression coefficients and reduce the variance of the estimates, in order to improve predictive ability of the model.

**Note:** When your data are highly collinear, the adaptive versions of Lasso and Elastic Net might not provide good solutions. This is because the adaptive versions presume that the MLE provides a good estimate. The Adaptive option is not recommended in such cases.

Two types of penalties are used in these techniques:

- the $l_1$ penalty, which penalizes the sum of the *absolute values* of the regression coefficients
- the $l_2$ penalty, which penalizes the sum of the *squares* of the regression coefficients

The default Estimation Method for observational data is the Lasso. If the data table contains a DOE script and no singularities, the default Estimation Method is Forward Selection with the Effect Heredity option enabled. If the data table contains a DOE script and a singularity in the design matrix, the default Estimation Method is Two-Stage Forward Selection with the Effect Heredity option enabled.

The following methods are available for model fitting:

**Estimation Methods with No Selection and No Penalty**

**Maximum Likelihood**  Computes maximum likelihood estimates (MLEs) for model parameters. No penalty is imposed. Maximum Likelihood is the only estimation method available for Quantile Regression. If you specified a Validation column in the Fit Model launch window, the maximum likelihood model is fit to the Training set. A maximum likelihood model report appears by default, as long as the following conditions are met:
There are no linear dependencies among the predictors.
- There are more observations than predictors.
- There are no more than 250 predictors.

The Maximum Likelihood option gives you a way to construct classical models for the response distributions supported by the Generalized Regression personality. In addition, a model based on maximum likelihood can serve as a baseline for model comparison.

When the specified Distribution is Normal or Binomial, the Maximum Likelihood method is called Standard Least Squares or Logistic Regression, respectively.

**Standard Least Squares** When the Normal distribution is specified, the Maximum Likelihood estimation method is replaced with the Standard Least Squares estimation method. The default report is a Standard Least Squares report that gives the usual standard least squares results.

**Logistic Regression** When the Binomial distribution is specified, the Maximum Likelihood estimation method is replaced with the Logistic Regression estimation method. The default report is a Logistic Regression report. The logistic results are identical to maximum likelihood results.

**Step-Based Estimation Methods**

**Note:** Step-based estimation methods are not available when the specified Distribution is Multinomial.

**Backward Elimination** Computes parameter estimates using backward elimination regression. The model chosen provides the best solution relative to the selected Validation Method. Backward elimination starts by including all parameters in the model and removing one effect at each step until reaching the intercept-only model. At each step, the Wald tests for each parameter is used to determine which parameter is removed.

**Caution:** The horizontal axis of the Solution Path for Backward Elimination is the reverse of the same axis in other estimation methods. Therefore, as you move left to right in the Solution Path for the Backward Elimination estimation method, terms are being removed from the model, rather than added.

**Forward Selection** Computes parameter estimates using forward stepwise regression. At each step, the effect with the most significant score test is added to the model. The model chosen is the one that provides the best solution relative to the selected Validation Method.

When there are interactions and the Effect Heredity option is enabled, compound effects are handled in the following manner. If the effect with the most significant score test at a given step is one that would violate effect heredity, then a compound effect is created. The
compound effect contains the effect with the most significant score test as well as any other inactive effects that are needed to satisfy effect heredity. If the compound effect has the most significant score test, then all of the effects in the compound effect are added to the model.

**Pruned Forward Selection** Computes parameter estimates using a mixture of forward and backward steps. The algorithm starts with an intercept-only model. At the first step, the effect with the most significant score test is added to the model. After the first step, the algorithm considers the following three possibilities at each step:

1. From the effects not in the model, add the effect that has the most significant score test.
2. From the effects in the model, remove the effect that has the least significant Wald test.
3. Do both of the above actions in a single step.

To choose the action taken at each step, the algorithm uses the specified Validation Method. For example, if the Validation Method is BIC, the algorithm chooses the action that results in the smallest BIC value. When there are interactions and the Effect Heredity option is enabled, compound effects are considered for adding effects, but they are not considered for removing effects.

When the model becomes saturated, the algorithm attempts a backward step to check if that improves the model. The maximum number of steps in the algorithm is 5 times the number of parameters. The model chosen is the one that provides the best solution relative to the selected Validation Method.

Pruned Forward Selection is an alternative to the Mixed Step option in the Stepwise Regression personality. However, it does not use the $p$-value to determine which variables enter or leave the model.

**Tip:** The Early Stopping option is not recommended for the Pruned Forward Selection Estimation Method.

**Best Subset** Computes parameter estimates by increasing the number of active effects in the model at each step. In each step, the model is chosen among all possible models with a number of effects given by the step number. The values on the horizontal axes of the Solution Path plots represent the number of active effects in the model. Step 0 corresponds to the intercept-only model. Step 1 corresponds to the best model of the ones that contain only one active effect. The steps continue up to the value of Max Number of Effects specified in the Advanced Controls in the Model Launch report. See “Advanced Controls” on page 307.

**Tip:** The Best Subset Estimation Method is computationally intensive. It is not recommended for large problems.
Two Stage Forward Selection  (Available only when there are second- or higher-order effects in the model.) Computes parameter estimates in two stages. In the first stage, a forward stepwise regression model is run on the main effects to determine which to retain in the model. In the second stage, a forward stepwise regression model is run on all of the higher-order effects that are composed entirely of the main effects chosen in the first stage. This method assumes strong effect heredity.

Terms that are not retained from the first stage still appear in the Parameter Estimates reports as zeroed terms. However, they are ignored in the fitting of the second stage model. Terms that are selected in the first stage are not forced into the second stage; they are available for selection in the second stage.

Penalized Estimation Methods

Dantzig Selector  (Available only when the specified Distribution is Normal and the No Intercept option is not selected.) Computes parameter estimates by applying an $l_1$ penalty using a linear programming approach. See Candes and Tao (2007). The Dantzig Selector is useful for analyzing the results of designed experiments. For orthogonal problems, the Dantzig Selector and Lasso give identical results. See “Dantzig Selector” on page 334.

Lasso  Computes parameter estimates by applying an $l_1$ penalty. Due to the $l_1$ penalty, some coefficients can be estimated as zero. Thus, variable selection is performed as part of the fitting procedure. In the ordinary Lasso, all coefficients are equally penalized.

Adaptive Lasso  Computes parameter estimates by penalizing a weighted sum of the absolute values of the regression coefficients. The weights in the $l_1$ penalty are determined by the data in such as way as to guarantee the oracle property (Zou 2006). This option uses the MLEs to weight the $l_1$ penalty. MLEs cannot be computed when the number of predictors exceeds the number of observations or when there are strict linear dependencies among the predictors. If MLEs for the regression parameters cannot be computed, a generalized inverse solution or a ridge solution is used for the $l_1$ penalty weights. See “Adaptive Methods” on page 336.

The Lasso and the adaptive Lasso options generally choose parsimonious models when predictors are highly correlated. These techniques tend to select only one of a group of correlated predictors. High-dimensional data tend to have highly correlated predictors. For this type of data, the Elastic Net might be a better choice than the Lasso. See “Lasso Regression” on page 335.

Elastic Net  Computes parameter estimates by applying both an $l_1$ penalty and an $l_2$ penalty. The $l_1$ penalty ensures that variable selection is performed. The $l_2$ penalty improves predictive ability by shrinking the coefficients as ridge does.
Adaptive Elastic Net  Computes parameter estimates using an adaptive $l_1$ penalty as well as an $l_2$ penalty. This option uses the MLEs to weight the $l_1$ penalty. MLEs cannot be computed when the number of predictors exceeds the number of observations or when there are strict linear dependencies among the predictors. If MLEs for the regression parameters cannot be computed, a generalized inverse solution or a ridge solution is used for the $l_1$ penalty weights. You can set a value for the Elastic Net Alpha in the Advanced Controls panel. See “Adaptive Methods” on page 336.

The Elastic Net tends to provide better prediction accuracy than the Lasso when predictors are highly correlated. (In fact, both Ridge and the Lasso are special cases of the Elastic Net.) In terms of predictive ability, the adaptive Elastic Net often outperforms both the Elastic Net and the adaptive Lasso. The Elastic Net has the ability to select groups of correlated predictors and to assign appropriate parameter estimates to the predictors involved. See “Elastic Net” on page 335.

Note: If you select an Elastic Net fit and set the Elastic Net Alpha to missing, the algorithm computes the Lasso, Elastic Net, and Ridge fits, in that order. If a fit is time intensive, a progress bar appears. When you click Accept Current Estimates, the calculation stops and the reported parameter estimates correspond to the best model fit at that point. The progress bar indicates when the algorithm is fitting Lasso, Elastic Net, and Ridge. You can use this information to decide when to click Accept Current Estimates.

Ridge  Computes parameter estimates using ridge regression. Ridge regression is a biased regression technique that applies an $l_2$ penalty and does not result in zero parameter estimates. It is useful when you want to retain all predictors in your model. See “Ridge Regression” on page 334.

Double Lasso  Computes parameter estimates in two stages. In the first stage, a Lasso model is fit to determine the terms to be used in the second stage. In the second stage, a Lasso model is fit using the terms from the first stage. The Solution Path results and the parameter estimate reports that appear are for the second-stage fit. If none of the variables enters the model in the first stage, there is no second stage, and the results of the first stage appear in the report.

The Double Lasso is especially useful when the number of observations is less than the number of predictors. By breaking the variable selection and shrinkage operations into two stages, the Lasso in the second stage is less likely to overly penalize the terms that should be included in the model. The double lasso is similar to the relaxed lasso. The relaxed lasso is described in Hastie et al. (2009, p. 91).
**Adaptive Double Lasso**  Computes parameter estimates in two stages. In the first stage, an adaptive Lasso model is fit to determine the terms to be used in the second stage. In the second stage, an adaptive Lasso model is fit using the terms from the first stage. The second stage considers only the terms that are included in the first stage model and uses weights based on the parameter estimates in the first stage. You can choose the method of calculating the weights using the Adaptive Penalty Weights option in the Advanced Controls. See “Advanced Control Options” on page 308. The results that are shown are for the second-stage fit. If none of the variables enters the model in the first stage, there is no second stage, and the results of the first stage appear in the report. See “Adaptive Methods” on page 336.

**Advanced Controls**

Use the Advanced Controls options to adjust various aspects of the model fitting process. A number of controls relate to the grid for the tuning parameter.

**Tuning Parameter**

The solution paths for the Lasso and Ridge Estimation Methods depend on a single tuning parameter. The solution path for the Elastic Net depends on a tuning parameter for the penalty on the likelihood as well as the Elastic Net Alpha. The penalty on the likelihood for the Elastic Net is a weighted sum of the penalties associated with the Lasso and Ridge Estimation Methods. The Elastic Net Alpha determines the weights of these two penalties. See “Statistical Details for Estimation Methods” on page 334 and “Statistical Details for Advanced Controls” on page 336.

When the tuning parameter is zero, the solution is unpenalized and maximum likelihood estimates are obtained. As the tuning parameter increases, the penalty increases.

The solution is the set of parameter estimates that minimizes the penalized negative log-likelihood function relative to the selected validation method. The current solution is designated by the solid red vertical line in the Solution Path Plots.

**Note:** The value of the tuning parameter increases as the Magnitude of Scaled Parameter Estimates in the Solution Path Plot decreases. Estimates close to the MLE are associated with large magnitudes and estimates that are heavily penalized are associated with small magnitudes.

It is important to be mindful of the following:

- When the tuning parameter is too small, the data are typically overfit and result in models with high variance.
- When the tuning parameter is too large, the data are typically underfit.
The Tuning Parameter Grid

To obtain a solution, the tuning parameter is increased over a fine grid.

- For the Lasso, Elastic Net with Elastic Net Alpha specified, and Ridge, the value of the tuning parameter that gives the solution is the one that provides the best fit over the grid of tuning parameters.

**Note:** Elastic Net Alpha is set to 0.99 by default.

- If you do not set a value for the Elastic Net Alpha, the value of alpha is also increased over a fine grid. For a fixed value of the tuning parameter, alpha is varied until ten consecutive values of alpha fail to improve upon the best fit as determined by the validation method. This process is repeated for the entire grid of tuning parameter values. The final values of the tuning parameter and alpha are the values that provide the best fit over the grid of tuning parameters.

The grid of tuning parameter values ranges from zero, in most cases, to the smallest value for which all of the non-intercept terms are zero. Define the smallest value of the tuning parameter for which all non-intercept terms are zero to be its upper bound. The lower bound for the tuning parameter is zero except in the following two cases where it is set to 0.0001:

- If the design matrix is singular, the maximum likelihood estimates cannot be computed. The lower bound of 0.0001 allows estimates close to the MLEs to be computed.
- If the selected distribution is binomial or multinomial, the lower bound of 0.0001 helps prevent separation.

Advanced Control Options

**Enforce effect heredity**  Requires lower-order effects to enter the model before their related higher order effects. In most cases, this means that \( X^2 \) is not in the model unless \( X \) is in the model. For estimation methods other than Forward Selection, however, it is possible for \( X^2 \) to enter the model and \( X \) to leave the model in the same step. If the data table contains a DOE script, this option is enabled, but it is off by default.

**Elastic Net Alpha**  Sets the \( \alpha \) parameter for the Elastic Net. This \( \alpha \) parameter determines the mix of the \( l_1 \) and \( l_2 \) penalty tuning parameters in estimating the Elastic Net coefficients. The default value is \( \alpha = 0.99 \), which sets the coefficient on the \( l_1 \) penalty to 0.99 and the coefficient on the \( l_2 \) penalty to 0.01. This option is available only when Elastic Net is selected as the Estimation Method. See “Statistical Details for Estimation Methods” on page 334.

**Number of Grid Points**  Specifies the number of grid points between the lower and upper bounds for the tuning parameter. At each grid point value, parameter estimates for that value of the tuning parameter are obtained. The default value is 150 grid points.
Minimum Penalty Fraction Indicates the minimum value for the ratio of the lower bound of the tuning parameter to its upper bound. When the lower bound for the tuning parameter is 0, the solution provides the MLE. In cases where you do not want to include the MLE or solutions very close to it, you can set the Minimum Penalty Fraction to a nonzero value. For the Double Lasso estimation method, the specified value of this option is used only in the first stage of the fit. When there is a singularity in the design matrix, the default value is 0.0001. Otherwise, the default value is 0.

Grid Scale Provides options for choosing the distribution of the grid scale. You can choose between a linear, square root, or log scale. Grid points equal in number to the specified Number of Grid Points are distributed according to the selected scale between the lower and upper bounds of the tuning parameter. The default grid scale is square root. See “Statistical Details for Advanced Controls” on page 336.

First Stage Solution Provides options for choosing the solution in the first stage of the Double Lasso and Two Stage Forward Selection. By default, the solution that is the best fit according to the specified Validation Method is selected and is the solution initially shown (Best Fit). You can choose to initially display models with larger or smaller $l_1$ norm values that lie in the green or yellow zones. For example, if you choose Smallest in Yellow Zone, the initially displayed solution is the model in the yellow zone that has the smallest $l_1$ norm. See “Comparable Model Zones” on page 319.

Max Number of Effects Specifies the maximum number of effects to consider in models for the Best Subset estimation method. You can use this to limit the number of computations needed to fit the model. The default value is 10.

Initial Displayed Solution Provides options for choosing the solution that is initially displayed as the current model in the Solution Path report. The current model is identified by a solid vertical line. See “Current Model Indicator” on page 317. The best fit solution is identified by a dotted vertical line. By default, the displayed solution is the one that is considered the best fit according to the specified Validation Method.

You can choose to initially display models with larger or smaller $l_1$ norm values that still lie in the green or yellow zones. For example, if you choose Smallest in Yellow Zone, the initially displayed solution is the model in the yellow zone that has the smallest $l_1$ norm. See “Comparable Model Zones” on page 319.

Adaptive Penalty Weights Provides options for the calculation of the penalty weights that are used in the second stage of the Adaptive Double Lasso. By default, the Inverse Solution option is selected. This option calculates the penalty weights using the parameter estimates from the first stage fit.

The Inverse Model Average option calculates the penalty weights using the parameter estimates from a solution that is the weighted average of the AICc or BIC models. The AICc models are used if the AICc Validation Method is selected. Otherwise, the BIC models are used. If you use the Inverse Model Average option, the maximum likelihood
solution, if it exists, appears as the right-most point in the Solution Path for the Adaptive Double Lasso model.

**Force Terms** Enables you to select which terms, if any, you want to force into the model. The terms that are forced into the model are not included in the penalty.

---

**Validation Method Options**

The following methods are available for validation of the model fit.

**Note:** The only Validation Method allowed for Quantile Regression is None. The only Validation Methods allowed for the Maximum Likelihood Estimation Method are None and Validation Column. The only Validation Methods allowed for Cox Proportional Hazards are BIC, AICc, and None. The only Validation Methods allowed for the Dantzig Selector Estimation Method are BIC and AICc.

**KFold** For each value of the tuning parameter, the following steps are conducted:

- The observations are partitioned into $k$ subsets, or *folds*.
- In turn, each fold is used as a validation set. A model is fit to the observations *not* in the fold. The log-likelihood based on that model is calculated for the observations *in* the fold, providing a *validation* log-likelihood.
- The mean of the validation log-likelihoods for the $k$ folds is calculated. This value serves as a validation log-likelihood for the value of the tuning parameter.

The value of the tuning parameter that has the maximum validation log-likelihood is used to construct the final solution. To obtain the final model, all $k$ models derived for the optimal value of the tuning parameter are fit to the entire data set. Of these, the model that has the highest validation log-likelihood is selected as the final model. The training set used for that final model is designated as the Training set and the holdout fold for that model is the Validation set. These are the Training and Validation sets used in plots and in the reported results for the final solution.

**Holdback** Randomly selects the specified proportion of the data for a validation set, and uses the other portion of the data to fit the model. The final solution is the one that minimizes the negative log-likelihood for the validation set. This method is useful for large data sets. The random selection is based on stratified sampling across the model factors to attempt to create training and validation sets that are more balanced than ones based on simple random sampling.

**Leave-One-Out** Performs leave-one-out cross validation. This is equivalent to KFold, with the number of folds equal to the number of rows. This option should not be used on moderate or large data sets. It can require long processing time for even a moderate
number of observations. The Training and (one-row) Validation sets used in plots and in the reported results for the final solution are determined as is done for KFold validation.

**BIC** Minimizes the Bayesian Information Criterion (BIC) over the solution path. See “Likelihood, AICc, and BIC” on page 559 in the “Statistical Details” appendix.

**AICc** Minimizes the corrected Akaike Information Criterion (AICc) over the solution path. AICc is the default setting for Validation Method. See “Likelihood, AICc, and BIC” on page 559 in the “Statistical Details” appendix.

**Note:** The AICc is not defined when the number of parameters approaches or exceeds the sample size.

**ERIC** Minimizes the Extended Regularized Information Criterion (ERIC) over the solution path. See “Model Fit Detail” on page 314. Available only for exponential family distributions and for the Lasso and adaptive Lasso estimation methods.

**None** Does not use validation. Available only for the Maximum Likelihood Estimation Method and Quantile Regression.

**Validation Column** Uses the column specified in the Fit Model window as having the Validation role. The final solution is the one that minimizes the negative log-likelihood for the validation set. This option is not available when the specified Estimation Method is Dantzig Selector or when the specified Distribution is Quantile Regression or Cox Proportional Hazards.

### Early Stopping

Early Stopping adds an early stopping rule:

- For Forward Selection, the algorithm terminates when 10 consecutive steps of adding variables to the model fail to improve upon the validation measure. The solution is the model at the step that precedes the 10 consecutive steps.

- For Lasso, Elastic Net, and Ridge, the algorithm terminates when 10 consecutive values of the tuning parameter fail to improve upon the best fit as determined by the validation method. The solution is the estimate corresponding to the tuning parameter value that precedes the 10 consecutive values.

**Note:** For the AICc and BIC validation methods, early stopping does not occur until at least four predictors have entered the model.
When you click Go, a report opens. The title of the report specifies the response distribution, the estimation method, and the validation method that you selected. You can return to the Model Launch control panel to perform additional analyses and choose other response distributions, estimation methods, and validation methods.

**Model Fit Reports**

For each Estimation Method and Validation Method that you specify in the Model Launch panel, a report is produced. The report specifies your selected Distribution, Estimation method, and Validation method in its title.

The following reports are presented by default:

- Regression Plot
- Model Summary
- Estimation Details (shown only for Lasso, Elastic Net, and Ridge)
- Solution Path (shown for all but the Maximum Likelihood Estimation Method and Quantile Regression)
- Parameter Estimates for Original Predictors
- Effect Tests

**Regression Plot**

*Note:* The Regression Plot report appears only when there is one continuous predictor and no more than one categorical predictor. It is not available if the Distribution option is set to Multinomial, Ordinal Logistic, or Cox Proportional Hazards. The response must be continuous.

The Regression Plot report shows a plot of the response values on the vertical axis and the continuous predictor on the horizontal axis. A regression line is shown over the points. If there is a categorical predictor in the model, each level of the categorical predictor has a separate regression line and a legend appears next to the plot. If the response is specified as the counts of the number of successes and the number of trials, the number of successes divided by the number of trials is plotted on the vertical axis.
**Model Summary**

The Model Summary report describes the model that you have fit and provides summary information about the fit itself.

**Model Description Detail**

The first part of the Model Summary report gives information that describes the model that you have fit.

- **Response**  The column assigned to the Y role in the Fit Model window. When two columns are used to specify interval censoring, both column names are listed.

- **Distribution**  The Distribution selected in the Fit Model window. For Quantile Regression, the value of the specified quantile for the response is also displayed.

- **Estimation Method**  The Estimation Method selected in the Model Launch panel.

- **Validation Method**  The Validation Method selected in the Model Launch panel.

- **Mean Model Link**  The link function for the model for the mean, based on the Distribution selected in the Fit Model window.

- **Location Model Link**  The link function for the model for the location parameter, shown when either Cauchy or t(5) is selected as the Distribution in the Fit Model window.

- **Scale Model Link**  The link function for the model for the scale parameter, based on the Distribution selected in the Fit Model window.

- **Probability Model Link**  The link function for the model for the probability, based on the Distribution selected in the Fit Model window.

- **Dispersion Model Link**  The link function for the model for the dispersion parameter, based on the Distribution selected in the Fit Model window.

- **Zero Inflation Model Link**  The link function for the model for the zero inflation parameter, based on the Distribution selected in the Fit Model window.

- **Lower Detection Limit**  The lower detection limit specified in a Detection Limits column property assigned to the response column.

- **Upper Detection Limit**  The upper detection limit specified in a Detection Limits column property assigned to the response column.

- **Censor Column**  The column assigned to the Censor role in the Fit Model window.

- **Censor Code**  The value in the Censor column that designates right-censored observations. This is the value that was specified in the Censor Code list in the Fit Model window.
Model Fit Detail

The second part of the Model Summary report gives statistics related to the model fit. If either Holdback or Validation Column is selected as the Validation Method, these statistics are computed separately for the training and validation sets. This part of the Model Summary report is not available if either KFold or Leave-One-Out is selected as the Validation Method.

**Number of rows**  The number of rows.

**Sum of Frequencies**  The sum of the values of a column assigned to the Freq or Weight role in the Fit Model window.

**Note:** For -LogLikelihood, BIC, AICc, and ERIC, smaller is better. See “Likelihood, AICc, and BIC” on page 559 in the “Statistical Details” appendix.

**-LogLikelihood**  The negative of the natural logarithm of the likelihood function for the current model. See “Likelihood, AICc, and BIC” on page 559 in the “Statistical Details” chapter.

**Note:** -LogLikelihood is not available for Quantile Regression.

**Objective Function**  (Available only for Quantile Regression.) The value of the function that is minimized to fit the specified quantile regression model. The function that is minimized is the check-loss function.

**Number of Parameters**  The number of nonzero parameters in the current model.

**BIC**  The Bayesian Information Criterion, which is defined as follows:

\[
BIC = -2 \log \text{Likelihood} + k \ln(n)
\]

See “Likelihood, AICc, and BIC” on page 559 in the “Statistical Details” chapter.

**AICc**  The corrected Akaike Information Criterion, which is defined as follows:

\[
\text{AICc} = -2 \log \text{Likelihood} + 2k + 2k(k + 1)/(n - k - 1)
\]

See “Likelihood, AICc, and BIC” on page 559 in the “Statistical Details” chapter.

**ERIC**  (Available only for exponential family distributions and when the Lasso or adaptive Lasso estimation method is specified.) The Extended Regularization Information Criterion. See Hui et al. (2015). ERIC is defined as follows:

\[
\text{ERIC} = -2 \log \text{Likelihood} + (k - 2) \ln(n\phi/\lambda)
\]

where \(\lambda\) is the value of the tuning parameter and \(\phi\) is the nuisance parameter.
**Generalized RSquare**  (Not available for Quantile Regression.) An extension of the RSquare measure that can be applied to general regression models. Generalized RSquare compares the likelihood of the fitted model ($L_M$) to the likelihood of the intercept-only (constant) model ($L_0$). It is scaled to have a maximum of 1. For distributions other than Binomial, the Generalized RSquare is defined as follows:

$$\text{Generalized RSquare} = 1 - \left( \frac{L_0}{L_M} \right)^{2/n}$$

When Binomial is the specified distribution, the Generalized RSquare is defined as follows:

$$\text{Generalized RSquare} = \frac{1 - \left( \frac{L_0}{L_M} \right)^{2/n}}{1 - L_0^{2/n}}$$

A Generalized RSquare value of 1 indicates a perfect model; a value of 0 indicates a model that is no better than a constant model. The Generalized RSquare measure simplifies to the traditional RSquare for continuous normal responses in the standard least squares setting. Generalized RSquare is also known as the Nagelkerke or Craig and Uhler $R^2$, which is a normalized version of Cox and Snell’s pseudo $R^2$. See Nagelkerke (1991).

**Note:** Generalized RSquare is replaced by RSquare when the Normal distribution is specified.

**Caution:** You should not compare Generalized RSquare values for models that use different response distributions. The comparison being made is to the intercept-only model with a given response distribution.

**RSquare**  (Available only when the Normal distribution is specified.) Estimates the proportion of variation in the response that can be attributed to the model rather than to random error. An RSquare value of 1 indicates a perfect model; a value of 0 indicates a model that is no better than a constant model. The RSquare value is calculated as follows:

$$1 - \frac{\sum_{i=1}^{N} (Y_i - \hat{Y}_i)^2}{\sum_{i=1}^{N} (Y_i - \bar{Y})^2}$$

**RSquare Adj**  (Available only when the Normal distribution is specified and the estimation method does not involve a penalty.) Adjusts the RSquare statistic for the number of parameters in the model. Rsquare Adj facilitates comparisons among models with
different numbers of parameters. The computation uses the degrees of freedom. The RSquare Adj value is calculated as follows:

\[
R^2_{\text{Adj}} = 1 - \frac{\frac{1}{N - (p - 1)} \sum_{i=1}^{N} (Y_i - \hat{Y}_i)^2}{\frac{1}{N - 1} \sum_{i=1}^{N} (Y_i - \bar{Y})^2}
\]

where \( N \) is the number of observations and \( p \) is the number of parameters.

**Note:** When there is a Validation set, the adjusted RSquare statistic is reported only for the Training set.

**RASE** (Available only when the Normal distribution is specified.) The Root Average Square Error (RASE) is the square root of the mean squared prediction error in the current model. See “RASE” on page 88 in the “Standard Least Squares Models” chapter.

**Lambda Penalty** (Available only for the Dantzig Selector, Lasso, Elastic Net, Ridge, and Double Lasso estimation methods.) The value of the tuning parameter \( \lambda \) for the current model. See “Statistical Details for Estimation Methods” on page 334.

### Estimation Details

The Estimation Details report shows the settings of the Advanced Controls for the Dantzig Selector, Lasso, Elastic Net, Ridge, and Double Lasso estimation methods. For more information about these controls, see “Advanced Controls” on page 307.

### Solution Path

**Note:** The Solution Path report appears for all Estimation Methods except Maximum Likelihood and all Distributions except Quantile Regression.

The Solution Path report shows two plots:

- The Solution Path Plot displays values of the estimated parameters.
- The Validation Plot displays values of the validation statistic corresponding to the selected validation method.
The horizontal scaling for both plots is given in terms of the Magnitude of Scaled Parameter Estimates. This is the $l_1$ norm, defined as the sum of the absolute values of the scaled parameter estimates for the model for the mean. (Estimates corresponding to the intercept, dispersion parameters, and zero-inflation parameters are excluded from the calculation of the $l_1$ norm.) Note the following:

- Estimates with large values of the $l_1$ norm are close to the MLE.
- Estimates with small values of the $l_1$ norm are heavily penalized.
- The value of the tuning parameter increases as the $l_1$ norm decreases.

**Current Model Indicator**

A solid vertical red line is placed in both plots at the value of the $l_1$ norm for the solution displayed in the Parameter Estimates for Original Predictors report. You can drag the arrow at the top of the vertical red line in either plot to change the magnitude of the penalty, indicating a new current model. In the Validation Plot, you can also click anywhere in the plot to change the model. As you drag the vertical red line to indicate a new model, the results in the report update to reflect the currently selected model. A dashed vertical line remains at the best fit model. You can click the **Reset Solution** button next to the Validation Plot to return the vertical red line and corresponding results to the initial solution. For some validation methods, the Validation Plot provides zones that identify comparable models. See “Comparable Model Zones” on page 319.

**Figure 6.5 Solution Path Report for Diabetes.jmp, Lasso with AICc Validation**

For more information about the Solution Path Plot, see “Solution Path Plot” on page 318. For more information about the Validation Plot, see “Validation Plot” on page 318.
Solution Path Plot

You can select paths in the Solution Path Plot to highlight the corresponding terms in the Parameter Estimates reports. This action also selects the corresponding columns in the data table. Selecting rows in either of the reports highlights the corresponding rows in the other report and the corresponding paths in the Solution Path Plot. Press Shift and click to select multiple paths or rows.

The Parameter Estimates are plotted using the vertical axis of the Solution Path Plot. These are the scaled parameter estimates. They are derived for a model expressed in terms of centered and scaled predictors (see “Parameter Estimates for Centered and Scaled Predictors” on page 320).

When the number of predictors is less than the number of observations, the Solution Path Plot usually shows the entire range of estimates from zero to the unpenalized fit given by the MLE. Otherwise, the plot extends to a magnitude that is close to the unpenalized solution. This occurs when the jump from the next-to-last grid point to the MLE solution is so large that the detail for solutions up to the next-to-last grid point is obscured. When this happens, as long as the MLE is not the final solution, the Solution Path Plot is rescaled so that the axis extends only to the next-to-last grid point.

The Solution ID

Internally, each solution in the Solution Path is assigned a Solution ID. When you adjust the tuning parameter to select a solution other than the one initially presented, the corresponding Solution ID appears in scripts created by the Save Script options. The Solution ID is the value N in the Set Solution ID( N ) command. Saving the Solution ID ensures that you can re-create your selected solution when you run the script.

Validation Plot

The Validation Plot shows plots of statistics that describe how well models fit across the values of the tuning parameter, or equivalently, across the values of the Magnitude of the Scaled Parameter Estimates. The statistics plotted depend on the selected Validation Method. For each Validation Method, Table 6.3 lists the statistic that is plotted. For all validation methods, smaller values are better. For the KFold and Leave-One-Out validation methods, and for a Validation Column with more than three values, the statistic that is plotted is the mean of the scaled negative log-likelihood values across the folds.

The Scaled -LogLikelihood in Table 6.3 is the negative log-likelihood divided by the number of observations in the set for which the negative log-likelihood is computed.
Comparable Model Zones

Although a model is estimated to be the best model, there can be uncertainty relative to this selection. Competing models might fit nearly as well and can contain useful information. For the AICc, BIC, KFold, and Leave-One-Out validation methods, and for a Validation Column with more than three values, the Validation Plot provides zones that identify competing models that might deserve consideration. Models that fall outside the zones are not recommended. See Burnham and Anderson (2004) and Burnham et al. (2011).

A zone is an interval of values of the validation statistics. The zones are plotted as green or yellow rectangles that span the entire horizontal axis. A model falls in a zone if the value of its validation statistic falls in the zone. You can drag the solid vertical red line to explore solutions within the zones. See “Current Model Indicator” on page 317.

Figure 6.6 shows a Validation Plot for Diabetes.jmp with the vertical axis expanded to show the two zones.
Zones for BIC, AICc, and ERIC Validation

For these validation methods, two regions are shown in the plot. Denote the validation BIC, AICc, and ERIC values for the best solutions by $V_{\text{best}}$.

- The green zone identifies models for which there is strong evidence that a model is comparable to the best model. The green zone is the interval $[V_{\text{best}}, V_{\text{best}} + 4]$.
- The yellow zone identifies models for which there is weak evidence that a model is comparable to the best model. The yellow zone is the interval $(V_{\text{best}} + 4, V_{\text{best}} + 10]$.

Zones for KFold Validation, Leave-One-Out Validation, and Validation Column with More Than Three Values

For these validation methods, two regions are shown in the plot. At the solution for the best model, the scaled negative log-likelihood functions are evaluated for each validation set. Denote the standard error of these values as $L_{\text{SE}}$. Denote the scaled negative log-likelihood for the best solution by $L_{\text{best}}$.

- The green zone identifies models for which there is strong evidence that a model is comparable to the best model. The green zone is the interval $[L_{\text{best}}, L_{\text{best}} + L_{\text{SE}}]$.
- The yellow zone identifies models for which there is weak evidence that a model is comparable to the best model. The yellow zone is the interval $(L_{\text{best}} + L_{\text{SE}}, L_{\text{best}} + 2.5L_{\text{SE}}]$.

Parameter Estimates for Centered and Scaled Predictors

The Parameter Estimates for Centered and Scaled Predictors report gives estimates and other results for all parameters in the model. The initial table includes the coefficients for the predictors in the model. An additional table includes other model parameters such as scale, dispersion, or zero inflation parameters. See “Distribution” on page 292. Both tables include the same columns of results.
Tip: You can click terms in the Parameter Estimates for Centered and Scaled Predictors report to highlight the corresponding paths in the Solution Path Plot. The corresponding columns in the data table are also selected. This is useful in terms of running further analyses. Press Shift and click the terms to select multiple rows.

For all fits in the Generalized Regression personality, every predictor is centered to have mean zero and scaled to have sum of squares equal to one:

- The mean is subtracted from each observation.
- Each difference is then divided by the square root of the sum of the squared differences from the mean.

This puts all predictors on an equal footing relative to the penalties applied.

Note: When the No Intercept option is selected in the launch window, the predictors are not centered and scaled.

The Parameter Estimates for Centered and Scaled Predictors report gives parameter estimates for the model expressed in terms of the centered and scaled predictors. The estimates are determined by the Validation Method that you specified. The estimates are depicted in the Solution Path Plots by a vertical red line.

The report provides the following information:

Term A list of the model terms. “Forced in” appears next to any terms that were forced into the model using the Advanced Controls option.

Estimate The parameter estimate corresponding to the centered and scaled model term.

Std Error The standard error of the estimate. This is obtained using M-estimation and a sandwich formula (Zou 2006; Huber and Ronchetti 2009).

Wald ChiSquare The ChiSquare value for a Wald test of whether the parameter is zero.

Prob > ChiSquare The $p$-value for the Wald test.

Lower 95% The lower bound for a 95% confidence interval for the parameter. You can change the $\alpha$ level in the Fit Model window by selecting Set Alpha Level from the Model Specification red triangle menu.

Upper 95% The upper bound for a 95% confidence interval for the parameter. You can change the $\alpha$ level in the Fit Model window by selecting Set Alpha Level from the Model Specification red triangle menu.

Singularity Details (Available only if there are linear dependencies among the model terms.) The linear function that the model term satisfies.
Parameter Estimates for Original Predictors

The Parameter Estimates for Original Predictors report gives estimates and other results for all parameters in the model. The initial table includes the coefficients for the predictors in the model. An additional table includes other model parameters such as scale, dispersion, or zero inflation parameters. See “Distribution” on page 292. Both tables include the same columns of results.

Tip: You can click terms in the Parameter Estimates for Original Predictors report to highlight the corresponding paths in the Solution Path Plot. The corresponding columns in the data table are also selected. This is useful when running further analyses. Press Shift and click the terms to select multiple rows.

The Parameter Estimates for Original Predictors report gives parameter estimates for the model expressed in terms of the original (uncentered and unscaled) predictors.

The report provides the following information:

Term  A list of the model terms. “Forced in” appears next to any terms that were forced into the model using the Advanced Controls option.

Estimate  The parameter estimate corresponding to the model term given in terms of the original measurements.

Std Error  The standard error of the estimate. This is obtained using M-estimation and a sandwich formula (Zou 2006 and Huber and Ronchetti 2009).

Wald ChiSquare  The ChiSquare value for a Wald test of whether the parameter is zero.

Prob > ChiSquare  The p-value for the Wald test.

Lower 95%  The lower bound for a 95% confidence interval for the parameter. You can change the $\alpha$ level in the Fit Model window by selecting Set Alpha Level from the Model Specification red triangle menu.

Upper 95%  The upper bound for a 95% confidence interval for the parameter. You can change the $\alpha$ level in the Fit Model window by selecting Set Alpha Level from the Model Specification red triangle menu.

Singularity Details  (Available only if there are linear dependencies among the model terms.) The linear function that the model term satisfies.

VIF  (Available only when the distribution is Normal. Appears only if you right-click in the parameter estimates table and select Columns > VIF.) The variance inflation factor (VIF) for each term in the model. High VIF values indicate a collinearity issue among the terms in the model.
The VIF for the $i^{th}$ term, $x_i$, is calculated as follows:

$$VIF_i = \frac{1}{1 - R_i^2}$$

where $R_i^2$ is the RSquare for the regression of $x_i$ as a function of the other explanatory variables.

Active Parameter Estimates

The Active Parameter Estimates report gives a subset of the Parameter Estimates for Original Predictors report. The Active Parameter Estimates report shows only the nonzero parameters.

Effect Tests

The Effect Tests report gives the following information:

Source  A list of the effects in the model.

Nparm  The number of parameters associated with the effect.

DF  The degrees of freedom for the Wald ChiSquare test. This is the number of nonzero parameter estimates associated with the effect in the model.

Wald ChiSquare  The ChiSquare value for a Wald test of whether all parameters associated with the effect are zero.

Prob > ChiSquare  The $p$-value for the Wald ChiSquare test.

The following columns appear in the report in place of Wald ChiSquare and Prob > ChiSquare when the Distribution is Normal and there is no penalty in the estimation method:

Sum of Squares  The sum of squares for the hypothesis that the effect is zero.

F Ratio  The F statistic for testing that the effect is zero. The F Ratio is the ratio of the mean square for the effect divided by the mean square for error. The mean square for the effect is the sum of squares for the effect divided by its degrees of freedom.

Prob > F  The $p$-value for the effect test.

If the coefficient for an effect has been estimated as zero, then:

- If the effect has one degree of freedom, the word “Removed” appears at the far right in the row for that effect.
- If the effect has multiple degrees of freedom, the phrase “Levels removed” appears, followed by the number of levels that correspond to terms with parameter estimates of zero.
Model Fit Options

Each model fit report has a red triangle menu with these options:

**Caution:** Many options in the platform are not available if you specify a column that has the Expression data type or Vector modeling type in the launch window.

**Regression Reports** Enables you to customize the reports that are shown for the specified model fit. All of the following reports are shown by default except for the Parameter Estimates for Centered and Scaled Parameter Estimates report and the Active Parameter Estimates report.

**Model Summary** Shows or hides the Model Summary report that includes information about the specification and goodness of fit statistics for the model. This option also displays the Estimation Details report for applicable models. See “Model Summary” on page 313 and “Estimation Details” on page 316.

**Solution Path** (Not available for Maximum Likelihood models.) Shows or hides the Solution Path and Validation Path plots. See “Solution Path” on page 316.

**Parameter Estimates for Centered and Scaled Predictors** Shows or hides a table of centered and scaled parameter estimates. See “Parameter Estimates for Centered and Scaled Predictors” on page 320.

**Parameter Estimates for Original Predictors** Shows or hides a table of parameter estimates in the original scale of the data. See “Parameter Estimates for Original Predictors” on page 322.

**Active Parameter Estimates** (Not available for Maximum Likelihood or Ridge Regression models.) Shows or hides a table of active, or nonzero, parameter estimates for the currently selected model.

**Show Solution Path Summary** (Not available for Maximum Likelihood or Ridge Regression models.) Shows or hides a report that contains a table of fit statistics for the points on the Solution Path and Validation Path plots where the active set changes. The statistics that are available depend on the estimation method. For more information about the conditional model probabilities that are available for Normal Lasso with BIC Validation models, see Hu et al. (2019). When BIC, AICc, or ERIC Validation is specified, the cells in the BIC and AICc columns are colored in the same manner as the Validation Plot. See “Comparable Model Zones” on page 319.
**Effect Tests**  Shows or hides tests for each effect. The effect test for a given effect tests the null hypothesis that all parameters associated with that effect are zero. A nominal or ordinal effect can have several associated parameters, based on its number of levels. The effect test for such an effect tests whether all of the associated parameters are zero. When the Distribution is Multinomial, the effects are combined over the levels of the response. See “Effect Tests” on page 323.

**Show Prediction Expression**  Shows or hides the Prediction Expression report that contains the equation for the estimated model. See “Show Prediction Expression” on page 115 in the “Standard Least Squares Models” chapter for an example.

**Select Nonzero Terms**  Highlights terms with nonzero coefficients in the report. Also selects all associated columns in the data table. This option is not available when Ridge Regression is selected as the Estimation Method.

**Select Zeroed Terms**  Highlights terms with zero coefficients in the report. Also selects all associated columns in the data table. This option is not available when Ridge Regression is selected as the Estimation Method.

**Relaunch Active Set**  (Not available for models that contain a predictor that has the Vector modeling type.) Contains options that open a Fit Model launch window where the Construct Model Effects list contains a set of terms based on the terms that have nonzero parameter estimates. These terms are the active effects. All other specifications in the launch window are those used in the original analysis.

**Note:** If you select any of the Relaunch Active Set options in a report that contains a By variable, the By variable is not added to the Fit Model launch window.

**Relaunch with Active Effects**  Populates the Construct Model Effects list only with the active effects.

**Relaunch Active Main Effects and Second Degree Factorial**  Populates the Construct Model Effects list with a second degree factorial constructed with the active effects.

**Relaunch Active Main Effects and Third Degree Factorial**  Populates the Construct Model Effects list with a third degree factorial constructed with the active effects.

**Relaunch Active Main Effects and Full Factorial**  Populates the Construct Model Effects list with a full factorial constructed with the active effects.

**Relaunch Active Main Effects and Second Degree Polynomial**  Populates the Construct Model Effects list with a second degree polynomial constructed with the active effects.

**Relaunch Active Main Effects and Third Degree Polynomial**  Populates the Construct Model Effects list with a third degree polynomial constructed with the active effects.
Relaunch Active Main Effects and Response Surface Model  Populates the Construct Model Effects list with a response surface model constructed with the active effects.

Hide Inactive Paths  Adjusts the transparency of the inactive paths in the Solution Path Parameter Estimates plot so that the paths that are not currently active appear faded.

Odds Ratios  (Available only when the specified Distribution is Binomial and the model contains an intercept. Not available for models that contain a predictor that has the Vector modeling type.) Displays a report that contains odds ratios for categorical predictors, and unit odds ratios and range odds ratios for continuous predictors. An odds ratio is the ratio of the odds for two events. The odds of an event is the probability that the event of interest occurs versus the probability that it does not occur. The event of interest is defined by the Target Level in the Fit Model launch window.

For each categorical predictor, an Odds Ratios report appears. Odds ratios are shown for all combinations of levels of a categorical model term.

If there are continuous predictors, two additional reports appear:

– Unit Odds Ratios Report. The unit odds ratio is calculated over a one-unit change in a continuous model term.

– Range Odds Ratios Report. The range odds ratio is calculated over the entire range of a continuous model term.

The confidence intervals in the Odds Ratios report are Wald-based intervals. Note that the odds ratio for a model term is meaningful only if the model term is not involved in any higher-order effects.

Note: If there are interactions in the model, you can use the Multiple Comparisons option to obtain odds ratios. See “Multiple Comparisons” on page 327.

Incidence Rate Ratios  (Available only when the specified Distribution is Poisson or Negative Binomial and the model contains an intercept.) Displays a report that contains incidence rate ratios for categorical predictors, and unit incidence rate ratios and range incidence rate ratios for continuous predictors. An incidence rate ratio is the ratio of the incidence rate for two events. The incidence rate for a model term is the number of new events that occur over a given time period.

For each categorical predictor, an Incidence Rate Ratios report appears. Incidence rate ratios are shown for all combinations of levels of a categorical model term.

If there are continuous predictors, two additional reports appear:

– Unit Incidence Rate Ratios Report. The unit incidence rate ratio is calculated over a one-unit change in a continuous model term.
– Range Incidence Rate Ratios Report. The *range incidence rate ratio* is calculated over the entire range of a continuous model term.

The confidence intervals in the Incidence Rate Ratios report are Wald-based intervals. Note that the incidence rate ratio for a model term is meaningful only if the model term is not involved in any higher-order effects.

**Hazard Ratios**  (Available only when the specified Distribution is Cox Proportional Hazards.) Displays a report that contains hazard ratios for categorical predictors, and unit hazard ratios and range hazard ratios for continuous predictors. A *hazard ratio* is the ratio of the hazard rate for two events. The *hazard rate* at time $t$ for an event is the conditional probability that the event will not survive an additional amount of time, given that it has survived to time $t$.

For each categorical predictor, a Hazard Ratios report appears. Hazard ratios are shown for all combinations of levels of a categorical model term.

If there are continuous predictors, two additional reports appear:

– Unit Hazard Ratios Report. The *unit hazard ratio* is calculated over a one-unit change in a continuous model term.

– Range Hazard Ratios Report. The *range hazard ratio* is calculated over the entire range of a continuous model term.

The confidence intervals in the Hazard Ratios report are Wald-based intervals. Note that the hazard ratio for a model term is meaningful only if the model term is not involved in any higher-order effects.

**Covariance of Estimates**  Displays a matrix showing the covariances of the parameter estimates. These are calculated using M-estimation and a sandwich formula (Zou 2006 and Huber and Ronchetti 2009). The covariance matrix does not contain zeroed terms.

**Correlation of Estimates**  Displays a matrix showing the correlations of the parameter estimates. These are calculated using M-estimation and a sandwich formula (Zou 2006 and Huber and Ronchetti 2009). The correlation matrix does not contain zeroed terms.

**Inverse Prediction**  (Not available for models that contain a predictor that has the Vector modeling type.) Predicts an X value, given specific values for Y and the other X variables. This can be used to predict continuous variables only. For more information about Inverse Prediction, see “Inverse Prediction” on page 142 in the “Standard Least Squares Models” chapter.

**Multiple Comparisons**  (Not available for models that contain a predictor that has the Vector modeling type or for models that do not contain any categorical predictors.) Displays the Multiple Comparisons launch window. For more information about the Multiple Comparisons launch window and report, see “Multiple Comparisons” on page 126 in the “Standard Least Squares Models” chapter. Note that the multiple comparisons are
performed on the linear predictor scale. When the specified Distribution is Binomial, the multiple comparisons are performed on the odds ratios. When the specified Distribution is Poisson, the multiple comparisons are performed on the incidence rate ratios. When the specified Distribution is Cox Proportional Hazards, the multiple comparisons are performed on the hazard ratios.

**Confusion Matrix**  (Available only when the specified Distribution is Binomial, Multinomial, or Ordinal Logistic.) Displays a matrix that tabulates the actual response levels and the predicted response levels. For a good model, predicted response levels should be the same as the actual response levels. The confusion matrix enables you to assess how the predicted responses align with the actual responses. If you used validation, a confusion matrix is shown for each of the Training, Validation, and Test sets.

**Set Probability Threshold**  (Available only when the specified Distribution is Binomial.) Specify a cutoff probability for classifying the response. By default, an observation is classified into the Target Level when its predicted probability exceeds 0.5. Change the threshold to specify a value other than 0.5 as the cutoff for classification into the Target Level. The Predicted Rate in the confusion matrix is updated to reflect classification according to the specified threshold.

If the response has a Profit Matrix column property, the initial value for the probability threshold is determined by the profit matrix.

**Profilers**  (Not available for models that contain a predictor that has the Vector modeling type.) Provides various profilers that enable you to explore the fitted model.

---

**Note:** When the number of rows is less than or equal to 500 and the number of predictors is less than or equal to 30, the Profiler plots update continuously as you drag the current model indicator in either Solution Path plot. Otherwise, they update when you release the mouse button.

**Profiler**  Displays the Prediction Profiler. Predictors that have parameter estimates of zero and that are not involved in any interaction terms with nonzero coefficients do not appear in the profiler. For more information about the prediction profiler, see Profilers.

**Distribution Profiler**  (Not available when the specified distribution is Binomial or Quantile Regression.) Displays a profiler of the cumulative distribution function of the predictors and the response. The response is shown in the right-most cell.

**Quantile Profiler**  (Not available when the specified distribution is Binomial or Quantile Regression.) Displays a profiler that shows the predicted response as a function of the predictors and the quantile of the cumulative distribution function. The quantile is called Probability and is shown in the right-most cell.
Survival Profiler  (Available only when the specified Distribution is Normal, Exponential, Weibull, Lognormal, or Cox Proportional Hazards.) Displays a profiler that shows the survival function as a function of the predictors and the response. The response is shown in the right-most cell.

Hazard Profiler  (Available only when the specified Distribution is Normal, Exponential, Weibull, Lognormal, or Cox Proportional Hazards.) Displays a profiler that shows the hazard rate as a function of the predictors and the response. The response is shown in the right-most cell.

Custom Test  Displays a Custom Test report that enables you to test a custom hypothesis. If the model has a Solution Path, the custom test results update as you update the solution. For more information about custom tests, see “Custom Test” on page 124 in the “Standard Least Squares Models” chapter. The Custom Test red triangle menu contains an option to remove the Custom Test report.

Diagnostic Plots  Provides various plots to help assess how well the current model fits. If a Validation column is specified or if KFold, Holdback, or Leave-One-Out is selected as the Validation Method, the options below enable you to view the training, validation, and, if applicable, test sets, or they construct separate plots for these sets. If KFold or Leave-One-Out is selected, then the plots correspond to the validation set that optimizes prediction error, and its corresponding training set. See “KFold” on page 310.

**Note:** All Diagnostic plots update continuously as you drag the current model indicator in either Solution Path plot.

Diagnostic Bundle  (Not available when the specified Distribution is Binomial, Multinomial, Ordinal Logistic, or Cox Proportional Hazards.) Displays a set of four graphs including a plot of residuals by predicted values, residuals by row number, a histogram of the residuals, and a histogram of the probability of observing a response larger than the observed response.

The graphs are constructed using all observations. If you used a Validation Column or if you selected KFold, Holdback, or Leave-One-Out as the Validation Method, check boxes enable you to select the Training, Validation, and, if applicable, Test sets. Rows corresponding to these sets are selected in the data table and the corresponding points and areas are highlighted in the graphs. Use this option to determine whether the model fit is similar across the sets.

The Fitted Probability of Observing a Larger Response histogram helps you assess goodness of fit of the model. Different criteria apply based on the distribution:

- For distributions other than zero-inflated distributions and quantile regression, the “correct” model should display an approximately uniform distribution of values.
For a zero-inflated distribution, the histogram should display a point mass at zero and an approximately uniform distribution elsewhere.

For quantile regression, the histogram should display an approximately uniform distribution of values to the left of the specified quantile and an approximately uniform distribution of slightly higher values to the right of the specified quantile.

**Plot Baseline Survival and Hazard** (Available only when the specified Distribution is Cox Proportional Hazards.) Displays the Baseline Survival and Hazard plots, which plot the survival and hazard functions for the baseline proportional hazards function versus the response variable. Below the plots, there is a table that contains the plotted values.

**Note:** If the specified Distribution is Cox Proportional Hazards, the Plot Baseline Survival and Hazard option is the only available Diagnostic Plot.

**ROC Curve** (Available only when the specified Distribution is Binomial, Multinomial, or Ordinal Logistic.) Displays the Receiver Operating Characteristic (ROC) curve. If you used validation, an ROC curve is shown for each of the Training, Validation, and Test sets.

The ROC curve measures the ability of the fitted probabilities to classify response levels correctly. The further the curve from the diagonal, the better the fit. An introduction to ROC curves is found in *Basic Analysis*.

If the response has more than two levels, the ROC Curve plot displays an ROC curve for each response level. For a given response level, this curve is the ROC curve for correct classification into that level. See *Predictive and Specialized Modeling* for more information about ROC curves.

**Lift Curve** (Available only when the specified Distribution is Binomial, Multinomial, or Ordinal Logistic.) Displays the lift curve for the model. If you used validation, an ROC curve is shown for each of the Training, Validation, and Test sets.

A lift curve shows how effectively response levels are classified as their fitted probabilities decrease. The fitted probabilities are plotted along the horizontal axis in descending order. The vertical coordinate for a fitted probability is the proportion of correct classifications for that probability or higher, divided by the overall correct classification rate. Use the lift curve to see whether you can correctly classify a large proportion of observations if you select only those with a fitted probability that exceeds a threshold value.

If the response has more than two levels, the Lift Curve plot displays a lift curve for each response level. For a given response level, this curve is the lift curve for correct classification into that level. See *Predictive and Specialized Modeling* for more information about lift curves.
Plot Actual by Predicted  (Not available when the specified Distribution is Binomial, Multinomial, Ordinal Logistic, or Cox Proportional Hazards.) Plots actual Y values on the vertical axis and predicted Y values on the horizontal axis. If you used validation, a plot is shown for each of the Training, Validation, and Test sets.

Plot Residual by Predicted  (Not available when the specified Distribution is Binomial, Multinomial, Ordinal Logistic, or Cox Proportional Hazards.) Plots the residuals on the vertical axis and the predicted Y values on the horizontal axis. If you used validation, a plot is shown for each of the Training, Validation, and Test sets.

Plot Residual by Predictor  (Not available when the specified Distribution is Binomial, Multinomial, Ordinal Logistic, or Cox Proportional Hazards. Not available for models that contain a predictor that has the Vector modeling type.) For each predictor in the model, plots the residuals on the vertical axis and the predictor values on the horizontal axis. There is a plot for each of the predictors in the model. If you used validation, a set of plots is shown for each of the Training, Validation, and Test sets.

Normal Quantile Plot  (Available only when the specified Distribution is Normal and there is no censoring.) Plots normal quantiles on the vertical axis and standardized residuals on the horizontal axis. If you used validation, a plot is shown for each of the Training, Validation, and Test sets.

Save Columns  Enables you to save columns based on the fitted model to the data table. See “Save Columns Options for Cox Proportional Hazards Models” on page 333 for the options that are available if Cox Proportional Hazards is selected as the Distribution. For all other Distributions, the following columns can be saved to the data table:

Save Functional Prediction Formulas  (Available only when the response columns contain the FDE FPC Num column property.) Saves a column for each FDE principal component response to the data table that contains a prediction formula for each functional principal component. This option also adds a model prediction formula that is a linear combination of the prediction formulas and the eigenfunction columns from the Functional Data Explorer platform. A script is added to the data table that enables you to use the model prediction formula to profile the original response, which is specified in the FDE Output column property of the FDE principal component response columns. For more information about functional principal components, see Predictive and Specialized Modeling.

Note: The Save Functional Prediction Formulas option saves formula columns for all FDE principal component responses in the report window. If multiple models are fit for a single response, the final model for each response is used to create the prediction formula for that response.
**Save Prediction Formula**  Saves a column to the data table that contains the prediction formula, given in terms of the observed (unstandardized) data values. The prediction formula does not contain zeroed terms. See “Statistical Details for Distributions” on page 337 for mean formulas.

When the response column is categorical, this option creates a probability column for each response level as well as a column that contains the most likely response. The Most Likely response column contains the level with the highest probability based on the model. If the Probability Threshold is a value other than 0.5, this option creates an additional column that contains the most likely response based on the probability threshold value.

**Mean Confidence Interval**  Saves two columns to the data table that contain the lower and upper 95% confidence limits for the mean response.

**Note:** You can change the $\alpha$ level for the confidence interval in the Fit Model window by selecting Set Alpha Level from the Model Specification red triangle menu.

**Std Error of Predicted**  Saves a column to the data table that contains the standard errors of the predicted mean response.

**Save Residual Formula**  Saves a column to the data table that contains a formula for the residuals, given in the form $Y$ minus the prediction formula. The residual formula does not contain zeroed terms. Not available if Binomial is selected as the Distribution.

**Save Variance Formula**  Saves a column to the data table that contains a formula for the variance of the prediction. The variance of the prediction is calculated using the formula for the variance of the selected Distribution. The value of the parameter involved in the link function is estimated by applying the inverse of the link function to the estimated linear component. Other parameters are replaced by their estimates. See “Statistical Details for Distributions” on page 337 for variance formulas. Not available if Binomial is selected as the Distribution.

**Save Linear Predictor**  Saves a column to the data table that contains a formula for the product of the design matrix and the vector of parameter estimates. This is commonly referred to as $X\beta$. The formula does not contain zeroed terms.

**Save Validation Column**  (Available only if the specified Validation Method is KFold, Holdback, or Leave-One-Out.) Saves a column that describes the assignment of rows to folds. For KFold, the column lists the fold to which the row was assigned. For Holdback, each row is identified as belonging to the Training or Validation set. For Leave-One-Out, the row’s value indicates its order in being left out.

**Note:** If you selected a Validation column in the launch window, the Save Validation Column option does not appear.
**Save Distribution Formula**  (Not available when the specified distribution is Binomial or Quantile Regression.) Saves a column to the data table that contains a formula for the cumulative distribution function.

**Save Survival Formula**  (Available only when the specified Distribution is continuous.) Saves a column to the data table that contains a formula for the probability of survival at the observed time. The survival function is equal to 1 minus the cumulative distribution function.

**Save Simulation Formula**  Saves a column to the data table that contains a formula that generates simulated values using the estimated parameters for the model that you fit. This column can be used in the Simulate utility as a Column to Switch In. See *Basic Analysis*.

**Cook’s D Influence**  (Available only if the specified Distribution is Normal and the specified Estimation Method is Standard Least Squares.) Saves a column to the data table that contains the values for Cook’s D Influence statistic.

**Hats**  (Available only if the specified Distribution is Normal and the specified Estimation Method is Standard Least Squares.) Saves a column to the data table that contains the diagonal elements of $X(X'X)^{-1}X'$. These values are sometimes called *hat values*.

**Publish Prediction Formula**  Creates prediction formulas and saves them as formula column scripts in the Formula Depot platform. If a Formula Depot report is not open, this option creates a Formula Depot report. See *Predictive and Specialized Modeling*.

**Save Columns Options for Cox Proportional Hazards Models**

**Save Survival Formula**  Saves a column to the data table that contains a formula for the probability of survival at the observed time.

**Save Cox Snell Residual Formula**  Saves a column to the data table that contains a formula for the Cox-Snell residuals. The Cox-Snell residuals are strictly positive. See Meeker and Escobar (1998, sec. 17.6.1) for a discussion of Cox-Snell residuals.

**Save Martingale Residual Formula**  Saves a column to the data table that contains a formula for the martingale residuals. The martingale residual is defined as the difference between the observed number of events for an individual and a conditionally expected number of events. The martingale residuals have a mean of zero and range between negative infinity and 1. See Fleming and Harrington (1991).

**Save Linear Predictor**  Saves a column to the data table that contains a formula for the product of the design matrix and the vector of parameter estimates. This is commonly referred to as $X\beta$. The formula does not contain zeroed terms.

**Remove Fit**  Removes the report for the fit.
**Statistical Details for the Generalized Regression Personality**

- “Statistical Details for Estimation Methods”
- “Statistical Details for Advanced Controls”
- “Statistical Details for Distributions”

**Statistical Details for Estimation Methods**

Penalized regression methods introduce bias to the regression coefficients by penalizing them.

**Ridge Regression**

An \( l_2 \) penalty is applied to the regression coefficients during ridge regression. Ridge regression coefficient estimates are given by the following:

\[
\hat{\beta}_{ridge} = \arg\min_{\beta} \left\{ \sum_{i=1}^{N} -\text{LogLikelihood}(\beta; y_i) + \frac{\lambda}{2} \sum_{j=1}^{p} \beta_j^2 \right\},
\]

where \( \sum_{j=1}^{p} \beta_j^2 \) is the \( l_2 \) penalty, \( \lambda \) is the tuning parameter, \( N \) is the number of rows, and \( p \) is the number of variables.

**Dantzig Selector**

An \( l_{\infty} \) penalty is applied to the regression coefficients during Dantzig Selector. Coefficient estimates for the Dantzig Selector satisfy the following criterion:

\[
\min_{\beta} \left\| X^T (y - X\beta) \right\|_{\infty} \quad \text{subject to} \quad \| \beta \|_1 \leq t
\]
where \( \|v\|_\infty \) denotes the \( l_\infty \) norm, which is the maximum absolute value of the components of the vector \( v \).

**Lasso Regression**

An \( l_1 \) penalty is applied to the regression coefficients during Lasso. Coefficient estimates for the Lasso are given by the following:

\[
\hat{\beta}^{lasso} = \arg\min_{\beta} \left\{ \frac{1}{2} \sum_{i=1}^{N} -\text{LogLikelihood}(\beta; y_i) + \lambda \sum_{j=1}^{p} |\beta_j| \right\},
\]

where \( \sum_{j=1}^{p} |\beta_j| \) is the \( l_1 \) penalty, \( \lambda \) is the tuning parameter, \( N \) is the number of rows, and \( p \) is the number of variables.

**Elastic Net**

The Elastic Net combines both \( l_1 \) and \( l_2 \) penalties. Coefficient estimates for the Elastic Net are given by the following:

\[
\hat{\beta}^{enet} = \arg\min_{\beta} \left\{ \sum_{i=1}^{N} -\text{LogLikelihood}(\beta; y_i) + \lambda \sum_{j=1}^{p} \left( \alpha |\beta_j| + \frac{(1-\alpha)}{2} \beta_j^2 \right) \right\},
\]

This is the notation used in the equation:

- \( \sum_{j=1}^{p} |\beta_j| \) is the \( l_1 \) penalty
- \( \sum_{j=1}^{p} \beta_j^2 \) is the \( l_2 \) penalty
- \( \lambda \) is the tuning parameter
- \( \alpha \) is a parameter that determines the mix of the \( l_1 \) and \( l_2 \) penalties
- \( N \) is the number of rows
- \( p \) is the number of variables

**Tip:** There are two sample scripts that illustrate the shrinkage effect of varying \( \alpha \) and \( \lambda \) in the Elastic Net for a single predictor. Select **Help > Sample Data**, click **Open the Sample Scripts Directory**, and select demoElasticNetAlphaLambda.jsl or demoElasticNetAlphaLambda2.jsl. Each script contains a description of how to use it and what it illustrates.
Adaptive Methods

The adaptive Lasso method uses weighted penalties to provide consistent estimates of coefficients. The weighted form of the $l_1$ penalty is

$$
\sum_{j=1}^{p} \left| \frac{\hat{\beta}_j}{\tilde{\beta}_j} \right|
$$

where $\tilde{\beta}_j$ is the MLE when the MLE exists. If the MLE does not exist and the response distribution is normal, estimation is done using least squares and $\tilde{\beta}_j$ is the solution obtained using a generalized inverse. If the response distribution is not normal, $\tilde{\beta}_j$ is the ridge solution.

For the adaptive Lasso, this weighted form of the $l_1$ penalty is used in determining the $\hat{\beta}_{lasso}$ coefficients.

The adaptive Elastic Net uses this weighted form of the $l_1$ penalty and also imposes a weighted form of the $l_2$ penalty. The weighted form of the $l_2$ penalty for the adaptive Elastic Net is

$$
\sum_{j=1}^{p} \left( \frac{\hat{\beta}_j}{\tilde{\beta}_j} \right)^2
$$

where $\tilde{\beta}_j$ is the MLE when the MLE exists. If the MLE does not exist and the response distribution is normal, estimation is done using least squares and $\tilde{\beta}_j$ is the solution obtained using a generalized inverse. If the response distribution is not normal, $\tilde{\beta}_j$ is the ridge solution.

Statistical Details for Advanced Controls

Grid

The tuning parameters for ridge regression and the Lasso that best minimize the penalized likelihood are found by searching a grid of tuning parameter values. This grid of values lies between a lower and an upper bound for the tuning parameter. You can specify the number of grid points under Advanced Controls.

The lower bound is zero except in special cases where it is set to 0.0001. See “Tuning Parameter” on page 307. When the lower bound for the tuning parameter is zero, the solution is unpenalized and the coefficients are the MLEs. The upper bound is the smallest value for which all of the non-intercept terms are zero.

The grid of values between the lower and upper bounds is iteratively searched to determine the best value of the tuning parameter. The grid of possible tuning parameters can be set up in three different scales: linear, log, and square root. The default grid scale is square root.
In some cases, there is a large gap between the unpenalized estimates and the previous step. This large gap can distort the solution path. The log scale focuses its search on small tuning parameter values with few large values, whereas the linear scale evenly disperses the search from the minimum to the maximum value. The square root scale is a compromise between the other two scales. Figure 6.7 shows the different grid scales.

**Figure 6.7 Options for Tuning Parameter Grid Scale**

![Graph showing Grid Scale vs. Tuning Parameter]

---

**Statistical Details for Distributions**

The distributions fit by the Generalized Regression personality are given below in terms of the parameters used in model fitting. Although it is not specifically stated as part of their descriptions, the Generalized Regression personality enables you to specify non-integer values for the discrete distributions.

**Continuous Distributions**

**Normal Distribution**

\[ f(y | \mu, \sigma) = \frac{1}{\sigma \sqrt{2\pi}} \exp\left[-\frac{1}{2\sigma^2}(y - \mu)^2\right], \quad -\infty < y < \infty \]

\[ E(Y) = \mu \]
\[ \text{Var}(Y) = \sigma^2 \]

**Cauchy Distribution**

\[ f(y|\mu, \sigma) = \left\{ \pi \sigma \left[ 1 + \left( \frac{y - \mu}{\sigma} \right)^2 \right] \right\}^{-1}, -\infty < y < \infty \]

\[ E(Y) = \text{undefined} \]
\[ \text{Var}(Y) = \text{undefined} \]

**t(5) Distribution**

\[ f(y|\mu, \sigma) = \frac{\Gamma\left(\frac{v+1}{2}\right)}{\sqrt{\pi v \sigma^2}} \frac{1}{\sqrt{\pi \sigma^2}} \left[ 1 + \left( \frac{x - \mu}{\sigma} \right)^2 \right]^{-\frac{v+1}{2}}, -\infty < y < \infty, \ v = 5 \]

\[ E(Y) = \mu \]
\[ \text{Var}(Y) = \sigma^2 \frac{v}{v-2} \]

**Exponential Distribution**

\[ f(y|\theta) = \frac{1}{\mu} \exp\left[ -\frac{y}{\mu} \right], y > 0 \]

\[ E(Y) = \mu \]
\[ \text{Var}(Y) = \mu^2 \]

**Gamma Distribution**

\[ f(y|\mu, \sigma) = \frac{\left(\frac{\mu}{\sigma}\right)^{-1} \exp\left[ -\frac{y}{\sigma} \right]}{\Gamma\left[ \frac{\mu}{\sigma} \right] \sigma^{\mu/\sigma}}, y > 0 \]

\[ E(Y) = \mu \]
\[ \text{Var}(Y) = \mu \sigma \]

**Weibull Distribution**

\[ f(y|\mu, \sigma) = \frac{1}{\gamma \sigma} \exp\left[ -\frac{(y - \mu)}{\sigma} \right] \exp\left[ -\exp\left[ -\frac{(y - \mu)}{\sigma} \right] \right], y > 0 \]
E(Y) = \exp(\mu)\Gamma[1 + \sigma]

Var(Y) = \exp(2\mu)\{\Gamma[1 + 2\sigma] - (\Gamma[1 + \sigma])^2\}

**LogNormal Distribution**

\[ f(y|\mu, \sigma) = \frac{1}{y\sigma\sqrt{2\pi}}\exp\left\{-\frac{1}{2\sigma^2}([\log(y) - \mu]^2)\right\}, \ y > 0 \]

E(Y) = \exp(\mu + \frac{\sigma^2}{2})

Var(Y) = [\exp(\sigma^2) - 1]\exp(2\mu + \sigma^2)

**Beta Distribution**

\[ f(y|\mu, \sigma) = \frac{\Gamma[1/\sigma]}{\Gamma[\mu/\sigma]\Gamma[(1 - \mu)/\sigma]}y^{\mu/\sigma - 1}(1-y)^{(1-\mu)/\sigma - 1}, \ y \in (0, 1) \]

E(Y) = \mu

Var(Y) = \mu(1 - \mu)\frac{\sigma}{\sigma + 1}

**Discrete Distributions**

**Binomial Distribution**

\[ f(y|n, p) = \binom{n}{y}p^y(1-p)^{n-y}, \ y = 0, 1, 2, \ldots, n \]

E(Y) = np

Var(Y) = np(1-p)

**Beta Binomial Distribution**

\[ f(y|n, p, \delta) = \binom{n}{y}\frac{\Gamma\left[\frac{1}{\delta} - 1\right]\Gamma\left[y + p\left(\frac{1}{\delta} - 1\right)\right]\Gamma\left[n - y + (1-p)\left(\frac{1}{\delta} - 1\right)\right]}{\Gamma\left[p\left(\frac{1}{\delta} - 1\right)\right]\Gamma\left(1-p\left(\frac{1}{\delta} - 1\right)\right]\Gamma\left[n - 1 + \frac{1}{\delta}\right]}, \ y = 0, 1, 2, \ldots, n \]

E(Y) = np

Var(Y) = np(1-p)[1 + (n-1)\delta]
Poisson Distribution

\[ f(y|\lambda) = \frac{\lambda^y}{y!} \exp(-\lambda), \ y = 0, 1, 2, \ldots \]

\[ E(Y) = \lambda \]

\[ Var(Y) = \lambda \]

Negative Binomial Distribution

\[ f(y|\mu, \sigma) = \frac{\Gamma[y + (1/\sigma)]}{\Gamma[y + 1] \Gamma[1/\sigma]} \left( \frac{(\mu \sigma)^y}{(1 + \mu \sigma)^{y + (1/\sigma)}} \right), \ y = 0, 1, 2, \ldots \]

\[ E(Y) = \mu \]

\[ Var(Y) = \mu + \sigma \mu^2 \]

Zero-Inflated Distributions

Zero-Inflated Binomial Distribution

\[ f(y|n, p, \pi) = \begin{cases} 
\pi + (1 - \pi)(1 - p)^n, \text{ for } y = 0 \\
(1 - \pi) \binom{n}{y} p^y (1 - p)^{n - y}, \text{ for } y = 1, 2, \ldots, n 
\end{cases} \]

\[ E(Y) = np(1 - \pi) \]

\[ Var(Y) = (1 - \pi)np(1 - p) + n^2 p^2 (1 - \pi)^2 \]

Zero-Inflated Beta Binomial Distribution

\[ f(y|n, p, \delta, \pi) = \begin{cases} 
\pi + (1 - \pi) \frac{\Gamma\left[\frac{1}{\delta} - 1\right] \Gamma\left[p\left(\frac{1}{\delta} - 1\right)\right] \Gamma\left[n + (1 - p)\left(\frac{1}{\delta} - 1\right)\right]}{\Gamma\left[p\left(\frac{1}{\delta} - 1\right)\right] \Gamma\left[(1 - p)\left(\frac{1}{\delta} - 1\right)\right] \Gamma\left[n - 1 + \frac{1}{\delta}\right]}, \text{ for } y = 0 \\
(1 - \pi) \binom{n}{y} \frac{\Gamma\left[\frac{1}{\delta} - 1\right] \Gamma\left[y + p\left(\frac{1}{\delta} - 1\right)\right] \Gamma\left[n - y + (1 - p)\left(\frac{1}{\delta} - 1\right)\right]}{\Gamma\left[p\left(\frac{1}{\delta} - 1\right)\right] \Gamma\left[(1 - p)\left(\frac{1}{\delta} - 1\right)\right] \Gamma\left[n - 1 + \frac{1}{\delta}\right]}, \text{ for } y = 1, 2, \ldots, n 
\end{cases} \]

\[ E(Y) = np(1 - \pi) \]
\[ Var(Y) = (1 - \pi)np\{1 + (1 - p)[1 + (n - 1)\delta]\} - [np(1 - \pi)]^2 \]

**Zero-Inflated Poisson Distribution**

\[ f(y|\lambda, \pi) = \begin{cases} 
\pi + (1 - \pi)\exp[-\lambda], & \text{for } y = 0 \\
(1 - \pi)\frac{\lambda^y}{y!}\exp[-\lambda], & \text{for } y = 1, 2, \ldots
\end{cases} \]

\[ E(Y) = (1 - \pi)/\lambda \]
\[ Var(Y) = \lambda(1 - \pi)(1 + \lambda\pi) \]

**Zero-Inflated Negative Binomial Distribution**

\[ f(y|\mu, \sigma, \pi) = \begin{cases} 
\pi + (1 - \pi)(1 + \mu\sigma)^{-1/\sigma}, & \text{for } y = 0 \\
(1 - \pi)\frac{\Gamma[y + (1/\sigma)]}{\Gamma[y + 1]\Gamma[1/\sigma]}\left[\frac{(\mu\sigma)^y}{(1 + \mu\sigma)^{y + (1/\sigma)}}\right], & \text{for } y = 1, 2, \ldots
\end{cases} \]

\[ E(Y) = (1 - \pi)/\mu \]
\[ Var(Y) = \mu(1 - \pi)[1 + \mu(\sigma + \pi)] \]

**Zero-Inflated Gamma Distribution**

\[ f(y|\mu, \sigma, \pi) = \begin{cases} 
\pi, & \text{for } y = 0 \\
(1 - \pi)\frac{\exp(-y/\sigma)}{\Gamma[\mu/\sigma]\sigma^{\mu/\sigma}y^{1-\mu/\sigma}}, & \text{for } y > 0
\end{cases} \]

\[ E(Y) = \mu(1 - \mu) \]
\[ Var(Y) = \mu(1 - \pi)(\sigma + \mu) - (1 - \pi)^2\mu^2 \]
Generalized Regression Models
Statistical Details for the Generalized Regression Personality

Chapter 6
Fitting Linear Models
This chapter provides examples with instructional material for several models fit using the Generalized Regression platform.

Poisson Generalized Regression Example

The Liver Cancer.jmp sample data table contains liver cancer Node Count values for 136 patients. It also includes measurements on six potentially related variables: BMI, Age, Time, Markers, Hepatitis, and Jaundice. These variables are described in the Notes column property in each column of the data table. To view the Notes column property, right-click a column name, select Column Info, and select Notes under Column Properties.

This example develops a prediction model for Node Count using the six predictors. Node Count is modeled using a Poisson distribution.

1. Select Help > Sample Data Library and open Liver Cancer.jmp.
2. Select Analyze > Fit Model.
3. Select Node Count from the Select Columns list and click Y.
4. Select BMI through Jaundice and click Macros > Factorial to Degree.
   This adds all terms up to degree 2 (the default in the Degree box) to the model.
5. Select Validation from the Select Columns list and click Validation.
6. From the Personality list, select Generalized Regression.
7. From the Distribution list, select Poisson.
8. Click Run.

The Generalized Regression report that appears contains a Model Comparison report, a Model Launch control panel, and a Poisson Maximum Likelihood with Validation Column report. Note that the default estimation method is the Lasso.

9. Select the Adaptive box.
10. Click Go.

11. Click the red triangle next to Poisson Adaptive Lasso with Validation Column and select Select Nonzero Terms.

The Solution Path is shown in Figure 7.1. The paths for terms that have nonzero coefficients are highlighted. Think of the solution paths as moving from right to left across the plot, as the solutions shrink farther from the MLE. A number of terms have paths that shrink them to zero fairly early.

The vertical axis in the Solution Path Plot represents the values of the parameter estimates for the standardized predictors. The vertical red line indicates their values at the optimal shrinkage, as determined by cross validation. At this point, 11 terms have nonzero coefficients. Notice that the vertical red line indicates the minimum Scaled −LogLikelihood value in the Validation set.
The Parameter Estimates for Original Predictors report (Figure 7.2) shows the parameter estimates for the uncentered and unscaled data. The 11 terms with nonzero parameter estimates are highlighted. These include interaction effects. In the data table, all six predictor columns are selected because every predictor column appears in a term that has a nonzero coefficient.

In the Effect Tests report, the 10 effects with zero coefficient estimates are designated as Removed. The Effect Tests report indicates that only one effect is significant at the 0.05 level: the Age*Markers interaction.

Fitting Linear Models

Binomial Generalized Regression Example

This example shows how to develop a prediction model for the binomial response, Severity, in the Liver Cancer.jmp sample data table.

1. Select Help > Sample Data Library and open Liver Cancer.jmp.
2. Select Analyze > Fit Model.
3. Select Severity from the Select Columns list and click Y.
4. Select BMI through Jaundice and click Macros > Factorial to Degree.
   All terms up to degree 2 (the default in the Degree box) are added to the model.
5. From the Personality list, select Generalized Regression.
   The Distribution list automatically shows the Binomial distribution. This is the only distribution available when Y is binary and has a Nominal modeling type.
6. Click Run.
   The Generalized Regression report that appears contains a Model Comparison report, a Model Launch control panel, and a Logistic Regression report. Note that the default estimation method is the Lasso.
7. Select Elastic Net as the Estimation Method.
8. Select the Adaptive box.
9. Click Go.
   A Binomial Adaptive Elastic Net with AICc Validation report appears. The Solution Path is shown in Figure 7.3.
The paths for terms that have nonzero coefficients are shown in blue. The optimal parameter values are substantially shrunken away from the MLE. The Validation Plot to the right indicates that several models can be considered as good as the best model. To view those models, slide the vertical red bar around in the region where the black line is in the green area.

10. Click the red triangle next to Binomial Adaptive Elastic Net with AICc Validation and select the **Select Zeroed Terms** option.

The 16 terms that have coefficient estimates of zero are highlighted in the Parameter Estimates for Original Predictors report. The Effect Tests report designates these terms as Removed.

The Effect Tests report also shows that there are no significant terms at the 0.05 level. However, the **Time**\(\times\)Markers interaction has a small \(p\)-value of 0.0626 and the Time effect has a small \(p\)-value of 0.1458.

11. Click the red triangle next to Binomial Adaptive Elastic Net with AICc Validation and select **Profiler > Profiler**.

Examine the Prediction Profiler to see how Time and the Time\(\times\)Markers interaction affect Severity.
Chapter 7
Fitting Linear Models

Generalized Regression Examples
Zero-Inflated Poisson Regression Example

Note: The predictor Hepatitis is not shown in the profiler because it does not appear in any active (nonzero) terms. Because Markers and Jaundice appear in active interaction terms, they appear in the profiler even though, as main effects, they are not active.

12. Move the red dashed line for Time from left to right to see its interaction with Markers (Figure 7.4 and Figure 7.5). For patients who enter the study with small values of Time since diagnosis, Markers have little impact on Severity. But for patients who enter the study having been diagnosed for a longer time, Markers are important. For those patients, normal markers suggest a lower probability of high Severity.

Figure 7.5 Profiler for Probability That Severity = High, Time High

Zero-Inflated Poisson Regression Example

The Fishing.jmp sample data table contains fictional data for a study of various factors that affect the number of fish caught by groups visiting a park. The data table contains 250 responses from families or groups of traveling companions. This example models the number of Fish Caught as a function of Live Bait, Fishing Poles, Camper, People, and Children. These variables are described in the Notes column property in each column of the data table. To view the Notes column property, right-click a column name, select Column Info, and select Notes under Column Properties.

The data table contains a hidden column called Fished. During data collection, it was never determined whether anyone in the group had actually fished. However, the Fished column is included in the table to emphasize the point that catching zero fish can happen in one of two ways: Either no one in the group fished, or everyone who fished in the group was unlucky.

Therefore, zero responses can come from two sources. To address this issue, you can fit a zero-inflated distribution. Because a Poisson distribution is appropriate for the count data resulting from people who fished, you fit a zero-inflated Poisson distribution.

1. Select Help > Sample Data Library and open Fishing.jmp.
2. Select Analyze > Fit Model.
3. Select Fish Caught from the Select Columns list and click Y.
4. Select Live Bait through Children and click **Macros > Factorial to Degree**. Terms up to degree 2 (the default in the **Degree** box) are added to the model.

5. Select Validation from the Select Columns list and click **Validation**.

6. From the Personality list, select **Generalized Regression**.

7. From the Distribution list, select **ZI Poisson**.

8. Click **Run**.

   The Generalized Regression report that appears contains a Model Comparison report, a Model Launch control panel, and a ZI Poisson Maximum Likelihood with Validation Column report. Note that the default estimation method is the Lasso.

9. From the Estimation Method List, select **Elastic Net**.

10. Click **Go**.

    A ZI Poisson Elastic Net with Validation Column report appears. The Solution Path, the Parameter Estimates for Original Predictors report, and the Effect Tests report indicate that one term is zeroed. The Zero Inflation parameter, whose estimate is shown on the last line of both Parameter Estimates reports, is highly significant. This indicates that some of the variation in the response, Fish Caught, might be due to the fact that some groups did not fish.

</table>

The Effect Tests report indicates that four terms are significant at the 0.05 level: Live Bait, Fishing Poles, Fishing Poles*Camper, and Fishing Poles*Children.

11. Click the red triangle next to ZI Poisson Elastic Net with Validation Column and select **Profilers > Profiler**.
12. Click the Prediction Profiler red triangle and select **Optimization and Desirability > Desirability Functions**.

A function is imposed on the response, which indicates that maximizing the number of Fish Caught is desirable. For more information about desirability functions, see *Profilers*.

13. Click the Prediction Profiler red triangle and select **Optimization and Desirability > Maximize Desirability**.

**Figure 7.7** Prediction Profiler with Fish Caught Maximized

You can vary the settings of the predictors to see the impact of the significant effects: Live Bait, Fishing Poles, Fishing Poles*Camper, and Fishing Poles*Children. For example, Live Bait is associated with more fish; a Camper tends to bring more fishing poles than someone who is not camping and therefore catches more fish.

14. Click the red triangle next to ZI Poisson Elastic Net with Validation Column and select **Save Columns > Save Prediction Formula** and **Save Columns > Save Variance Formula**.

Two columns are added to the data table: Fish Caught Prediction Formula and Fish Caught Variance.

15. In the data table, right-click either column heading and select **Formula** to view the formula. Alternatively, click the plus sign to the right of the column name in the Columns panel. Note the appearance of the estimated zero-inflation parameter, 0.781522155, in both of these formulas.
Generalized Regression Example for Wide Data

When there are more predictors than there are observations, traditional regression methods are not practical. Regression methods that incorporate variable selection enable you to fit a regression model in these situations. In this example, you compare three models with varying degrees of variable selection. The three models are all located within the green zone on the Validation Plot, so there is strong evidence that any of these models are comparable to the best model.

The Prostate Cancer.jmp sample data table contains results of serum samples collected from 165 men, approximately half of whom had prostate cancer. There are 667 proteins measured in the serum samples.

1. Select Help > Sample Data Library and open Prostate Cancer.jmp.
2. Select Analyze > Fit Model.
3. Select Status from the Select Columns list and click Y.
   Because this is a Nominal response column, the Personality changes to Nominal Logistic and the Target Level option appears. The default value for this option is CCD, because that is the value specified in the Target Level column property in the data table.
4. From the Personality list, select Generalized Regression.
   The Distribution list automatically shows the Binomial distribution. This is the only distribution available when Y is binary and has a Nominal modeling type.
5. Select the Proteins column group from the Select Columns list and click Add.
   This adds all 667 columns in the column group to the model.
6. Click Run.
   The Generalized Regression report that appears contains a Model Launch control panel. There is no initial Logistic Regression model fit because the number of predictors is greater than the number of observations.
7. Select Elastic Net as the Estimation Method.
8. Click the gray disclosure icon next to Advanced Controls.
Figure 7.8 Advanced Controls

9. Select **Smallest in Green Zone** as the Initial Displayed Solution.
10. Click **Go**.

Figure 7.9 Smallest in Green Zone Model

The Solution Path shows the smallest model that is considered comparable to the minimum AICc model, where smallest model means the one with the fewest parameters.

11. Click the gray disclosure icon next to Binomial Elastic Net with AICc Validation.
12. Click the gray disclosure icon next to Model Launch.
13. Select **Best Fit** as the Initial Displayed Solution.
14. Click **Go**.
Figure 7.10  Best Fit Model

The Solution Path shows the best fit model, where best fit means the one with the minimum AICc value.

15. Click the gray disclosure icon next to Binomial Elastic Net with AICc Validation.
16. Click the gray disclosure icon next to Model Launch.
17. Select **Biggest in Green Zone** as the Initial Displayed Solution.
18. Click **Go**.

Figure 7.11  Biggest in Green Zone Model

The Solution Path shows the largest model that is considered comparable to the minimum AICc model, where largest model means the one with the most parameters.

19. Click the gray disclosure icon next to Binomial Elastic Net with AICc Validation.
The Model Comparison report shows the three models. You can identify the size of each model using the Nonzero Parameters column. As the number of parameters in the models increases, the Generalized RSquare values increase. Because these models are all in the green zone, there is strong evidence that any of these models are comparable to the best model.

Generalized Regression Example for Wide Data

Chapter 7
Fitting Linear Models
The Mixed Models personality of the Fit Model platform is available only in JMP Pro.

In JMP Pro, the Fit Model platform’s Mixed Model personality fits a wide variety of linear models for continuous responses with complex covariance structures. These models include random coefficients, repeated measures, spatial data, and data with multiple correlated responses. Use the Mixed Model personality to specify linear mixed models and their covariance structures conveniently using an intuitive interface, and to fit these models using maximum likelihood methods.

The modeling results are supported by interactive visualization tools such as profilers, surface plots, and contour plots. You can use these tools to complement your understanding of the model.

Overview of the Mixed Model Personality

In JMP Pro, the Mixed Model personality lets you analyze models with complex covariance structures. The situations that can be analyzed include:

- Split plot experiments
- Random coefficients models
- Repeated measures designs
- Spatial data
- Correlated response data

Split plot experiments are experiments with two or more levels, or sizes, of experimental units resulting in multiple error terms. Such designs are often necessary when some factors are easy to vary and others are more difficult to vary. See the Design of Experiments Guide.

Random coefficients models are also known as hierarchical or multilevel models (Singer 1998; Sullivan et al. 1999). These models are used when batches or subjects are thought to differ randomly in intercept and slope. Drug stability trials in the pharmaceutical industry and individual growth studies in educational research often require random coefficient models.

Repeated measures designs, spatial data, and correlated response data share the property that observations are not independent, requiring that you model their correlation structure.

- Repeated measures designs, also known as within-subject designs, model changes in a response over time or space while allowing errors to be correlated.
- Spatial data are measurements made in two or more dimensions, typically latitude and longitude. Spatial measurements are often correlated as a function of their spatial proximity.
- Correlated response data result from making several measurements on the same experimental unit. For example, height, weight, and blood pressure readings taken on individuals in a medical study, or hardness, strength, and elasticity measured on a manufactured item, are likely to be correlated. Although these measurements can be studied individually, treating them as correlated responses can lead to useful insights.

Failure to account for correlation between observations can result in incorrect conclusions about treatment effects. However, estimating covariance structure parameters uses information in the data. The number of parameters being estimated impacts power and the Type I error rate. For this reason, you must choose covariance models judiciously. See “Repeated Measures Example” on page 387.
Example Using Mixed Model

In a study of wheat yield, 10 varieties of wheat are randomly selected from the population of varieties of hard red winter wheat adapted to dry climate conditions. These are randomly assigned to six one-acre plots of land. The preplanting moisture content of the plots could influence the germination rate and hence the eventual yield of the plots. Thus, the amount of preplanting moisture in the top 36 inches of soil is determined for each plot. You are interested in determining if the moisture content affects yield.

Because the varieties are randomly selected, the regression model for each variety is a random model selected from the population of variety models. The intercept and slope are random for each variety and might be correlated. The random coefficients are centered at the fixed effects. The fixed effects are the population intercept and the slope, which are the expected values of the population of the intercepts and slopes of the varieties. This example is taken from Littell et al. (2006, p. 320).

Fitting the model using REML in the Standard Least Squares personality lets you view the variation in intercepts and slopes (Figure 8.2). Note that the slopes do not have much variability, but the intercepts have quite a bit. The intercept and slope might be negatively correlated; varieties with lower intercepts seem to have higher slopes.

Figure 8.2 Standard Least Squares Regression

To model the correlation between the intercept and the slope, use the Mixed Models personality. You are interested in determining the population regression equation as well as variety-specific equations.

1. Select Help > Sample Data Library and open Wheat.jmp.
2. Select Analyze > Fit Model.
3. Select Yield and click Y.
   When you add this column as Y, the fitting Personality becomes Standard Least Squares.
4. Select Mixed Model from the Personality list. Alternatively, you can select the Mixed Model personality first, and then click Y to add Yield.
5. Select Moisture and click Add on the Fixed Effects tab.

Figure 8.3 Completed Fit Model Launch Window Showing Fixed Effects

7. Select Moisture and click Add.
8. Select Variety from the Select Columns list, select Moisture from the Random Effects tab, and then click Nest Random Coefficients.
Random effects are grouped by variety, and the intercept is included as a random component.

9. (Optional.) Click the Model Specification red triangle and check the setting of the **Center Polynomials** option.

   Even if the Center Polynomials option is selected, the Moisture effect will not be centered at its mean because it is involved in a random effect.

10. Click **Run**.

    The Fit Mixed report is shown in Figure 8.5. The Actual by Predicted plot shows no discrepancy in terms of model fit and underlying assumptions.

Because there are no apparent problems with the model fit, you can now interpret the statistical tests and obtain the regression equation. The effect of moisture upon yield is significant, as shown in the Fixed Effects Tests report. The estimates given in the Fixed Effects Parameter Estimates indicate that the following equation is the estimated population regression equation:

\[
Yield = 33.43 + 0.66 \times Moisture
\]

The Random Effects Covariance Parameter Estimates report gives estimates of the variance of the varieties’ intercepts, Var(Intercept), and slopes, Var(Moisture), and their covariance, Cov(Moisture, Intercept). In this case, the intercept and slope are not significantly correlated, because the confidence interval for the estimate includes zero. The report also gives an estimate of the residual variance.
Although you have an estimate of the population regression equation, you are also interested in Variety 2’s estimated yield.

11. Open the Random Coefficients report to see the estimates of the variety effects for Intercept and Moisture. These coefficients estimate how each variety differs from the population.
From the Fixed Effects Parameter Estimates and Random Coefficients reports, you obtain the following prediction equation for Variety 2:

\[
Yield = 33.433 + 0.662 \times Moisture - 2.284 - 0.067 \times Moisture
\]

\[
Yield = 31.149 + 0.595 \times Moisture
\]

Variety 2 starts with a lower yield than the population average and increases with Moisture at a slower rate than the population average.

Launch the Mixed Model Personality

Mixed Model is one of several personalities that you can select in the Fit Model launch window. This section describes how you select Mixed Model as your fitting methodology in the Fit Model launch window. Options that are specific to this selection are also covered.

Fit Model Launch Window

You can specify models with fixed effects, random effects, a repeated structure or a combination of those. The options differ based on the nature of the model that you specify.

To fit models using the mixed model personality, select Analyze > Fit Model and then select Mixed Model from the Personality list. Note that when you enter a continuous variable in the Y list before selecting a Personality, the Personality defaults to Standard Least Squares. For more information about the options in the Select Columns red triangle menu, see Using JMP.
When fitting models using the Mixed Model personality, you can allow unbounded variance components. This means that variance components that have negative estimates are not reported as zero. This option is selected by default. It should remain selected if you are interested in fixed effects, because bounding the variance estimates at zero leads to bias in the tests for fixed effects. See “Negative Variances” on page 190 in the “Standard Least Squares Models” chapter for more information about the Unbounded Variance Components option.

**Fixed Effects Tab**

Add all fixed effects on the Fixed Effects tab. Use the Add, Cross, Nest, Macros, and Attributes options as needed. For more information about these options, see the “Model Specification” chapter on page 29.

**Note:** If a continuous column is involved in a random effect, that column is not centered, even if the Center Polynomials option in the Model Specifications red triangle menu is selected.

The fixed effects for analysis of the Split Plot.jmp sample data table appear in Figure 8.7. Note that it is possible to have no fixed effects in the model. For an example, see “Spatial Example: Uniformity Trial” on page 408.

**Figure 8.7** Fit Model Launch Window Showing Completed Fixed Effects

---

**Random Effects Tab**

Specify traditional variance component models and random coefficients models using the Random Effects tab.
**Note:** If a continuous column is involved in a random effect, that column is not centered, even if the Center Polynomials option in the Model Specifications red triangle menu is selected.

**Variance Components**

For a traditional variance component model, specify terms such as random blocks, whole plot error terms, and subplot error terms using the Add, Cross, or Nest options. For more information about these options, see the “Model Specification” chapter on page 29.

Figure 8.8 shows the random effects specification for the Split Plot.jmp sample data where Carcass is a random block. “Split Plot Example” on page 402 describes the example in detail.

Figure 8.8  Fit Model Launch Window Showing Completed Random Effects Tab

**Random Coefficients**

To construct random coefficients models, use the Nest Random Coefficients button to create groups of random coefficients.

1. Select the continuous columns from the Select Columns list that are predictors.
2. Select the Random Effects tab and then Add.
3. Select these effects in the Random Effects tab. Also select the column that contains the random effect whose levels define the individual regression models. This column is essentially the subject in a random statement in SAS PROC MIXED.
4. Click the Nest Random Coefficients button.
This last step creates random intercept and random slope effects that are correlated within the levels of the random effect. The subject is nested within the other effects due to the variability among subjects. If you believed that the intercept might be fixed for all groups, you would select Intercept[<group>] & Random Coefficients(1) and then click Remove.

You can define multiple groups of random coefficients in this fashion, as in hierarchical linear models. This might be necessary when you have both a random batch effect and a random batch by treatment effect on the slope and intercept coefficients. This might also be necessary in a hierarchical linear model: when you have a random student effect and random school effect on achievement scores and students are nested within school.

Random coefficients are modeled using an unstructured covariance structure. Figure 8.9 shows the random coefficients specification for the Wheat.jmp sample data. (See also “Example Using Mixed Model” on page 360.)

Figure 8.9 Completed Fit Model Launch Window Showing Random Coefficients
**Repeated Structure Tab**

Use the Repeated Structure tab to select a covariance structure for repeated effects in the model.

**Figure 8.10** Completed Fit Model Launch Window Showing Repeated Structure Tab

![Figure 8.10](image)

**Structure**

The repeated structure is set to Residual by default. The Residual structure specifies that there is no covariance between observations, namely, the errors are independent. Besides the Residual and Unequal Variances structures, all other covariance structures model covariance between observations. For more information about the structures, see “Repeated Measures” on page 426 and “Spatial and Temporal Variability” on page 432 in the Statistical Details section.

Table 8.1 lists the covariance structures available, the requirements for using each structure, and the number of covariance parameters for the given structure. The number of observation times is denoted by $J$.

</tbody>
</table>
If you enter a Repeated or Subject column with the Residual structure, those columns are ignored. This alert appears: “Repeated columns and subject columns are ignored when the Residual covariance structure is selected.”

**Type**

When you select one of the spatial covariance structures, a Type list appears from which you select a type of spatial structure. Four Types are available: Power, Exponential, Gaussian, and Spherical. Figure 8.10 shows the Spatial Spherical selection for the Uniformity Trial.jmp sample data.

**Repeated**

Enter columns that define the repeated measures structure. The modeling types of Repeated columns depend on the covariance structure. See Table 8.1 for more information about the requirements for each repeated measures covariance structure.

**Subject**

Enter one or more columns that define the Subject. Subject columns must be categorical.

**Data Format**

The Mixed Models personality in the Fit Model platform requires that all response measurements be contained in one response column. Repeated measures data are sometimes recorded in multiple columns, where each row is a subject and the repeated measurements are recorded in separate response columns. Data that are in this format must be stacked before running the Mixed Models personality. The Cholesterol.jmp and Cholesterol Stacked.jmp sample data tables illustrate the wide format and the stacked format, respectively. Notice that each row in the wide table corresponds to one level of Patient in the stacked table.

**The Fit Mixed Report**

The Fit Mixed red triangle menu contains the following options:

**Model Reports** Produces reports that relate to the mixed model fit. These reports give estimates and tests for model parameters, as well as fit statistics. See “Model Reports” on page 372.

**Linear Combination of Variance Components** Shows a report that enables you to compute confidence intervals for linear combinations of variance components. Initially, the report contains an editable text box and a table of variance components in the model. Use the text box to label the linear combination. Enter values in the cells in the right column of the table.
to specify the linear functions for your confidence intervals. After you specify a linear combination of parameters and click Done, a table appears that contains confidence intervals for the specified linear combination.

The table contains an estimate and standard error, as well as two types of confidence intervals (Satterthwaite and Wald) and a Wald $p$-value. The Wald $p$-value corresponds to a hypothesis test that the estimate differs from zero.

**Tip:** The Satterthwaite confidence interval is restricted to positive values, so it is not recommended for cases where the specified coefficients are negative. If the estimate is negative, the Satterthwaite confidence interval cannot be constructed and is reported as missing.

**Multiple Comparisons** Opens the Multiple Comparisons dialog window where you can select one or more effects and initial comparisons. This report is available for categorical fixed effects. See “Multiple Comparisons” on page 380.

**Compare Slopes** (Available only when there is one nominal term, one continuous term, and their interaction effect for the fixed effects.) Produces a report that enables you to compare the slopes of each level of the interaction effect in an analysis of covariance (ANCOVA) model. See “Compare Slopes” on page 380.

**Inverse Prediction** For one or more values of the response, predicts values of explanatory variables. See “Inverse Prediction” on page 142 in the “Standard Least Squares Models” chapter.

**Marginal Model Inference** Produces plots based on marginal predicted values and marginal residuals. These plots display the variation due to random effects. See “Marginal Model Inference” on page 380.

**Conditional Model Inference** Produces plots based on conditional predicted values and conditional residuals. These plots display the variation that remains, once random effects are accounted for. See “Conditional Model Inference” on page 382.

**Save Columns** Contains options to save various model results as columns in the data table. See “Save Columns” on page 386.

**Model Dialog** Opens the completed Fit Model launch window for the current analysis. See “Fit Model Launch Window” on page 364.

See Using JMP for more information about the following options:

**Local Data Filter** Shows or hides the local data filter that enables you to filter the data used in a specific report.
Redo  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

Save Script  Contains options that enable you to save a script that reproduces the report to several destinations.

Save By-Group Script  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.

Model Reports

The reports available under Model Reports are determined by the type of analysis that you conduct. Several of these reports are shown by default.

Indicator Parameterization Estimates  (Available only when there are nominal columns among the fixed effects.) Displays the Indicator Function Parameterization report. This report gives parameter estimates for the fixed effects based on a model where nominal fixed effect columns are coded using indicator (SAS GLM) parameterization and are treated as continuous. Ordinal columns remain coded using the usual JMP coding scheme. The SAS GLM and JMP coding schemes are described in “The Factor Models” on page 534 in the “Statistical Details” appendix.

Caution: Standard errors, t-ratios, and other results given in the Indicator Function Parameterization report differ from those in the Parameter Estimates report. This is because the estimates are estimating different parameters.

Random Coefficients  Shows report of random coefficients. This report appears when you specify random effects in the launch window. See “Random Coefficients” on page 378.
Random Effects Predictions  Shows report of random effect predictions. This report appears when you specify random effects in the launch window. See “Random Effects Predictions” on page 378.

Fixed Effects Test  (Available only for models that contain at least one fixed effect.) Shows tests of fixed effects. This report appears when you specify fixed effects in the launch window. See “Fixed Effects Tests” on page 378.

Sequential Tests  (Available only for models that contain at least one fixed effect.) Shows the Sequential (Type 1) Tests report that contains the sums of squares as effects are added to the model sequentially. Conducts $F$ tests based on the sequential sums of squares. See “Sequential Tests” on page 379.

Fit Statistics

The Fit Statistics report gives statistics used for model comparison. For all fit statistics, smaller is better. A likelihood ratio test between two models can be performed if one model is contained within the other. If not, a cautious comparison of likelihoods can be informative. For an example, see “Fit a Spatial Structure Model” on page 408.

Description of the Fit Statistics Report uses the following notation:

- Specify the mixed model:
  \[ y = X\beta + Z\gamma + \varepsilon \]
  Here $y$ is the $n \times 1$ vector of observations, $\beta$ is a vector of fixed-effect parameters, $\gamma$ is a vector of random-effect parameters, and $\varepsilon$ is a vector of errors.

- The vectors $\gamma$ and $\varepsilon$ are assumed to have a multivariate normal distribution where
  \[
  E \begin{bmatrix} \gamma \\ \varepsilon \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}
  \]
  and
  \[
  Var \begin{bmatrix} \gamma \\ \varepsilon \end{bmatrix} = \begin{bmatrix} G & 0 \\ 0 & R \end{bmatrix}
  \]

- With these assumptions, the variance of $y$ is calculated as follows:
  \[
  V = ZGZ' + R
  \]

-2 Residual Log Likelihood  The final evaluation of twice the negative residual log-likelihood, the objective function.
Mixed Models

Chapter 8

The Fit Mixed Report

Fitting Linear Models

where

\[ r = y - X(X'V^{-1}X)^{-1}(X'V^{-1}y) \]

and \( p \) is the rank of \( X \). Use the residual likelihood only for model comparisons where the fixed effects portion of the model is identical. See “Likelihood, AICc, and BIC” on page 559 in the “Statistical Details” appendix.

-2 Log Likelihood

The evaluation of twice the negative log-likelihood function. See “Likelihood, AICc, and BIC” on page 559 in the “Statistical Details” appendix.

Use the log-likelihood for model comparisons in which the fixed, random, and repeated effects differ in any of the models.

AICc

Corrected Akaike’s Information Criterion. See “Likelihood, AICc, and BIC” on page 559 in the “Statistical Details” appendix.

BIC

Bayesian Information Criterion. See “Likelihood, AICc, and BIC” on page 559 in the “Statistical Details” appendix.

Convergence Score Test

If there are problems with model convergence, a warning message is displayed below the fit statistics. Figure 8.11 shows the warning that suggests the cause and possible solutions to the convergence issue. It also includes a test of the relative gradient at the final iteration. If this test is non-significant, the model might be correct but not fully reaching the convergence criteria. In this case, consider using the model and results with caution. See “Convergence Score Test” on page 424.
Random Effects Covariance Parameter Estimates

The Random Effects Covariance Parameter Estimates report provides details for the covariance parameters of the random effects that you specified in the model.

**Covariance Parameter**  Lists all the covariance parameters of the random effects that you specified in the model.

**Note:** This column is labeled Variance Component when the model contains only variance components.

**Subject**  Lists the subject from which the block diagonal covariance matrix was formed.

**Estimate**  Gives the estimated variance or covariance component for the effect.

**Note:** When the model is equivalent to a REML model, a row for a Total covariance parameter is added to the table. The estimate for the Total covariance component is the sum of the positive variance components only.

**Std Error**  Gives the standard error for the covariance component estimate.

**95% Lower**  Gives the lower 95% confidence limit for the covariance component. See “Confidence Intervals for Variance Components” on page 376.

**95% Upper**  Gives the upper 95% confidence limit for the covariance component. See “Confidence Intervals for Variance Components” on page 376.
**Wald p-Value**  Gives the $p$-value for the test that the covariance parameter is equal to zero. This column appears only when you have selected Unbounded Variance Components in the Fit Model launch window.

**Confidence Intervals for Variance Components**

The method used to calculate the confidence limits depends on whether you have selected Unbounded Variance Components in the Fit Model launch window. Note that the Unbounded Variance Components is selected by default.

- If Unbounded Variance Components is selected, Wald-based confidence intervals are computed. These intervals are valid asymptotically, but note that they can be unreliable with small samples. The intervals are wider, which might lead you to mistakenly believe that an estimate is not significantly different from zero.

- If Unbounded Variance Components is not selected, meaning that the parameters have a lower boundary constraint of zero, a Satterthwaite approximation is used (Satterthwaite 1946). The confidence intervals are also bounded at zero.

**Fixed Effects Parameter Estimates**

The Fixed Effects Parameter Estimates report provides details for the fixed effect parameters specified in the model. For each parameter, the report provides the following details:

- the estimate
- the standard error (Std Error)
- a $t$ test for the hypothesis that the estimate equals zero
- a 95% confidence interval on the estimate

The Fixed Effects Parameter Estimates report contains the following columns:

**Term**  Gives the model term corresponding to the estimated parameter. The first term is always the intercept, unless you selected the No Intercept option in the Fit Model launch window. Continuous columns that are part of higher order terms are centered by default. Nominal or ordinal effects appear with values of levels in brackets. See “The Factor Models” on page 534 for information about the coding of nominal and ordinal terms.

**Note:** If a continuous column is involved in a random effect, that column is not centered, even if the Center Polynomials option in the Model Specifications red triangle menu was selected.

**Estimate**  Gives the parameter estimate for each term. This is the estimate of the term’s coefficient in the model.
**Std Error**  Gives an estimate of the standard error for the parameter estimate.

**DFDen**  Gives the denominator degrees of freedom, that is, the degrees of freedom for error, for the effect test. DFDen is calculated using the Kenward-Roger first order approximation. See “The Kackar-Harville Correction” on page 435.

**t Ratio**  Tests whether the true value of the parameter is zero. The $t$ Ratio is the ratio of the estimate to its standard error. Given the usual assumptions about the model, the $t$ Ratio has a Student’s $t$ distribution under the null hypothesis.

**Prob>|t|**  Lists the $p$-value for a two-sided test of the $t$ Ratio.

**95% Lower**  Shows the lower 95% confidence limit for the parameter.

**95% Upper**  Shows the upper 95% confidence limit for the parameter.

### Repeated Effects Covariance Parameter Estimates

The Repeated Effects Covariance Parameter Estimates report provides details for the covariance parameters of the repeated effects that you specified in the model. It includes the Estimate, Standard Error, and 95% confidence bounds for each parameter. For isotropic spatial models, the covariance parameter estimates have interpretations in terms of range, nugget, and sill. See “Variogram” on page 433.

**Note:** Variances are covariances of effects with themselves.

The Repeated Effects Covariance Parameter Estimates report contains the following columns:

**Covariance Parameter**  Lists all the covariance parameters for the repeated effects in the model.

**Estimate**  Gives the estimated variance or covariance component for the effect.

**Std Error**  Gives the standard error for the variance or covariance component estimate.

**95% Lower**  Gives the lower 95% confidence limit for the covariance component. See “Confidence Intervals for Variance Components” on page 376.

**95% Upper**  Gives the upper 95% confidence limit for the covariance component. See “Confidence Intervals for Variance Components” on page 376.
Random Coefficients

For each random effect, the Mixed Models personality provides a report showing estimated coefficients and a report showing the matrix of covariance estimates. Each row of the coefficients report corresponds to one level of the random effect. The row shows all coefficient estimates associated with that level of the random effect. The random coefficient estimates are used in conjunction with fixed effect estimates to create predictions for any specific level of the random effect.

Random Effects Predictions

For each random effect in the model, this report gives an estimate known as the best linear unbiased predictor (BLUP), its standard error, degrees of freedom, and a Satterthwaite-based confidence interval.

Estimation of the standard errors requires calculation of the BLUP covariance matrix, which can be time-intensive. If the calculation time is noticeable, a progress bar appears.

Fixed Effects Tests

This report shows a significance test for each fixed effect in the model. The test for a given effect tests the null hypothesis that all parameters associated with that effect are zero. An effect might have only one parameter as for a single continuous explanatory variable. In this case, the test is equivalent to the $t$ test for that term in the Fixed Effects Parameter Estimates report. A nominal or ordinal effect can have several associated parameters, based on its number of levels. The effect test for such an effect tests whether all of the associated parameters are zero.

The Fixed Effects Tests report contains the following columns:

Source  Lists the fixed effects in the model.

Nparm  Shows the number of parameters associated with the effect. A continuous effect has one parameter. The number of parameters for a nominal or ordinal effect is one less than its number of levels. The number of parameters for a crossed effect is the product of the number of parameters for each individual effect.

DFNum  Shows the numerator degrees of freedom for the effect test.

DFDen  Shows the denominator degrees of freedom for the effect test (the degrees of freedom for error). DFDen is calculated using the Kenward-Roger first order approximation. See “The Kackar-Harville Correction” on page 435.

F Ratio  Gives the computed $F$ ratio for testing that the effect is zero.
Prob > F  Gives the \( p \)-value for the effect test.

**Sequential Tests**

This report shows sequential (type I) tests of the fixed effects. The report contains the sums of squares as effects are added to the model sequentially. The order of entry is defined by the order of effects as they appear in the Fit Model launch window’s Construct Model Effects list.

The sums of squares that form the basis for sequential tests are also called *Type I Sums of Squares*. They are computed by fitting models in steps following the specified entry order of effects. Consider a specific effect. Compute the model sum of squares for a model containing all effects entered *prior* to that effect. Then compute the model sum of squares for a model containing those effects *and* the specified effect. The sequential sum of squares for the specified effect is the increase in the model sum of squares.

Sequential tests are considered appropriate in the following situations:

- balanced analysis of variance models specified in proper sequence (that is, two-way interactions follow main effects in the effects list, and so on)
- purely nested models specified in the proper sequence
- polynomial regression models specified in the proper sequence.

The Sequential (Type I) Tests report contains the following columns:

**Source**  Lists the fixed effects in the model.

**Nparm**  Shows the number of parameters associated with the effect. A continuous effect has one parameter. The number of parameters for a nominal or ordinal effect is one less than its number of levels. The number of parameters for a crossed effect is the product of the number of parameters for each individual effect.

**DFNum**  Shows the numerator degrees of freedom for the effect test.

**DFDen**  Shows the denominator degrees of freedom for the effect test (the degrees of freedom for error). DFDen is calculated using the Kenward-Roger first order approximation. See “The Kackar-Harville Correction” on page 435.

**F Ratio**  Gives the computed \( F \) ratio for testing that the effect is zero.

**Prob > F**  Gives the \( p \)-value for the effect test.
Multiple Comparisons

The Multiple Comparisons option provides various methods for comparing least squares means of main effects and interaction effects. For more information about the multiple comparisons options, see “Multiple Comparisons” on page 126 in the “Standard Least Squares Models” chapter. For mixed model examples, see “Compare All Treatments in June” on page 399 and “Split Plot Example” on page 402.

Only the fixed effect portion of the model is used in the multiple comparisons. The Multiple Comparisons report shows estimates of the least squares means, standard error, a t test of no effect, and a 95% confidence interval. This report is followed by the multiple comparisons test that you select. The All Pairwise Comparisons report provides equivalence tests.

Compare Slopes

The Compare Slopes option appears when there is one nominal term, one continuous term, and their interaction effect for the fixed effects. This option produces a report that enables you to compare the slopes in an analysis of covariance (ANCOVA) model. The report compares the slopes of each level of the interaction effect to the overall slope. The comparison uses analysis of means (ANOM) with the overall average. For more information about the analysis of means (ANOM) report, see “Comparisons with Overall Average” on page 131 in the “Standard Least Squares Models” chapter.

The overall average slope is a weighted average of the slopes, where the weights are inversely proportional to the variances of the slope estimates. These variances are the squared values of the Std Error column in the Differences from Overall Average Slope table.

Marginal Model Inference

The marginal model plots are based on marginal predicted values and marginal residuals.

- **Actual by Predicted Plot**  Plots actual values versus values predicted by the model, but without accounting for the random effects. The Actual by Predicted Plot appears by default. See “Actual by Predicted Plot” on page 381.

- **Residual Plots**  Provides residual plots that assess model fit, without accounting for the random effects. See “Residual Plots” on page 381.

- **Profiler, Contour Profiler, Mixture Profiler, Surface Profiler**  Provides profilers to examine the relationship between the response and the model terms, without accounting for random effects. See “Profilers” on page 381.
Actual by Predicted Plot

The Actual by Predicted plot appears by default. It provides a visual assessment of model fit that reflects variation due to random effects. It plots the observed values of \( Y \) against the marginal predicted values of \( Y \). These are the predicted values obtained if you select Save Columns > Prediction Formula.

Denote the linear mixed model by \( E[Y | \gamma] = X\beta + Z\gamma \). Here \( \beta \) is the vector of fixed effect coefficients and \( \gamma \) is the vector of random effect coefficients. The marginal predictions are the predictions from the fixed effects part of the predictive model, given by \( X\hat{\beta} \).

Residual Plots

Marginal residuals reflect the prediction error based only on the fit of fixed effects. Marginal residuals are the differences between actual values and the predicted values obtained if you select Save Columns > Prediction Formula.

Denote the linear mixed model by \( E[Y | \gamma] = X\beta + Z\gamma \). Here \( \beta \) is the vector of fixed effect coefficients and \( \gamma \) is the vector of random effect coefficients. The marginal residuals are the residuals from the fixed effects part of the predictive model:

\[
r = Y - X\hat{\beta}
\]

The Residual Plots option provides three visual methods to assess model fit:

- **Residual by Predicted Plot**  Shows the residuals plotted against the predicted values of \( Y \). You typically want to see the residual values scattered randomly about zero.

- **Residual Quantile Plot**  Shows the quantiles of the residuals plotted against the quantiles of a standard normal distribution. Also shown is a bar chart of the residuals. If the residuals are normally distributed, the points on the normal quantile plot should approximately fall along the red diagonal line. This type of plot is also called a quantile-quantile plot, or Q-Q plot. The normal quantile plot also shows Lilliefors confidence bounds (Conover 1999).

- **Residual by Row Plot**  Shows residuals plotted against row numbers. This plot can help you detect patterns that result from the row ordering of the observations.

Profilers

The plots in the Marginal Model Profiler are based on marginal predicted values. These are the predicted values obtained if you select Save Columns > Prediction Formula.

Denote the linear mixed model by \( E[Y | \gamma] = X\beta + Z\gamma \). Here \( \beta \) is the vector of fixed effect coefficients and \( \gamma \) is the vector of random effect coefficients. The marginal predictions are the predictions from the fixed effects part of the predictive model, given by \( X\hat{\beta} \).
Note: Marginal model profiler plots show predictions for distinct settings of the fixed effects only. The Profiler shows only cells corresponding to fixed effects. In other profilers, where random effects can be displayed, only the settings of the fixed effects determine the predicted values.

Four types of profilers are provided:

- Profiler
- Contour Profiler
- Mixture Profiler
- Surface Profiler

Options that are appropriate for the model that you are fitting are enabled. See Figure 8.21 for an example of a profiler. See Figure 8.42 for an example of a Surface Profiler. For more information about the surface profiler, see Profilers.

Conditional Model Inference

The conditional model diagnostic plots are based on conditional residuals. Conditional residuals reflect the prediction error once both fixed and random effects have been fit.

Actual by Conditional Predicted Plot  Plots actual values versus values predicted by the model, accounting for the random effects. When there are random effects, the Actual by Conditional Predicted Plot appears by default. See “Actual by Conditional Predicted Plot” on page 383.

Conditional Residual Plots  Provides residual plots that assess model fit, accounting for the random effects. See “Conditional Residual Plots” on page 383.

Conditional Profiler, Conditional Contour Profiler, Conditional Mixture Profiler, Conditional Surface Profiler  Provides profilers to examine the relationship between the response and the model terms, accounting for random effects. See “Conditional Profilers” on page 383.

Variogram  Provides a variogram plot that shows the change in covariance as the distance between observations increases. When the Residual structure is selected, you can select the columns to use as temporal or spatial coordinates. See “Variogram” on page 384.
Actual by Conditional Predicted Plot

The Actual by Conditional Predicted plot appears by default. It provides a visual assessment of model fit that accounts for variation due to random effects. It plots the observed values of $Y$ against the conditional predicted values of $Y$. These are the predicted values obtained if you select Save Columns > Conditional Prediction Formula.

Denote the linear mixed model by $E[Y|\gamma] = X\beta + Z\gamma$. Here $\beta$ is the vector of fixed effect coefficients and $\gamma$ is the vector of random effect coefficients. The *conditional predictions* are the predictions obtained from the model given by $X\hat{\beta} + Z\hat{\gamma}$.

Conditional Residual Plots

Conditional residuals reflect the prediction error based on fitting both fixed and random effects. Conditional residuals are the differences between actual values and the conditional predicted values obtained if you select Save Columns > Conditional Prediction Formula.

Denote the linear mixed model by $E[Y|\gamma] = X\beta + Z\gamma$. Here $\beta$ is the vector of fixed effect coefficients and $\gamma$ is the vector of random effect coefficients. The *conditional residuals* are calculated as follows:

$$ r = Y - (X\hat{\beta} + Z\hat{\gamma}) $$

The Conditional Residual Plots option provides three visual methods to assess model fit:

- **Conditional Residual by Predicted Plot**  Shows the conditional residuals plotted against the conditional predicted values of $Y$. You typically want to see the conditional residual scattered randomly about zero.

- **Conditional Residual Quantile Plot**  Shows the quantiles of the conditional residuals plotted against the quantiles of a standard normal distribution. Also shown is a bar chart of the conditional residuals. If the conditional residuals are normally distributed, the points on the normal quantile plot should approximately fall along the red diagonal line. This type of plot is also called a quantile-quantile plot, or Q-Q plot. The normal quantile plot also shows Lilliefors confidence bounds (Conover 1999).

- **Conditional Residual by Row Plot**  Shows conditional residuals plotted against row numbers. This plot can help you detect patterns that result from the row ordering of the observations.

Conditional Profilers

The conditional model profiler plots are based on conditional predicted values. These are the predicted values obtained if you select Save Columns > Conditional Prediction Formula.
Denote the linear mixed model by $E[Y|\gamma] = X\beta + Z\gamma$. Here $\beta$ is the vector of fixed effect coefficients and $\gamma$ is the vector of random effect coefficients. The conditional predictions are the predictions obtained from the model given by $X\hat{\beta} + Z\hat{\gamma}$.

Four types of profilers are provided:

- Conditional Profiler
- Conditional Contour Profiler
- Conditional Mixture Profiler
- Conditional Surface Profiler

Options that are appropriate for the model that you are fitting are enabled. See Figure 8.21 for an example of a Profiler. See Figure 8.42 for an example of a Surface Profiler. For more information about the profiler, see Profilers.

### Variogram

A Variogram plot describes the spatial or temporal correlation of observations in terms of their distance. The plot shows the semivariance as a function of distance or time. The theoretical semivariance is one half of the variance of the difference between response values at locations that are a given distance apart. Note that semivariance and correlation at a given distance are inversely related. If the correlation between values at a given distance is small, the semivariance between observations at that distance is large.

When you specify any isotropic Repeated Structure (AR(1), Spatial, or Spatial with Nugget) in the Fit Model window, a Variogram plot is shown by default. If you specify the Residual structure, selecting the Variogram option in the red triangle menu enables you to select the continuous columns to be used in calculating the variogram. You can include any number of columns that describe the spatial or temporal structure of your data.

The initial Variogram report shows a plot of the empirical semivariance against distance. For additional background and more information, see “Antedependent Covariance Structure” on page 431.

### Semivariance Curves for Isotropic Structures

Semivariance curves are provided for the isotropic covariance structures: AR(1), Power, Exponential, Gaussian, and Spherical. For the spatial structures, curves are provided for models with and without nuggets.

The curves for the theoretical models are fit using the covariance parameter estimates. For the underlying formulas, see Chilès and Delfiner (2012) and Cressie (1993).
Use the theoretical models to determine whether your data conform to your selected isotropic structure. If you have selected the Residual structure, you can use the empirical variogram to determine whether your data exhibit some temporal or spatial structure. If the points seem follow a horizontal line, this suggests that the correlation does not change with distance and that the Residual structure is appropriate. If the points show a pattern, fitting various isotropic models might suggest an appropriate Repeated structure with which to refit your model.

**Nugget**

The *nugget* is the vertical jump from the value of 0 at the origin of the variogram to the value of the semivariance at a very small separation distance. A variogram model with a nugget has a discontinuity at the origin. The value of the theoretical curve for distances just above 0 is the nugget.

**Variogram Options**

- **AR(1)**  Plots a variogram for an AR(1) covariance structure.
- **Spatial**  Plots a variogram for an Exponential, Gaussian, Power, or Spherical covariance structure.
- **Spatial with Nugget**  Plots a variogram for an Exponential, Gaussian, Power, or Spherical covariance structure with nugget.

**Covariance and Correlation Matrices**

The Covariance and Correlations Matrices menu contains options to view the covariance matrices that are associated with the model.

- **Covariance of Fixed Effects**  Shows or hides the covariance matrix for the fixed effects in the model.
- **Covariance of Covariance Parameters**  Shows or hides the covariance matrix for the random effects in the model. The effects in the matrix are ordered as follows: G-side random effects, R-side random effects, and residual effects.
- **Covariance of All Parameters**  Shows or hides the covariance matrix for all effects in the model. The effects in the matrix are ordered as follows: fixed effects, G-side random effects, R-side random effects, and residual effects.
- **Correlation of Fixed Effects**  Shows or hides the correlation matrix for the fixed effects in the model.
Save Columns

Each option in the Save Columns menu adds one or more new columns to the data table.

**Prediction Formula**  Creates a new column called Pred Formula <colname> that contains both the formula and the marginal mean predicted values. A Predicting column property is added, noting the source of the prediction. See “Marginal Model Inference” on page 380.

**Standard Error of Predicted**  Creates a new column called StdErr Pred <colname> that contains standard errors for the predicted marginal mean responses.

**Mean Confidence Interval**  Creates two new columns called Lower 95% Mean <colname> and Upper 95% Mean <colname>. These columns contain the lower and upper 95% confidence limits for the mean response. These intervals include the variation in the estimation, but not in the response.

**Indiv Confidence Interval**  (Available for models that contain only G-side effects.) Creates two new columns called Lower 95% Indiv <colname> and Upper 95% Indiv <colname>. These columns contain lower and upper 95% confidence limits for individual response values. These intervals include the variation in both the response and its estimation.

**Residuals**  Creates a new column called Residual <colname> that contains the observed response values minus their marginal mean predicted values. See “Marginal Model Inference” on page 380.

**Conditional Prediction Formula**  Creates a new column called Cond Pred Formula <colname> that contains both the formula and the conditional mean predicted values. A Predicting column property is added, noting the source of the prediction. See “Conditional Profilers” on page 383.

**Standard Error of Conditional Predicted**  Creates a new column called StdErr Cond Pred <colname> that contains standard errors for the predicted conditional mean responses.

**Conditional Mean CI**  (Available for models that contain a G-side effect.) Creates two new columns called Lower 95% Cond Mean <colname> and Upper 95% Cond Mean <colname>. These columns contain the lower and upper 95% confidence limits for the expected value from conditional prediction. The confidence intervals include random effect estimates for models with random effects. See “Conditional Model Inference” on page 382.

**Conditional Residuals**  Creates a new column called Cond Residual <colname> that contains the observed response values minus their conditional mean predicted values. See “Conditional Model Inference” on page 382.

**Save Simulation Formula**  (Available only for variance component and random coefficient models.) Saves a column to the data table that contains a formula that generates simulated...
values using the estimated parameters for the model that you fit. This column can be used in the Simulate utility as a Column to Switch In. See Basic Analysis.

**Additional Examples of the Mixed Models Personality**

- “Repeated Measures Example”
- “Split Plot Example”
- “Spatial Example: Uniformity Trial”
- “Correlated Response Example”

**Repeated Measures Example**

Consider the Cholesterol Stacked.jmp sample data table. A study was performed to test two new cholesterol drugs against a control drug. Twenty patients with high cholesterol were randomly assigned to each of four treatments (the two experimental drugs, the control, and a placebo). Each patient’s total cholesterol was measured at six times during the study: the first day in April, May, and June in the morning and afternoon. You are interested in whether either of the new drugs is effective at lowering cholesterol and in whether time and treatment interact.

**Background**

Two methods have historically been used to analyze such a design:

- Multivariate analysis of variance (MANOVA)
- A split-plot in time univariate analysis of variance (ANOVA) with either the Huynh-Feldt (1976) or Greenhouse-Geisser (1959) correction

Both of these options are available using the MANOVA personality in Fit Model. These two options are the two extremes for modeling the covariance structure. The MANOVA analysis assumes an unstructured covariance structure where all variances and covariances are estimated individually. The independent split-plot in time analysis assumes that all errors are independent. In the Gaussian data case, this is equivalent to assuming a compound symmetry covariance structure.
These two models can result in vastly different conclusions about the treatment effects. When you assume a complex covariance structure, information in the data is used to estimate the covariance parameters. If you fit too many covariance parameters, you run the risk of overfitting your model. When you model repeated measures data, you must find a covariance structure that balances these issues.

- When the model is overfit, the power to detect differences is smaller than if you were to assume a less complex covariance structure.
- When the model is underfit, Type I error control is lost. In some cases, this leads to inflated rejection rates. In other cases, decreased rejection rates occur due to inflated variance.

**Covariance Structures**

The Mixed Model personality fits a variety of covariance structures. For repeated measures in time, both the Toeplitz covariance structure and the first-order autoregressive (AR(1)) covariance structures often provide appropriate correlation structures. These structures allow for correlated observations without overfitting the model. The AR(1) assumes a common variance parameter, whereas the Toeplitz covariance matrix with unequal variances estimates unique variances for each unit of the repeated measure variable. See “Repeated Covariance Structure Requirements” on page 369.

In this example, you fit the four covariance structures. The number of observation times, \( J \), is equal to six.

- **“Covariance Structure: Unstructured”** on page 389. The Unstructured model fits all covariance parameters, \( J(J+1)/2 \) in total. In this example, the model fits 21 variances.
- **“Covariance Structure: Residual”** on page 391. The Residual model is equivalent to the usual variance components structure. In this example, the model fits two variances.
- **“Covariance Structure: Toeplitz”** on page 393. The Toeplitz model fits \( 2J-1 \) covariance parameters. In this example, the model fits 11 variances.
- **“Covariance Structure: AR(1)”** on page 395. This model fits two covariance parameters. One parameter determines the variance and the other determines how the covariance changes with time.

You use AICc to evaluate model fits. The BIC criterion can also be used. In this case, the same model is chosen by both criteria. You select a best covariance structure and then continue to do additional analysis:

- **“Further Analysis Using AR(1) Structure”** on page 397
- **“Regression Model for AR(1) Model Example”** on page 401

**Tip:** Leave the Fit Model launch window open as you work through this example.
Data Structure

The Cholesterol.jmp data table is in a format that is typically used for recording repeated measures data. To use the Mixed Model personality to analyze these data, each cholesterol measurement needs to be in its own row, as in Cholesterol Stacked.jmp. To construct Cholesterol Stacked.jmp, the data in Cholesterol.jmp were stacked using Tables > Stack.

The Days column in the stacked table was constructed using a formula. The Days column gives the number days into the study when the cholesterol measurement was taken. Its modeling type is continuous. This is necessary because the AR(1) covariance structure requires the repeated effect be continuous.

Covariance Structure: Unstructured

Begin by fitting a model using an Unstructured covariance structure.

1. Select Help > Sample Data Library and open Cholesterol Stacked.jmp.
2. Select Analyze > Fit Model.
3. Select Keep dialog open so that you can return to the launch window in the next example.
4. Select Y and click Y.
5. Select Mixed Model from the Personality list.
6. Select Treatment, Month, and AM/PM, and then select Macros > Full Factorial.

Figure 8.12  Fit Model Launch Window Showing Completed Fixed Effects Tab

7. Select the Repeated Structure tab.
8. Select **Unstructured** from the Structure list.

9. Select **Time** and click **Repeated**. The **Repeated** column defines the repeated measures within a subject.

10. Select **Patient** and click **Subject**.

**Note:** The Unstructured covariance model does not allow the repeated structure variables to assume duplicate values. Suppose that, in this example, the subject was nested within treatment, and that the patients had been numbered using the values 1, 2, 3, 4, and 5 within each treatment. A warning would be given when you run this analysis. You would need to renumber the patients to have different identifiers for each value of the Repeated variable. Or you would need to create a column in the data table that represents nesting within treatment and enter this effect as Subject.

11. Click **Run**.

The Fit Mixed report is shown in Figure 8.14. Because you want to compare your three models using AICc or BIC, you are interested in the Fit Statistics report. The AICc for the unstructured model is 703.84.

The Repeated Effects Covariance Parameter Estimates report shows estimates of all 21 covariance parameters. As you would expect, observations taken closer in time have higher covariance than those farther apart. Also, variance increases with time.
Figure 8.14  Fit Mixed Report - Unstructured Covariance Structure

Covariance Structure: Residual

The Residual covariance structure is appropriate when you fit a split-plot model.

2. On the Repeated Structure tab, select Residual from the Structure list.
3. If you are continuing from the previous example, remove Time and Patient.

Otherwise, a warning appears: “Repeated columns and subject columns are ignored when the Residual covariance structure is selected.” You are given the option to click OK to continue the analysis.
4. Select the **Random Effects** tab.

5. Select Patient and click **Add**.

6. Select Patient in the Random Effects area, select the Treatment column, and then click **Nest**.

**Figure 8.15** Fit Model Launch Window Showing Completed Random Effects Tab

7. Click **Run**.

The Fit Mixed report is shown in Figure 8.16. The Fit Statistics report shows that the AICc for the Residual model is 832.55, as compared to 703.84 for the Unstructured model.

The estimates of the two covariance parameters are shown in the Random Effects Covariance Parameter Estimates report. These are estimates of the variance of Patient within Treatment, and of the Residual variance.
Figure 8.16  Fit Mixed Report - Residual Error Covariance Structure

Covariance Structure: Toeplitz

Fit the model using the Toeplitz Unequal Variances structure.

2. If you are continuing from the previous example, select Patient[Treatment] on the Random Effects tab and then click Remove.
   
   If you include both random effects and repeated effects, there is often insufficient data to estimate both effects.
3. Select the Repeated Structure tab.
4. Select Toeplitz Unequal Variances from the Structure list.
5. Select Time and click Repeated.
6. Select Patient and click Subject.
7. Click **Run**.
Figure 8.18  Fit Mixed Report - Toeplitz Unequal Variances Structure

Note: The Mixed Models personality in JMP reports correlations, whereas PROC MIXED in SAS reports covariances.

The Fit Statistics report shows that the AICc for the Toeplitz with Unequal Variances model is 788.03. Compare this number to 832.55 for the Residual Model and 703.84 for the Unstructured model.

The Toeplitz Unequal Variances structure requires the estimation of eleven covariance parameters. These estimates are shown in the Repeated Effects Covariance Parameter Estimates report. The Toeplitz correlation estimates are shown, followed by the variance estimates for each time point. See “Repeated Measures” on page 426 for information about how this matrix is parameterized.

Covariance Structure: AR(1)

Finally, fit the AR(1) structure.

2. If you are continuing from the previous example, select Time in the Repeated box and then click Remove.

AR(1) requires a continuous variable for the repeated value.

3. Select AR(1) from the Structure list.

4. Select Days and click Repeated.

Figure 8.19  Fit Model Launch Window Showing Completed Repeated Structure Tab

5. Click Run.

The Fit Mixed report is shown in Figure 8.20. The Fit Statistics report shows that the AICc for the AR(1) model is 652.63. Compare this number to 832.55 for the Residual model, 703.84 for the Unstructured model, and 788.03 for the Toeplitz Unequal Variances model. Based on the AICc criterion, the AR(1) model is the best of the four models.

The AR(1) structure requires the estimation of two covariance parameters. These estimates are shown in the Repeated Effects Covariance Parameter Estimates report. The AR(1) Days parameter estimate is an estimate of $\rho$, the correlation parameter in the AR(1) structure.

The Variogram plot shows the empirical semivariances and the curve for the AR(1) model. Since there are only five nonzero values for Days, only four distance classes are possible and only four points are shown. The AR(1) structure seems appropriate. To explore other structures, select options from the Variogram red triangle menu. For more information about Variogram options, see “Variogram” on page 384.
Because the AR(1) model gives the best fit, you adopt it as your model and proceed with your analysis. The Fixed Effects Tests report indicates that there is a significant interaction between Treatment and Month as well as a main effect of AM/PM. Here, we explore these significant effects.

1. Click the Fit Mixed red triangle and select Marginal Model Inference > Profiler.

The Marginal Model Profiler report (Figure 8.21) enables you to see the effect on cholesterol levels (Y) for various settings of Treatment, Month, and AM/PM.

2. In the plot for Month, drag the vertical dotted red line from April to May and then to June.
Notice that the predicted AM measurements for $Y$ decrease over the three months from a mean of 277.4 in April to a mean of 177.7 in June.

3. In the plot for Treatment, drag the vertical dotted red line from A to B.

By dragging the line in the plot for Month from April to June, you see that, for Treatment B, the predicted AM mean for $Y$ decreases from 276.8 in April to 191.2 in June.

4. In the plot for Treatment, drag the vertical dotted line to Control and then to Placebo.

Notice that when you set Treatment to Control or Placebo, you see virtually no change over the three months (Figure 8.22).

Next, you explore the effect of AM/PM.

5. Set Treatment and Month to all twelve combinations of their levels by dragging the vertical red lines.

For all twelve combinations, the predicted cholesterol level is consistently higher in the afternoon than in the morning, demonstrating the main effect.

Note that Treatment A seems to result in lower cholesterol readings in May than Treatment B does. If this effect is significant, it might indicate that Treatment A acts more quickly than B. The next section, “Compare All Treatments in June” on page 399, shows you how to evaluate the treatments.

Figure 8.21 Marginal Profiler Plot for Treatment A

Figure 8.22 Marginal Profiler Plot for Control
Compare All Treatments in June

The study is conducted over the months of April, May, and June. You are interested in which treatments differ on the PM measurement in June.

1. Click the Fit Mixed red triangle and select **Multiple Comparisons**.
2. Under Types of Estimates, select **User-Defined Estimates**.
3. From the Choose Treatment levels panel, select all four treatment types.
4. From the Choose Month levels panel, select June.
5. From the Choose AM/PM levels panel, select PM.
6. Click Add Estimates.
7. From the Choose Initial Comparisons list, select **All Pairwise Comparisons - Tukey HSD**.

**Figure 8.23  Completed Multiple Comparisons Window**

8. Click **OK**.
The Tukey HSD All Pairwise Comparisons report shows an All Pairwise Differences report and an All Pairwise Comparisons Scatterplot. All treatments other than the Control and Placebo differ significantly on the June PM measurements.

Consider the difference between treatments A and B. The difference in means is -14.414 and the confidence interval ranges from -26.108 to -2.7196. You conclude that the reduction in cholesterol measurements due to treatment A exceeds the reduction by treatment B by somewhere between 2.7 and 26.1 points. Both treatments A and B are highly effective compared to the Control and Placebo.
Regression Model for AR(1) Model Example

Using the Month and AM/PM categorical effects, you have compared four covariance structures for the cholesterol data. (Note that a categorical effect was required for the Unstructured fit.) You have decided to use an AR(1) covariance structure.

Suppose now that you want to model the effect of treatment in terms of the continuous effect Days instead of the categorical effects. You can then predict cholesterol levels at arbitrary time during treatment.

1. After following step 1 to step 4 in “Covariance Structure: AR(1)” on page 395, return to the Fit Model launch window.
2. On the Fixed Effects tab, select the existing fixed effects and click **Remove**.
3. Select Treatment and Days then select **Macros > Full Factorial**.

**Figure 8.25** Fit Model Launch Window Showing Fixed Effects Tab

4. Click the Model Specification red triangle and deselect **Center Polynomials**.

**Note:** In the default setting, the continuous effects used in interaction terms are centered. By turning off the Center Polynomials option, the continuous effects used in interaction terms are not centered.

5. Click **Run**.

The Fit Mixed report is shown in Figure 8.26. You see that the interaction of Treatment and Days is highly significant indicating different regressions for the drugs.
Note: To predict outcomes for the drugs at different days, use the profiler. See Profilers.

Figure 8.26  Fit Mixed Report - AR(1) Covariance Structure with Continuous Fixed Effect

Split Plot Example

The Mixed Model personality offers a straightforward approach to specifying and analyzing split-plot experiments. Mixed Model provides tabs for specifying effects. The resulting analysis is targeted to random effects. Note, however, that split-plot experiments can also be analyzed using the Standard Least Squares personality.

The data in the Split Plot.jmp sample data table come from a study of the effects of tenderizer and length of cooking time on meat. Six beef carcasses were randomly selected from carcasses at a meat packaging plant. From the right rib-eye muscle of each carcass, three rolled roasts were prepared under uniform conditions. Each of these three roasts was assigned a tenderizing treatment at random. After treatment, a coring device was used to mark four cores of meat near the center of each.
The three roasts from the same carcass were placed together in a preheated oven and allowed to cook. After 30 minutes, one of the cores was taken at random from each roast. Cores were removed in this fashion again after 36 minutes, 42 minutes, and 48 minutes. As each set cooled to serving temperature, the cores were measured for tenderness using the Warner-Bratzler device. Larger measurements indicate tougher meat.

Your interest centers on the effects of tenderizer, roasting time, and especially whether there is an interaction between tenderizer and roasting time. This design addresses that goal.

1. Select Help > Sample Data Library and open Split Plot.jmp.
2. Select Analyze > Fit Model.
3. Select Y and click Y.
4. Select Mixed Model from the Personality list.
5. Select Tenderizer and Roasting Time, and then select Macros > Full Factorial.

**Figure 8.27** Fit Model Launch Window Showing Completed Fixed Effects Tab

7. Select Carcass and click Add to create the random carcass effect.
8. Select Carcass and Tenderizer and click Cross.

The Carcass*Tenderizer interaction is the error term for the whole plot factor, Tenderizer. This is equivalent to the Carcass*Tenderizer&Random term in Standard Least Squares.
Figure 8.28  Fit Model Launch Window Showing Completed Random Effects Tab

9. Click Run.

The Fit Mixed report is shown in Figure 8.29.

The Actual by Predicted Plot and the Actual by Conditional Predicted Plot show no issues with model fit, so you can proceed to interpret the results. The Fixed Effects Tests report indicates that there is a significant interaction between tenderizer and roasting time.
Explore the Interaction between Tenderizer and Roasting Time

1. Click the Fit Mixed red triangle and select Marginal Model Inference > Profiler.
2. Move the red dashed vertical line in the Roasting Time panel to 36, 42, and 48.

   In Figure 8.30, notice that both the papain and vinegar tenderizers result in significantly lower tenderness scores than the control when roasting time is either 30 or 36 minutes. However, at 42 minutes, there are no significant differences. At 48 minutes, papain gives a value lower than the control, but vinegar does not. Papain gives lower tenderness scores than does vinegar at all times except 42 minutes.

3. Click the Fit Mixed red triangle and select **Multiple Comparisons**.

4. Select **Tenderizer*Roasting Time**.

5. Select **All Pairwise Comparisons - Tukey HSD** and then click **OK**.

   Figure 8.31 shows a partial list of pairwise comparisons. Most of the differences between papain and vinegar that you observed in the profiler are statistically significant. Therefore, it appears that papain is the better tenderizer.

#### Tukey HSD All Pairwise Comparisons

Quantile = 3.84501, Adjusted DF = 45.0, Adjustment = Tukey-Kramer

#### All Pairwise Differences
Spatial Example: Uniformity Trial

Consider the Uniformity Trial.jmp sample data table. An agronomic uniformity trial was conducted on an 8x8 grid of plots. In a uniformity trial, a test crop is grown on a field with no experimental treatments applied. The response variable, often yield, is measured. The idea is to characterize variability in the field as background for planning a designed experiment to be conducted on that field. (See Littell et al. 2006, p. 447.)

Your objective is to use the information from these data to design a yield trial with 16 treatments. Specifically, you want to decide whether to conduct future experiments on the field:

- a complete block design with 4 blocks (denoted Quarter in the data)
- an incomplete block design with 16 blocks (denoted Subquarter in the data)
- a completely randomized design with spatially correlated errors

With this objective, spatial data can be treated as repeated measures with two or more dimensions as repeated effects. So, you can compare and choose an appropriate model using the values in the Fit Statistics report. You start by determining if there is significant spatial variability, then you determine whether there is a nugget effect.

Once you have established whether there is a nugget effect, you determine the best fitting spatial covariance structure. Finally, you fit the blocking models and compare these to the best spatial structure. In this example, both AICc and BIC are used to select a best model. “Spatial Correlation Structure” on page 433 provides more information about nugget effects and other spatial terminology.

Tip: This section walks you through many aspects of fitting spatial data (from fitting the model to deciding on the best covariance structure). Leave the Fit Model launch window open as you work through each example.

Fit a Spatial Structure Model

To determine whether there is significant spatial variability, you can fit a model that accounts for spatial variability. Then you can compare the likelihood for this spatial model to the likelihood for a model that does not account for spatial variability. You can do this because the independent errors model is nested within the spatial model family: The independent errors model is a spatial model with spatial correlation, \( \rho \), equal to 0. This means that you can perform a formal likelihood ratio test of the two models.

First, fit the model that accounts for spatial structure.

1. Select Help > Sample Data Library and open Uniformity Trial.jmp.
2. Select Analyze > Fit Model.
3. Select **Keep dialog open** so that you can return to the launch window in the next example.
4. Select **Yield** and click **Y**.
5. Select **Mixed Model** from the Personality list.
6. Select the **Repeated Structure** tab.
7. Choose **Spatial** from the list next to Structure.
8. Choose **Spherical** from the list next to Type.
9. Select **Row** and **Column** and click **Repeated**.

Figure 8.32 Completed Fit Model Launch Window Showing Repeated Structure Tab

10. Click **Run**.
In the Fit Mixed report, the Actual by Predicted Plot shows that the predicted yield is a single value. This is because only spatial covariance was fit. The Fit Statistics report shows that -2 Log Likelihood is 227.68, and the AICc is 234.08.
Because an isotropic spatial structure was fit, a Variogram plot is shown. Because the trials are laid out in an 8 by 8 grid, there are more pairs of points at small distances than at very large distances. See Figure 8.37 for the layout. The Variogram shows that a spherical spatial structure is an excellent fit for distances up to about 8.4. The distance class for the final distance consists of only the two diagonal pairs of points.

The Repeated Effects Covariance Parameter Estimates report gives estimates of the range (Spatial Spherical = 2.71) and the sill (Residual = 3.26). See “Variogram” on page 433.

**Fit the Independent Errors Model**

Next, fit the independent errors model.

1. Return to the Fit Model Launch Window.
2. Select **Repeated Structure** tab.
3. Select **Residual** from the Structure list.
4. Remove Row and Column from the Repeated effects list.
   
   Otherwise, a warning appears: “Repeated columns and subject columns are ignored when the Residual covariance structure is selected.”
5. Click **Run**.

   The fit statistics for the independent errors model are: -2 Log Likelihood = 254.22, and AICc = 258.41. Each of these exceeds the corresponding value for the spatial correlation model, where -2 Log Likelihood is 227.68 and the AICc is 234.08. Because smaller values of these statistics indicate a better fit, the spatial model might provide a better fit.

**Conduct a Likelihood Ratio Test (Optional)**

A formal likelihood ratio test shows whether the spatial correlation model explains significant variation. One model must be nested in another model to create valid likelihood ratio tests.

Typically, spatial models are compared using AICc or BIC rather than through formal likelihood ratio testing. Evaluating the AICc or BIC is faster, and many spatial models are not nested.

You can conduct a likelihood ratio test in this example, because the independent errors model is nested within the spatial model family. The independent errors model is a spatial model with spatial correlation, $\rho$, equal to 0. This means that you can perform a formal likelihood ratio test of the two models.

In this example, the likelihood ratio test statistic is $254.22 - 227.68 = 26.54$. Comparing this to a Chi-square distribution on one degree of freedom, the null hypothesis of no spatial correlation is rejected with a $p$-value < 0.0001. You can conclude that these data contain significant spatial variability.
Select the Type of Spatial Covariance

Next, you determine which spatial covariance structure best fits the data:

- with or without a nugget effect (variation over relatively small distances)
- isotropic (spatial correlation is equal in all directions) or anisotropic (spatial correlation differs in the two directions)
- type of structure, spherical, Gaussian, exponential, or power.

1. Return to the Fit Model launch window.
2. Select the **Repeated Structure** tab.
3. Select Row and Column and click **Repeated**.
4. Select **Spatial with Nugget** from the Structure list.
5. Select **Spherical** from the Type list.
6. Click **Run**.

The Fit Mixed report is shown in Figure 8.34. Notice that the log-likelihoods are essentially equal to those of the spherical with no nugget model, and the AICc is slightly higher (236.36 compared to 234.08). The Repeated Effects Covariance Parameter Estimates report shows that the Nugget covariance parameter has an estimate of zero. There does not appear to be any evidence for a nugget effect.
Figure 8.34  Fit Mixed Report - Spatial Spherical with Nugget

7. Click the Variogram red triangle and select **Spatial > Spherical**.

Figure 8.35  Fit Mixed Report - Variogram
The two variograms are virtually identical. This also suggests that there is no evidence of a nugget effect.

8. Return to the Fit Model launch window.
10. To test anisotropy, select **Spatial Anisotropic** from the Structure list.
11. Select **Spherical** from the Type list.
12. Click **Run**.

The Fit Mixed report is shown in Figure 8.36. The fit statistics indicate not as good a fit as the isotropic (spatial structure) spherical model (AICc 240.54 compared to 234.08). The Repeated Effects Covariance Parameter Estimates report shows that the estimates for the Row (Spatial Spherical Row) and Column (Spatial Spherical Column) covariances are very close. There is no evidence to suggest that spatial correlations within rows and columns of the grid differ.

**Figure 8.36** Fit Mixed Report - Spatial Anisotropic Spherical

---

**Determine the Type of the Spatial Structure**

An isotropic spatial structure with no nugget is appropriate. To determine the type of the spatial structure, you can compare the available types.

1. Return to the Fit Model launch window.
2. Select the **Repeated Structure** tab.
3. Select Row and Column and click **Repeated**.
4. Select **Spatial** from the Structure list.
5. Select **Power** from the Type list.
6. Click **Run**.

Note the AICc and BIC values for the model fit.
7. Return to the Fit Model launch window.
8. Select **Exponential** from the Type list.
9. Click **Run**.
   Note the AICc and BIC values for the model fit.
10. Return to the Fit Model launch window.
11. Select **Gaussian** from the Type list.
12. Click **Run**.
   Note the AICc and BIC values for the model fit.

The observed AICc values for these types and the other fits that you performed are summarized in Table 8.2.

### Table 8.2  Fit Statistics for Spatial Models Fit

The best fitting model (using the smallest AICc value) is the Spatial structure model with Spherical covariance structure. Now you will compare this model to the complete and incomplete block models to complete the objectives of the uniformity trial.

### Compare the Model to Block Designs

1. Return to the Uniformity Trial data table.
2. In the Tables panel, run the Graph Builder script.
**Figure 8.37** Graph Builder Plot of Proposed Complete and Incomplete Block Designs

This plot shows the proposed complete and incomplete block designs for the field. The color indicates the quarter fields that would serve as complete blocks. The numbered points represent the sub-quarter fields that would serve as incomplete blocks.

To fit the complete block model, follow these steps:

1. Return to the Fit Model launch window.
2. Select **Repeated Structure** tab.
3. Select **Residual** from the Structure list.
4. Remove Row and Column from the effect.
   Otherwise, a pop-up window appears, stating, “Repeated columns and subject columns are ignored when the Residual covariance structure is selected.”
5. Select the **Random Effects** tab.
6. Select Quarter and click **Add**.
7. Click **Run**.

To fit the incomplete block model, follow these steps:

1. Return to the Fit Model launch window.
2. Select the **Random Effects** tab.
3. Select Quarter and click **Remove**.
4. Select Subquarter and click **Add**.
5. Click **Run**.

The following list shows both AICc and BIC values for the competing models. The spherical covariance structure results in the best model fit. This indicates that, for future studies using this field, a completely randomized design with spatially correlated errors is preferred.

- **Spherical model** (see “Determine the Type of the Spatial Structure” on page 414)
  - AICc: 234.08
  - BICc: 240.16
- **Complete block (RCBD) model**
  - AICc: 259.90
  - BICc: 265.97
- **Incomplete block model**
  - AICc: 248.77
  - BICc: 254.85

**Correlated Response Example**

In this example, the effect of two layouts dealing with wafer production is studied for a characteristic of interest. Each of 50 wafers is partitioned into four quadrants and the characteristic is measured on each of these quadrants. Data of this type are usually presented in a format where each row contains all of the repeated measurements for one of the units of interest. Data of this type are often analyzed using separate models for each response. However, when repeated measurements are taken on a single unit, it is likely that there is within-unit correlation. Failure to account for this correlation can result in poor decisions and predictions. You can use the Mixed Model personality to account for and model the possible correlation.

For Mixed Model analysis of repeated measures data, each repeated measurement needs to be in its own row. If your data are in the typical format where all repeated measurements are in the same row, you can construct an appropriate data table for Mixed Model analysis by using Tables > Stack. See *Using JMP*. 
In this example, you first fit univariate models using the usual data table format. Then you use the Mixed Model personality to fit models for the four responses while simultaneously accounting for possible correlation among the responses.

**Fit Univariate Models**

Use Standard Least Squares to fit a univariate model for each of the four quadrants.

1. Select **Help > Sample Data Library** and open **Wafer Quadrants.jmp**.
   
   This data table is structured for Mixed Model analysis, with one row for each Y measurement on each Quadrant. To conduct univariate analyses, you split the table using a saved script.

2. In the **Wafer Quadrants.jmp** data table, click the green triangle next to the **Split Y by Quadrant** script.

   The new data table is in the format often used to record repeated measures data. Each value of Wafer ID defines a row and the four measurements for that wafer are given in the single row.

3. Select **Analyze > Fit Model**.

   Since there is a Model script in the data table, the Model Specification window is already filled in. Note that the columns High, High through Low, Low are entered as Y and that Layout is the single model effect.

4. Click **Run**.
The report indicates that Layout has a statistically significant effect for all quadrants except the High, Low quadrant.

**Perform Mixed Model Analysis**

Using the Mixed Model analysis, you can obtain more information.

1. Return to Wafer Quadrants.jmp. Or, if you have closed it, select **Help > Sample Data Library** and open Wafer Quadrants.jmp.
2. Select **Analyze > Fit Model**.
3. Select Y and click Y.
4. Select **Mixed Model** from the Personality list.
5. Select Quadrant and Layout from the **Select Columns** list and click **Macros > Full Factorial**. This model specification enables you to explore the effect of Layout on the repeated measurements as well as the possible interaction of Layout with Quadrant.

**Figure 8.39** Fit Model Launch Window Showing Completed Fixed Effects Tab

6. Select the **Repeated Structure** tab.
7. Select **Unstructured** from the Structure list.
8. Select Quadrant and click **Repeated**.
9. Select Wafer ID and click **Subject**.
10. Click **Run**.

The Repeated Effects Covariance Parameter Estimates report gives the estimated variances and covariances for the four responses. Note that the confidence interval for the covariance of Low, High with High, High does not include zero. This suggests that there is a positive covariance between measurements in these two quadrants. This is information that the Mixed Model analysis uses and that is not available when the responses are modeled independently.
The Fixed Effects Tests report indicates that there is a significant Layout by Characteristic interaction.

**Explore the Layout by Characteristic Interaction with the Profiler**

1. Click the Fit Mixed red triangle and select **Marginal Model Inference > Profiler**.
2. In the Profiler plot, compare the predicted values for Y across the quadrants by first setting the vertical red dotted line at Layout A and then at Layout B.

**Figure 8.42** Profile for Quadrant for Layout A

![Marginal Model Profiler](image)

**Figure 8.43** Profile for Quadrant for Layout B

![Marginal Model Profiler](image)

The differences in the profiles at each setting of Layout give you insight into the significant interaction. It appears that the interaction is partially driven by the differences for the High, High quadrant.

**Plot of Y by Layout and by Quadrant**

Use Graph Builder to explore the nature of the interaction.

1. Click the Fit Mixed red triangle and select **Save Columns > Prediction Formula**.

   The prediction formula is saved to the data table in the column Pred Formula Y.
2. Select **Graph > Graph Builder**.
3. Drag Horizontal to the X zone.
4. Drag Vertical to the Y zone.
5. Drag Pred Formula Y to the **Color** zone.
6. Drag Layout to the **Wrap** zone.
7. Click **Done** to hide the control panel.

**Figure 8.44** Completed Graph Builder Plot

![Completed Graph Builder Plot](image)

**Note:** Because the points in Graph Builder are randomly jittered, your plot might not match Figure 8.44 exactly.

The plot shows the predicted differences for the eight Layout and Quadrant combinations using a color intensity scale. The predicted values for the High, Low quadrant are in the lower right. The color gradient shows relatively little difference for these predicted values. Other differences are clearly indicated.
Statistical Details for the Mixed Models Personality

- “Convergence Score Test”
- “Random Coefficient Model”
- “Repeated Measures”
- “Repeated Covariance Structures”
- “Spatial and Temporal Variability”
- “The Kackar-Harville Correction”

Convergence Score Test

The convergence failure warning shows the score test for the following hypothesis: that the unknown maximum likelihood estimate (MLE) is consistent with the parameter given in the final iteration of the model-fitting algorithm. This hypothesis test is possible because the relative gradient criterion is algebraically equivalent to the score test statistic. Remarkably, the score test does not require knowledge of the true MLE.

Score Test

Consider first the case of a single parameter, $\theta$. Let $l$ be the log-likelihood function for $\theta$ and let $x$ be the data. The score is the derivative of the log-likelihood function with respect to $\theta$:

$$U(\theta) = \frac{\partial l(\theta|x)}{\partial \theta}$$

The observed information is:

$$I(\theta) = -\frac{\partial^2 l(\theta|x)}{\partial \theta^2}$$

The statistic for the score test of $H_0$: $\theta = \theta_0$ is:

$$S(\theta_0) = \frac{U(\theta_0)^2}{I(\theta_0)}$$

This statistic has an asymptotic Chi-square distribution with 1 degree of freedom under the null hypothesis.

The score test can be generalized to multiple parameters. Consider the vector of parameters $\theta$. Then the test statistic for the score test of $H_0$: $\theta = \theta_0$ is:
Chapter 8
Mixed Models

Fitting Linear Models
Statistical Details for the Mixed Models Personality

\[ S(\theta_0) = U'(\theta_0)I^{-1}(\theta_0)U(\theta_0) \]

where
\[ U(\theta) = \frac{\partial l(\theta|x)}{\partial \theta} \]

and
\[ I(\theta) = -\frac{\partial^2 l(\theta|x)}{\partial \theta \partial \theta'} \]

and \( U' \) denotes the transpose of the matrix \( U \).

The test statistic is asymptotically Chi-square distribution with \( k \) degrees of freedom. Here \( k \) is the number of unbounded parameters.

**Relative Gradient**

The convergence criterion for the Mixed Model fitting procedure is based on the relative gradient \( g' H^{-1} g \). Here, \( g(\theta) = U(\theta) \) is the gradient of the log-likelihood function and \( H(\theta) = -I(\theta) \) is its Hessian.

Let \( \theta_0 \) be the value of \( \theta \) where the algorithm terminates. Note that the relative gradient evaluated at \( \theta_0 \) is the score test statistic. A \( p \)-value is calculated using a Chi-square distribution with \( k \) degrees of freedom. This \( p \)-value gives an indication of whether the value of the unknown MLE is consistent with \( \theta_0 \). The number of unbounded parameters listed in the Random Effects Covariance Parameter Estimates report equals \( k \).

**Random Coefficient Model**

The standard random coefficient model specifies a random intercept and slope for each subject. Let \( y_{ij} \) denote the measurement of the \( j^{th} \) observation on the \( i^{th} \) subject. Then the random coefficient model can be specified as follows:

\[ y_{ij} = a_i + b_i x_{ij} + e_{ij} \]

where
\[ i = 1, 2, ..., t \]
\[ j = 1, 2, ..., n_i \]

\[ \begin{bmatrix} a_i \\ b_i \end{bmatrix} \sim iid \ N \left( \begin{bmatrix} \alpha \\ \beta \end{bmatrix}, G \right) \]
You can reformulate the model to reflect the fixed and random components that are estimated:

\[ y_{ij} = (\alpha + a_i^*) + (\beta + b_i^*)x_{ij} + e_{ij} \]

where

\[ a_i^* = \alpha_i - \alpha \]
\[ b_i^* = \beta_i - \beta \]

and

\[
\begin{bmatrix}
  a_i^* \\
  b_i^*
\end{bmatrix}
\sim iid \ N\left( \begin{bmatrix} 0 \\ 0 \end{bmatrix}, G \right)
\]

with \( G \) and \( e_{ij} \) defined as above.

### Repeated Measures

The form of the repeated measures model is \( y_{ijk} = \alpha_{ij} + s_{ik} + e_{ijk} \) where

- \( \alpha_{ij} \) can be written as a treatment and time factorial
- \( s_{ik} \) is the random effect of the \( k \)th subject assigned to the \( i \)th treatment
- \( j = 1, \ldots, m \) denotes the repeated measurements over time.

Assume that the \( s_{ik} \) are independent and identically distributed \( N(0, \sigma_s^2) \) variables. Denote the number of treatment factors by \( t \) and the number of subjects by \( s \). Then the distribution of \( e_{ijk} \) is \( N(0, \Sigma) \), where

\[
\Sigma = I_{ts} \otimes Var(y_{ik}|s_{ik})
\]

and

\[
y'_{ik}|s_{ik} = \left[ y_{i1k} y_{i2k} \cdots y_{imk} \right]|s_{ik}
\]
Denote the block diagonal component of the covariance matrix $\Sigma$ corresponding to the $i_k$th subject within treatment by $\Sigma_{i_k}$. In other words, $\Sigma_{i_k} = \text{Var}(y_{i_k}|s_{i_k})$. Because observations over time within a subject are not typically independent, it is necessary to estimate the variance of $y_{ijk}|s_{i_k}$. Failure to account for the correlation leads to distorted inference.

See “Repeated Covariance Structures” on page 427 and “Spatial and Temporal Variability” on page 432 for more information about the covariance structures available for $\Sigma_{i_k}$.

### Repeated Covariance Structures

This section gives the parameterizations for the following covariance structures:

- “Unequal Variances Covariance Structure” on page 427
- “Unstructured Covariance Structure” on page 428
- “Compound Symmetry Covariance Structure” on page 428
- “AR(1) Covariance Structure” on page 430
- “Toeplitz Covariance Structure” on page 431
- “Antedependent Covariance Structure” on page 431

#### Unequal Variances Covariance Structure

$$
\Sigma = \begin{bmatrix}
\sigma_1^2 & 0 & 0 & \ldots & 0 \\
0 & \sigma_2^2 & 0 & \ldots & 0 \\
0 & 0 & \sigma_3^2 & \ldots & 0 \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
0 & 0 & 0 & \ldots & \sigma_m^2
\end{bmatrix}
$$

Here, the variance among observations taken at time $j$ is:

$$
\sigma_j^2 = \text{Var}(y_{ijk}|s_{i_k})
$$

The variances are allowed to differ across the levels of the repeated column. The covariances between observations at different levels are zero.
Unstructured Covariance Structure

\[ \Sigma = \begin{pmatrix} \sigma_1^2 & \sigma_{12} & \sigma_{13} & \cdots & \sigma_{1[m-1]} & \sigma_{1m} \\ \sigma_{12} & \sigma_2^2 & \sigma_{23} & \cdots & \sigma_{2[m-1]} & \sigma_{2m} \\ \sigma_{13} & \sigma_{23} & \sigma_3^2 & \cdots & \sigma_{3[m-1]} & \sigma_{3m} \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ \sigma_{1[m-1]} & \sigma_{2[m-1]} & \sigma_{3[m-1]} & \cdots & \sigma_{[m-1]m} & \sigma_{[m-1]m} \\ \sigma_{1m} & \sigma_{2m} & \sigma_{3m} & \cdots & \sigma_{[m-1]m} & \sigma_m^2 \end{pmatrix} \]

Here, the variance among observations taken at time \( j \) is:

\[ \sigma_j^2 = \text{Var}(y_{ijk} | s_{ik}) \]

The covariance between observations taken at times \( j \) and \( j' \) is:

\[ \sigma_{jj'} = \text{Cov}(y_{ijk}, y_{ij'k} | s_{ik}) \]

The variances are allowed to differ across the levels of the repeated column. The covariances between observations at different levels is unique.

Compound Symmetry Covariance Structure

In JMP, a compound symmetry covariance structure is implemented using a mixed model with independent errors approach. Random effects are classified into two categories: G-side or R-side. See Searle et al. (1992).

The G-side random effects are associated with the design matrix for random effects. The R-side random effects are associated with residual error. Within-subject variance is part of the design structure and is modeled on the G-side. Between-subject variance falls into the residual structure and is modeled R-side. The variances in the independent structure are modeled in the following manner:

- The random effects G-side variance is modeled by \( s_{ik} \sim \text{iid } N(0, \sigma_s^2) \).
- The R-side variance is modeled by \( e_{ijk} \sim \text{iid } N(0, \sigma^2) \).
Then the covariance matrix is defined as follows:

$$
\Sigma_{ik} = \sigma_s^2 J + \sigma^2 I = \begin{bmatrix}
\sigma_s^2 + \sigma^2 & \sigma_s^2 & \ldots & \sigma_s^2 \\
\sigma_s^2 & \sigma_s^2 + \sigma^2 & \ldots & \sigma_s^2 \\
\vdots & \vdots & \ddots & \vdots \\
\sigma_s^2 & \sigma_s^2 & \ldots & \sigma_s^2 + \sigma^2
\end{bmatrix}
$$

where \( J \) is a matrix consisting of 1s and \( I \) is an identity matrix.

Alternatively, all variance could be modeled on the R-side. Under the Gaussian assumption, this compound-symmetry covariance structure is equivalent to the independence model (Type=CS in SAS). This structure is available in JMP by using the Compound Symmetry structure in the repeated structure tab. Here, the correlation between pairs of repeated observations is the same regardless of the time difference between the observations. Thus, the correlation matrix can be specified as follows:

$$
C = \begin{bmatrix}
1 & \rho & \ldots & \rho \\
1 & \cdots & \rho \\
\vdots & \ddots & \vdots \\
1 & \cdots & \cdots & 1
\end{bmatrix}
$$

Using the Compound Symmetry structure in JMP also assumes a common variance, \( \sigma_e^2 \), among observations taken at any time point. The covariance structure is then \( \Sigma = \sigma_e^2 C \) where

$$\sigma_e^2 = \sigma_s^2 + \sigma^2$$

and

$$\rho = \frac{\sigma_s^2}{\sigma_s^2 + \sigma^2}.$$
Here, $\rho$ is the intra-class correlation coefficient and $\sigma^2_e$ is the residual variance. Another option is to use the Compound Symmetry Unequal Variances structure in JMP, which allows the variance to vary across time points. This leads to the following covariance matrix:

$$
\Sigma = \begin{bmatrix}
\sigma_1^2 & \rho \sigma_1 \sigma_2 & \rho \sigma_1 \sigma_3 & \cdots & \rho \sigma_1 \sigma_{m-1} & \rho \sigma_1 \sigma_m \\
\rho \sigma_1 \sigma_2 & \sigma_2^2 & \rho \sigma_2 \sigma_3 & \cdots & \rho \sigma_2 \sigma_{m-1} & \rho \sigma_2 \sigma_m \\
\rho \sigma_1 \sigma_3 & \rho \sigma_2 \sigma_3 & \sigma_3^2 & \cdots & \rho \sigma_3 \sigma_{m-1} & \rho \sigma_3 \sigma_m \\
\cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\
\rho \sigma_1 \sigma_{m-1} & \rho \sigma_2 \sigma_{m-1} & \rho \sigma_3 \sigma_{m-1} & \cdots & \sigma_{m-1}^2 & \rho \sigma_{m-1} \sigma_m \\
\rho \sigma_1 \sigma_m & \rho \sigma_2 \sigma_m & \rho \sigma_3 \sigma_m & \cdots & \rho \sigma_{m-1} \sigma_m & \sigma_m^2 \\
\end{bmatrix}
$$

**AR(1) Covariance Structure**

$$
\Sigma = \begin{bmatrix}
\sigma_1^2 & \rho |t_1-t_2| \sigma_1^2 & \rho |t_1-t_3| \sigma_1^2 & \cdots & \rho |t_1-t_{m-1}| \sigma_1^2 & \rho |t_1-t_m| \sigma_1^2 \\
\rho |t_1-t_2| \sigma_1^2 & \sigma_2^2 & \rho |t_2-t_3| \sigma_2^2 & \cdots & \rho |t_2-t_{m-1}| \sigma_2^2 & \rho |t_2-t_m| \sigma_2^2 \\
\rho |t_1-t_3| \sigma_1^2 & \rho |t_2-t_3| \sigma_2^2 & \sigma_3^2 & \cdots & \rho |t_3-t_{m-1}| \sigma_3^2 & \rho |t_3-t_m| \sigma_3^2 \\
\cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\
\rho |t_1-t_{m-1}| \sigma_1^2 & \rho |t_2-t_{m-1}| \sigma_2^2 & \rho |t_3-t_{m-1}| \sigma_3^2 & \cdots & \sigma_{m-1}^2 & \rho |t_{m-1}-t_m| \sigma_{m-1}^2 \\
\rho |t_1-t_m| \sigma_1^2 & \rho |t_2-t_m| \sigma_2^2 & \rho |t_3-t_m| \sigma_3^2 & \cdots & \rho |t_{m-1}-t_m| \sigma_{m-1}^2 & \sigma_m^2 \\
\end{bmatrix}
$$

Here $t_j$ is the time of observation $j$. In this structure, observations taken at any given time have the same variance, $\sigma^2$. The parameter $\rho$, where $-1 < \rho < 1$, is the correlation between two observations that are one unit of time apart. As the time difference between observations increases, their covariance decreases because $\rho$ is raised to a higher power. In many applications, AR(1) provides an adequate model of the within subject correlation, providing more power without sacrificing Type I error control.
Toeplitz Covariance Structure

In the Toeplitz structure, observations that are separated by a fixed number of time units have the same correlation. In contrast to the AR(1) correlation structure, the Toeplitz correlations at a fixed time difference are arbitrary. Denote the correlation for observations $d$ units apart by $\rho_d$. The correlation matrix is defined as follows:

$$
C = \begin{bmatrix}
1 & \rho_1 & \rho_2 & \ldots & \rho_{m-1} & \rho_m \\
1 & \rho_1 & \rho_2 & \ldots & \rho_{m-2} & \rho_{m-1} \\
1 & \ldots & \rho_{m-3} & \rho_{m-2} \\
\vdots & \vdots & \vdots \\
1 & \rho_1 & & & & \\
1 & & & & & \\
\end{bmatrix}
$$

Two options in JMP use this correlation matrix:

- The Toeplitz structure assumes a common variance, $\sigma^2$, for observations from any time point. The covariance structure is $\Sigma = \sigma^2 C$.

- Alternatively, the Toeplitz Unequal Variances structure allows the variance to vary across time points:

$$
\Sigma = \begin{bmatrix}
\sigma_1^2 & \rho_1 \sigma_1 \sigma_2 & \rho_2 \sigma_1 \sigma_3 & \ldots & \rho_{m-1} \sigma_1 \sigma_{m-1} & \rho_m \sigma_1 \sigma_m \\
\sigma_2^2 & \rho_1 \sigma_2 \sigma_3 & \rho_2 \sigma_2 \sigma_4 & \ldots & \rho_{m-2} \sigma_2 \sigma_{m-1} & \rho_{m-1} \sigma_2 \sigma_m \\
\sigma_3^2 & \ldots & \rho_{m-3} \sigma_3 \sigma_{m-1} & \rho_{m-2} \sigma_3 \sigma_m \\
\vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\
\sigma_m^2 & \rho_{m-1} \sigma_{m-1} \sigma_m \\
\end{bmatrix}
$$

Antedependent Covariance Structure

The antedependence model is a general model that is flexible and allows the correlation structure to change over time. In this model, the correlation between two observations at adjacent time points $j - 1$ and $j$ is unique and is denoted $\rho_{[j-1]}$.

The correlation between pairs of observations at non-adjacent time points $j$ and $j'$ is the product of all the adjacent correlations in between.

$$
\text{Corr}(y_{ijk}, y_{ij'k} | s_{ik}) = \prod_{k=j}^{j' - 1} \rho_{k[k-1]}
$$
For example, the correlation between the pair of observations at time points \( j=2 \) and \( j'=6 \) would be \( \rho_{21}\rho_{32}\rho_{43}\rho_{54} \).

The correlation matrix is defined as follows:

\[
C = \begin{bmatrix}
1 & \rho_{10} & \rho_{10}\rho_{21} & \cdots & \rho_{10}\cdots\rho_{[m-1][m-2]} & \rho_{10}\cdots\rho_{m[m-1]} \\
1 & \rho_{21} & \cdots & \rho_{21}\cdots\rho_{[m-1][m-2]} & \rho_{21}\cdots\rho_{m[m-1]} \\
1 & \cdots & \rho_{32}\cdots\rho_{[m-1][m-2]} & \rho_{32}\cdots\rho_{m[m-1]} \\
\vdots & \cdots & \cdots & \cdots & \cdots \\
1 & \rho_{m[m-1]} \\
1 & \end{bmatrix}
\]

Two options in JMP use this correlation matrix:

- The Antedependent Equal Variance structure assumes equal variances across observation times while still allowing for the correlations to change. The variance among observations at any time is \( \sigma^2 \) and the covariance matrix is \( \Sigma = \sigma^2 C \).

- The Antedependent structure allows the variance among observations at any given time to vary. Denote the variance among observations taken at time \( j \) as \( \sigma_j^2 \). Then the covariance matrix is defined as follows:

\[
\Sigma = \begin{bmatrix}
\sigma_1^2 & \rho_{10}\sigma_1\sigma_2 & \rho_{10}\rho_{21}\sigma_1\sigma_3 & \cdots & \rho_{10}\cdots\rho_{[m-1][m-2]}\sigma_1\sigma_{m-1} & \rho_{10}\cdots\rho_{m[m-1]}\sigma_1\sigma_m \\
\sigma_2^2 & \rho_{21}\sigma_2\sigma_3 & \cdots & \rho_{21}\cdots\rho_{[m-1][m-2]}\sigma_2\sigma_{m-1} & \rho_{21}\cdots\rho_{m[m-1]}\sigma_2\sigma_m \\
\sigma_3^2 & \cdots & \rho_{32}\cdots\rho_{[m-1][m-2]}\sigma_3\sigma_{m-1} & \rho_{32}\cdots\rho_{m[m-1]}\sigma_3\sigma_m \\
\vdots & \cdots & \cdots & \cdots & \cdots \\
\sigma_{m-1}^2 & \rho_{m[m-1]}\sigma_{m-1}\sigma_m \\
\sigma_m^2 & \end{bmatrix}
\]

**Spatial and Temporal Variability**

Consider the simple model \( y_i = \mu + e_i \). The spatial or temporal structure is modeled through the error term, \( e_i \). In general, the spatial correlation model can be defined as \( \text{Var}(e_i) = \sigma_i^2 \) and \( \text{Cov}(e_i, e_j) = \sigma_{ij} \).
Let \( s_i \) denote the location of \( y_i \), where \( s_i \) is specified by coordinates reflecting space or time. The spatial or temporal structure is typically restricted by assuming that the covariance is a function of the Euclidean distance, \( d_{ij} \), between \( s_i \) and \( s_j \). The covariance can be written as
\[
\text{Cov}(e_i, e_j) = \sigma^2 [f(d_{ij})],
\]
where \( f(d_{ij}) \) represents the correlation between observations \( y_i \) and \( y_j \).

In the case of two or more location coordinates, if \( f(d_{ij}) \) does not depend on direction, then the covariance structure is isotropic. If it does, then the structure is anisotropic.

### Spatial Correlation Structure

The correlation structures for spatial models available in JMP are shown below. These are parametrized by \( \rho \), which is positive unless it is otherwise constrained.

- **Spherical**
  \[
  f(d_{ij}) = [1 - 1.5(d_{ij}/\rho) + 0.5(d_{ij}/\rho)^3] \times 1_{\{d_{ij} < \rho\}}
  \]
  where \( 1_{\{d_{ij} < \rho\}} = \begin{cases} 1, & \text{if } d_{ij} < \rho \\ 0, & \text{if } d_{ij} \geq \rho \end{cases} \)

- **Exponential**
  \[
  f(d_{ij}) = \exp(-d_{ij}/\rho)
  \]

- **Gaussian**
  \[
  f(d_{ij}) = \exp(-d_{ij}^2/\rho^2)
  \]

- **Power**
  \[
  f(d_{ij}) = \rho^{d_{ij}}
  \]

For an anisotropic model, the correlation function contains a parameter, \( \rho_{\kappa} \), for each direction.

### Variogram

When the spatial process is second-order stationary, the structures listed in “Spatial Correlation Structure” on page 433 define variograms. Borrowed from geostatistics, the variogram is the standard tool for describing and estimating spatial variability. It measures spatial variability as a function of the distance, \( d_{ij} \), between observations using the semivariance.
Let \( Z(s) \) denote the value of the response at a location \( s \). The semivariance between observations at \( s_i \) and \( s_j \) is defined as follows:

\[
\gamma(s_i, s_j) = \frac{(Var(Z(s_i) - Z(s_j)))}{2}
\]

If the response has a constant mean, then the expression can be simplified to the following:

\[
\gamma(s_i, s_j) = \frac{E[(Z(s_i) - Z(s_j))^2]}{2}
\]

If the process is isotropic, the semivariance depends only on the distance \( h \) between points and the function can be specified as follows:

\[
\gamma(h) = \frac{E[(Z(s_i) - Z(s_i + h))^2]}{2}
\]

The following terms are associated with variograms:

**Nugget**  Defined as the intercept. This represents a jump discontinuity at \( h = 0 \).

**Sill**  Defined as the value of the semivariogram at the plateau reached for larger distances. It corresponds to the variance of an observation. In models with no nugget effect, the sill is \( \sigma^2 \). In models with a nugget effect, the sill is \( \sigma^2 + c_1 \), where \( c_1 \) represents the nugget. The partial sill is defined as \( \sigma^2 \).

**Range**  Defined as the distance at which the semivariogram reaches the sill. At distances less than the range, observations are spatially correlated. For distances greater than or equal to the range, spatial correlation is effectively zero. In spherical models, \( \rho \) is the range. In exponential models, \( 3\rho \) is the practical range. In Gaussian models, \( \rho / \sqrt{3} \) is the practical range. The practical range is defined as the distance where covariance is reduced to 95% of the sill.

In Figure 8.34 on page 413, the repeated effects covariance parameter estimates represent the various semivariogram features:

**Spatial Spherical**  An estimate of the range, \( \rho \).

**Nugget**  A scaled estimate of \( c_1 \). The Residual times the Nugget is \( c_1 \).

**Residual**  The partial sill or the sill in no nugget models.

**Variogram Estimate**

For a given isotropic spatial structure, the estimated variogram is obtained using a nonlinear least squares fit of the observed data to the appropriate function in “Spatial Correlation Structure” on page 433.
Empirical Semivariance

To compute the *empirical semivariance*, the distances between all pairs of points for the variables selected for the variogram covariance are computed. The range of the distances is divided into 10 equal intervals. If the data do not allow for 10 intervals, then as many intervals as possible are constructed.

Distance classes consisting of pairs of points are constructed. The $h^{th}$ distance class consists of all pairs of points whose distances fall in the $h^{th}$ interval.

Consider the following notation:

- $n$ total number of pairs of points
- $C_h$ distance class consisting of points whose distance falls into the $h^{th}$ largest interval
- $Z(x)$ value of the response at $x$, where $x$ is a vector of temporal or spatial coordinates
- $\gamma(h)$ semivariance for distance class $C_h$

The semivariance function, $\gamma$, is defined as follows:

$$
\gamma(h) = \begin{cases} 
\frac{1}{2n} \sum_{(x, y) \in C_h} [Z(x) - Z(y)]^2 & \text{for } h > 0 \\
\hat{c}_1 & \text{for } h = 0
\end{cases}
$$

Here $\hat{c}_1$ is an estimate of the nugget effect.

The Kackar-Harville Correction

The variance matrix of the fixed effects is always modified to include a Kackar-Harville correction. The variance matrix of the BLUPs, and the covariances between the BLUPs and the fixed effects, are not Kackar-Harville corrected. The rationale for this approach is that corrections for BLUPs can be computationally and memory intensive when the random effects have many levels. In SAS, the Kackar-Harville correction is done for both fixed effects and BLUPs only when the DDFM=KENWARDROGER is set.

For covariance structures that have nonzero second derivatives with respect to the covariance parameters, the Kenward-Roger covariance matrix adjustment includes a second-order term. This term can result in standard error shrinkage. Also, the resulting adjusted covariance matrix can then be indefinite and is not invariant under reparameterization. The first-order Kenward-Roger covariance matrix adjustment eliminates the second derivatives from the calculation. All spatial structures and the AR(1) structure are covariance structures that generally lead to nonzero second derivatives.
Because JMP implements the Kenward-Roger first-order adjustment

- Standard errors for linear combinations involving only fixed effects parameters match PROC MIXED DDFM=KENWARDROGER(FIRSTORDER). This presumes that one has taken care to transform between the different parameterizations used by PROC MIXED and JMP.
- Standard errors for linear combinations involving only BLUP parameters match PROC MIXED DDFM=SATTERTHWAITE.
- Standard errors for linear combinations involving both fixed effects and BLUPS do not match PROC MIXED for any DDFM option if the data are unbalanced. However, these standard errors are between those obtained using the DDFM=SATTERTHWAITE and DDFM=KENWARDROGER options. If the data are balanced, JMP matches SAS regardless of the DDFM option, because the Kackar-Harville correction is null.

**Degrees of Freedom**

The degrees of freedom for tests involving only linear combinations of fixed effect parameters are calculated using the first-order Kenward-Roger correction. Therefore, the JMP results for these tests match PROC MIXED using the DDFM=KENWARDROGER (FIRSTORDER) option. If there are BLUPs in the linear combination, JMP uses a Satterthwaite approximation to get the degrees of freedom. The results then follow a pattern similar to what is described for standard errors in the preceding paragraph.

For more information about the Kackar-Harville correction and the Kenward-Roger DF approach, see Kenward and Roger (1997). The Satterthwaite method is described in detail in the MIXED Procedure chapter in SAS Institute Inc. (2020d, ch. 83).
Multivariate models fit several responses (Y variables) to a set of effects. The functions across the Y variables can be tested with appropriate response designs.

In addition to creating standard MANOVA (Multivariate Analysis of Variance) models, you can use the following techniques:

- Repeated measures analysis when repeated measurements are taken on each subject and you want to analyze effects both between subjects and within subjects across the measurements. This multivariate approach is especially important when the correlation structure across the measurements is arbitrary.

- Canonical correlation to find the linear combination of the X and Y variables that has the highest correlation.

- Discriminant analysis to find distance formulas between points and the multivariate means of various groups so that points can be classified into the groups that they are most likely to be in. A more complete implementation of discriminant analysis is in the Discriminant platform.

The multivariate fit begins with a rudimentary preliminary analysis that shows parameter estimates and least squares means. You can then specify a response design across the Y variables and multivariate tests are performed.

Example of a Multiple Response Model

This example uses the Golf Balls.jmp sample data table (McClave and Dietrich 1988). The data are a comparison of distances traveled and a measure of durability for three brands of golf balls. A robotic golfer hit a random sample of ten balls for each brand in a random sequence. The hypothesis to test is that distance and durability are the same for the three golf ball brands.

1. Select Help > Sample Data Library and open Golf Balls.jmp.
2. Select Analyze > Fit Model.
3. Select Distance and Durability and click Y.
4. Select Brand and click Add.
5. For Personality, select Manova.

Figure 9.1 Manova Setup

6. Click Run.
The initial results might not be very interesting in themselves, because no response design has been specified yet. After you specify a response design, the multivariate platform displays tables of multivariate estimates and tests. For more information about specifying a response design, see “Response Specification” on page 442.
The Manova Report

The Manova report window contains the following elements:

**Manova Fit red triangle menu**   Contains save options. See “The Manova Fit Options” on page 441.

**Response Specification**   Enables you to specify the response designs for various tests. See “Response Specification” on page 442.

**Parameter Estimates**   Contains the parameter estimates for each response variable (without details like standard errors or *t* tests). There is a column for each response variable.

**Least Squares Means**   Reports the overall least squares means of all of the response columns, least squares means of each nominal level, and least squares means plots of the means.

**Partial Correlation**   Shows the covariance matrix and the partial correlation matrix of residuals from the initial fit, adjusted for the *X* effects.

**Overall E&H Matrices**   Shows the E and H matrices:

- The elements of the *E* matrix are the cross products of the residuals.
- The *H* matrices correspond to hypothesis sums of squares and cross products.

There is an *H* matrix for the whole model and for each effect in the model. Diagonal elements of the *E* and *H* matrices correspond to the hypothesis (numerator) and error (denominator) sum of squares for the univariate *F* tests. New *E* and *H* matrices for any given response design are formed from these initial matrices, and the multivariate test statistics are computed from them.

The Manova Fit Options

The following Manova Fit options are available:

**Save Discrim**   Performs a discriminant analysis and saves the results to the data table. See “Discriminant Analysis” on page 456.

**Save Predicted**   Saves the predicted responses to the data table.

**Save Residuals**   Saves the residuals to the data table.

**Model Dialog**   Shows the completed launch window for the current analysis.

See *Using JMP* for more information about the following options:
**Local Data Filter**  Shows or hides the local data filter that enables you to filter the data used in a specific report.

**Redo**  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

**Save Script**  Contains options that enable you to save a script that reproduces the report to several destinations.

**Save By-Group Script**  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.

---

**Response Specification**

Specify the response designs for various tests using the Response Specification panel.

**Figure 9.3  Response Specification Panel**

![Response Specification Panel]

**Choose Response**  Provides choices for the M matrix. See “Choose Response Options” on page 443.

**Univariate Tests Also**  Obtains adjusted and unadjusted univariate repeated measures tests and multivariate tests. Use in repeated measures models.

**Test Each Column Separately Also**  Obtains univariate ANOVA tests and multivariate tests on each response.

The following buttons are available only after you have chosen a response option:

**Run**  Performs the analysis and shows the multivariate estimates and tests. See “Multivariate Tests” on page 447.

**Help**  Shows the Help for the Response Specification panel.

**Orthogonalize**  Orthonormalizes the matrix. Orthonormalization is done after the column contrasts (sum to zero) for all response types except Sum.

**Delete Last Column**  Reduces the dimensionality of the transformation.
Choose Response Options

The response design forms the M matrix. The columns of an M matrix define a set of transformation variables for the multivariate analysis. The Choose Response button contains the following options for the M matrix:

**Repeated Measures**  Constructs and runs both Sum and Contrast responses.

**Sum**  Sum of the responses that gives a single value.

**Identity**  Uses each separate response, the identity matrix.

**Contrast**  Compares each response and the first response.

**Polynomial**  Constructs a matrix of orthogonal polynomials.

**Helmert**  Compares each response with the combined responses listed below it.

**Profile**  Compares each response with the following response.

**Mean**  Compares each response with the mean of the others.

**Compound**  Creates and runs several response functions that are appropriate if the responses are compounded from two effects.

**Custom**  Uses any custom M matrix that you enter.

The most typical response designs are **Repeated Measures** and **Identity** for multivariate regression. There is little difference in the tests given by the **Contrast**, **Helmert**, **Profile**, and **Mean** options, since they span the same space. However, the tests and details in the Least Squares means and Parameter Estimates tables for them show correspondingly different highlights.

The **Repeated Measures** and the **Compound** options display dialogs to specify response effect names. They then fit several response functions without waiting for further user input. Otherwise, selections expand the control panel and give you more opportunities to refine the specification.

Custom Test Option

Set up custom tests of effect levels using the **Custom Test** option.

**Note:** For instructions on how to create custom tests, see “Custom Test” on page 124 in the “Standard Least Squares Models” chapter.
Options for Model Effects

The menu icon beside each effect name gives you the following options to request additional information about the multivariate fit:

**Test Details** Displays the eigenvalues and eigenvectors of the $E^{-1}H$ matrix used to construct multivariate test statistics. See “Test Details” on page 444.

**Centroid Plot** Plots the centroids (multivariate least squares means) on the first two canonical variables formed from the test space. See “Centroid Plot” on page 445.

**Save Canonical Scores** Saves variables called Canon[1], Canon[2], and so on, as columns in the current data table. These columns have both the values and their formulas. For an example, see “Save Canonical Scores” on page 446. For technical details, see “Canonical Details” on page 460.

**Contrast** Performs the statistical contrasts of treatment levels that you specify in the contrasts dialog.

---

**Note:** The Contrast command is the same as for regression with a single response. See the “LSMeans Contrast” on page 102 in the “Standard Least Squares Models” chapter, for a description and examples of the LSMeans Contrast commands.

---

**Test Details**

The Test Details report gives canonical details about the test for the whole model or the specified effect.

**Eigenvalue** The eigenvalues of the $E^{-1}H$ matrix used in computing the multivariate test statistics.

**Canonical Corr** The canonical correlations associated with each eigenvalue. This is the canonical correlation of the transformed responses with the effects, corrected for all other effects in the model.

**Eigvec** The eigenvectors of the $E^{-1}H$ matrix, or equivalently of $(E + H)^{-1}H$.

**Example of Test Details**

1. Select Help > Sample Data Library and open Iris.jmp.
   
   The Iris data (Mardia et al. 1979) have three levels of Species named Virginica, Setosa, and Versicolor. There are four measures (Petal length, Petal width, Sepal length, and Sepal width) taken on each sample.

2. Select Analyze > Fit Model.

3. Select Petal length, Petal width, Sepal length, and Sepal width and click Y.
4. Select Species and click Add.
5. For Personality, select Manova.
6. Click Run.
7. Click the Choose Response button and select Identity.
8. Click Run.
9. Click the Species red triangle and select Test Details.

The eigenvalues, eigenvectors, and canonical correlations appear.

Centroid Plot

The Centroid Plot command (accessed from the Species red triangle) plots the centroids (multivariate least squares means) on the first two canonical variables formed from the test space, as in Figure 9.5. The first canonical axis is the vertical axis so that if the test space is only one dimensional the centroids align on a vertical axis. The centroid points appear with a circle corresponding to the 95% confidence region (Mardia et al. 1979). When centroid plots are created under effect tests, circles corresponding to the effect being tested appear in red. Other circles appear blue. Biplot rays show the directions of the original response variables in the test space. See “Details for Centroid Plot Option” on page 461.

Click the Centroid Val disclosure icon to show additional information, shown in Figure 9.5.

The first canonical axis with an eigenvalue accounts for much more separation than does the second axis. The means are well separated (discriminated), with the first group farther apart than the other two. The first canonical variable seems to load the petal length variables against the petal width variables. Relationships among groups of variables can be verified with Biplot Rays and the associated eigenvectors.
Figure 9.5  Centroid Plot and Centroid Values

Save Canonical Scores

Saves columns called Canon[i] to the data table, where $i$ refers to the $i^{th}$ canonical score for the $Y$ variables. The canonical scores are computed based on the $E^{-1}H$ matrix used to construct the multivariate test statistic. Canonical scores are saved for eigenvectors corresponding to nonzero eigenvalues.

Canonical Correlation

Canonical correlation analysis is not a specific command, but it can be performed using a sequence of commands in the multivariate fitting platform.

1. Follow step 1 through step 8 in “Example of Test Details” on page 444.
2. Click the Whole Model red triangle and select Test Details.
3. Click the Whole Model red triangle and select Save Canonical Scores.

The details list the canonical correlations (Canonical Corr) next to the eigenvalues. The saved variables are called Canon[1], Canon[2], and so on. These columns contain both the values and their formulas.

To obtain the canonical variables for the $X$ side, repeat the same steps, but interchange the $X$ and $Y$ variables. If you already have the columns Canon[n] appended to the data table, the new columns are called Canon[n] 2 (or another number) that makes the name unique.

This is an additional example of canonical correlation analysis.

1. Select Help > Sample Data Library and open Exercise.jmp.
2. Select **Analyze > Fit Model**.
3. Select chins, situps, and jumps and click **Y**.
4. Select weight, waist, and pulse and click **Add**.
5. For **Personality**, select **Manova**.
6. Click **Run**.
7. Click the **Choose Response** button and select **Identity**.
8. Click **Run**.
9. Click the Whole Model red triangle and select **Test Details**.
10. Click the Whole Model red triangle and select **Save Canonical Scores**.

</tr>
</tbody>
</table>

The output canonical variables use the eigenvectors shown as the linear combination of the $Y$ variables. For example, Canon[1] is calculated as follows:

$$0.02503681 \times \text{chins} + 0.00637953 \times \text{situps} - 0.0052909 \times \text{jumps}$$

This canonical analysis does not produce a standardized variable with mean 0 and standard deviation 1, but it is easy to define a new standardized variable with the calculator that has these features.

**Multivariate Tests**

**Example Choosing a Response**

1. Complete step 1 through step 6 in “Example of a Multiple Response Model” on page 439.
2. Click the **Choose Response** button and select **Identity**.
3. Click **Run**.
The **M Matrix** report gives the response design that you specified. The **M-transformed Parameter Estimates** report gives the original parameter estimates matrix multiplied by the transpose of the M matrix.

**Note:** Initially in this chapter, the matrix names E and H refer to the error and hypothesis cross products. After specification of a response design, E and H refer to those matrices transformed by the response design, which are actually \( M'EM \) and \( M'HM \).

### The Extended Multivariate Report

In multivariate fits, the sums of squares due to hypothesis and error are matrices of squares and cross products instead of single numbers. And there are lots of ways to measure how large a value the matrix for the hypothesis sums of squares and cross products (called **H** or **SSCP**) is compared to that matrix for the residual (called E). JMP reports the four multivariate tests that are commonly described in the literature. If you are looking for a test at an exact significance level, you might need to go hunting for tables in reference books. Fortunately, all four tests can be transformed into an approximate \( F \) test. If the response design yields a single value, or if the hypothesis is a single degree of freedom, the multivariate tests are equivalent and yield the same exact \( F \) test. JMP labels the test **Exact F**. Otherwise, JMP labels it **Approx. F**.

In the golf balls example, there is only one effect, so the Whole Model test and the test for **Brand** are the same, which show the four multivariate tests with approximate \( F \) tests. There is only a single intercept with two DF (one for each response), so the \( F \) test for it is exact and is labeled **Exact F**.

The red triangle menus on the Whole Model, Intercept, and Brand reports contain options to generate additional information, which includes eigenvalues, canonical correlations, a list of centroid values, a centroid plot, and a **Save** command that lets you save canonical variates.
The effect (Brand in this example) pop-up menu also includes the option to specify contrasts.

The custom test and contrast features are the same as those for regression with a single response. See the “Standard Least Squares Models” chapter on page 73.

To see formulas for the MANOVA table tests, see “Multivariate Tests” on page 458.

The extended Multivariate Report contains the following columns:

**Test**  Labels each statistical test in the table. If the number of response function values (columns specified in the \( M \) matrix) is 1 or if an effect has only one degree of freedom per response function, the exact \( F \) test is presented. Otherwise, the standard four multivariate test statistics are given with approximate \( F \) tests: Wilks’ Lambda (\( \Lambda \)), Pillai’s Trace, the Hotelling-Lawley Trace, and Roy’s Maximum Root.

**Value**  Value of each multivariate statistical test in the report.

**Approx. F** (or Exact \( F \))  \( F \)-values corresponding to the multivariate tests. If the response design yields a single value or if the test is one degree of freedom, this is an exact \( F \) test.

**NumDF**  Numerator degrees of freedom.

**DenDF**  Denominator degrees of freedom.

**Prob>F**  Significance probability corresponding to the \( F \)-value.

**Note:** For more information about the Sphericity Test table, see “Univariate Tests and the Test for Sphericity” on page 450.

### Comparison of Multivariate Tests

Although the four standard multivariate tests often give similar results, there are situations where they differ, and one might have advantages over another. Unfortunately, there is no clear winner. In general, here is the order of preference in terms of power:

1. Pillai’s Trace
2. Wilks’ Lambda
3. Hotelling-Lawley Trace
4. Roy’s Maximum Root

When there is a large deviation from the null hypothesis and the eigenvalues differ widely, the order of preference is the reverse (Seber 1984).
Univariate Tests and the Test for Sphericity

There are cases, such as a repeated measures model, that allow transformation of a multivariate problem into a univariate problem (Huynh and Feldt 1970). Using univariate tests in a multivariate context is valid in the following situations:

- If the response design matrix $M$ is orthonormal ($M'M = \text{Identity}$).
- If $M$ yields more than one response the coefficients of each transformation sum to zero.
- If the sphericity condition is met. The sphericity condition means that the $M$-transformed responses are uncorrelated and have the same variance. $M'\Sigma M$ is proportional to an identity matrix, where $\Sigma$ is the covariance of the $Y$ variables.

If these conditions hold, the diagonal elements of the $E$ and $H$ test matrices sum to make a univariate sums of squares for the denominator and numerator of an $F$ test. Note that if the above conditions do not hold, then an error message appears. In the case of Golf Balls.jmp, an identity matrix is specified as the $M$-matrix. Identity matrices cannot be transformed to a full rank matrix after centralization of column vectors and orthonormalization. So the univariate request is ignored.

Example of Univariate and Sphericity Test

1. Select Help > Sample Data Library and open Dogs.jmp.
2. Select Analyze > Fit Model.
3. Select LogHist0, LogHist1, LogHist3, and LogHist5 and click Y.
4. Select drug and dep1 and click Add.
5. In the Construct Model Effects panel, select drug. In the Select Columns panel, select dep1. Click Cross.
6. For Personality, select Manova.
7. Click Run.
8. Select the check box next to Univariate Tests Also.
9. In the Choose Response menu, select Repeated Measures.
   Time should be entered for YName, and Univariate Tests Also should be selected.
10. Click OK.

Figure 9.8  Sphericity Test
The sphericity test checks the appropriateness of an unadjusted univariate $F$ test for the within-subject effects using the Mauchly criterion to test the sphericity assumption (Anderson 1958). The sphericity test and the univariate tests are always done using an orthonormalized $M$ matrix. Use the following guidelines to interpret the sphericity test:

- If the true covariance structure is spherical, you can use the unadjusted univariate $F$ tests.
- If the sphericity test is significant, the test suggests that the true covariance structure is not spherical. Therefore, you can use the multivariate or the adjusted univariate tests.

The univariate $F$ statistic has an approximate $F$ distribution even without sphericity, but the degrees of freedom for numerator and denominator are reduced by some fraction epsilon ($\epsilon$). Box (1954), Greenhouse and Geisser (1959), and Huynh-Feldt (1976) offer techniques for estimating the epsilon degrees-of-freedom adjustment. Muller and Barton (1989) recommend the Greenhouse-Geisser version, based on a study of power.

The epsilon adjusted tests in the multivariate report are labeled G-G (Greenhouse-Geisser) or H-F (Huynh-Feldt). The epsilon adjustment is shown in the value column.

---

**Multivariate Model with Repeated Measures**

One common use of multivariate fitting is to analyze data with repeated measures, also called longitudinal data. A subject is measured repeatedly across time, and the data are arranged so that each of the time measurements form a variable. Because of correlation between the measurements, data should not be stacked into a single column and analyzed as a univariate model unless the correlations form a pattern termed sphericity. See the previous section, “Univariate Tests and the Test for Sphericity” on page 450, for more information about this topic.

With repeated measures, the analysis is divided into two layers:

- Between-subject (or across-subject) effects are modeled by fitting the sum of the repeated measures columns to the model effects. This corresponds to using the **Sum** response function. This response function is an $M$-matrix that is a single vector of 1s.

- Within-subjects effects (repeated effects, or time effects) are modeled with a response function that fits differences in the repeated measures columns. This analysis can be done using the **Contrast** response function or any of the other similar differencing functions: **Polynomial**, **Helmert**, **Profile**, or **Mean**. When you model differences across the repeated measures, think of the differences as being a new within-subjects effect, usually time. When you fit effects in the model, interpret them as the interaction with the within-subjects effect. For example, the effect for Intercept becomes the Time (within-subject) effect, showing overall differences across the repeated measures. If you have an effect $A$, the within-subjects tests are interpreted to be the tests for the $A*Time$ interaction.
interaction, which model how the differences across repeated measures vary across the A effect.

Table 9.1 on page 453 shows the relationship between the response function and the model effects compared with what a univariate model specification would be. Using both the Sum (between-subjects) and Contrast (within-subjects) models, you should be able to reconstruct the tests that would have resulted from stacking the responses into a single column and obtaining a standard univariate fit.

There is a direct and an indirect way to perform the repeated measures analyses:

- The direct way is to use the pop-up menu item Repeated Measures. This prompts you to name the effect that represents the within-subject effect across the repeated measures. Then it fits both the Contrast and the Sum response functions. An advantage of this way is that the effects are labeled appropriately with the within-subjects effect name.

- The indirect way is to specify the two response functions individually. First, do the Sum response function and second, do either Contrast or one of the other functions that model differences. You need to remember to associate the within-subjects effect with the model effects in the contrast fit.

**Repeated Measures Example**

For example, consider a study by Cole and Grizzle (1966). The results are in the Dogs.jmp table in the sample data folder. Sixteen dogs are assigned to four groups defined by variables drug and dep1, each having two levels. The dependent variable is the blood concentration of histamine at 0, 1, 3, and 5 minutes after injection of the drug. The log of the concentration is used to minimize the correlation between the mean and variance of the data.

1. Select Help > Sample Data Library and open Dogs.jmp.
2. Select Analyze > Fit Model.
3. Select LogHist0, LogHist1, LogHist3, and LogHist5 and click Y.
4. Select drug and dep1 and select Full Factorial from the Macros menu.
5. For Personality, select Manova.
6. Click Run.
7. In the Choose Response menu, select Repeated Measures.
   Time should be entered for YName. If you check the Univariate Tests Also check box, the report includes univariate tests, which are calculated as if the responses were stacked into a single column.
8. Click OK.
Table 9.1 shows how the multivariate tests for a **Sum** and **Contrast** response designs correspond to how univariate tests would be labeled if the data for columns LogHist0, LogHist1, LogHist3, and LogHist5 were stacked into a single $Y$ column. The new rows are identified with a nominal grouping variable, Time.

<table>
<thead>
<tr>
<th><strong>Sum M-Matrix</strong></th>
<th><strong>Contrast M-Matrix</strong></th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Between Subjects</strong></td>
<td><strong>Within Subjects</strong></td>

<td>Univariate Test</td>
</tr>
<tr>
<td>Intercept</td>
<td>Intercept</td>
</tr>
<tr>
<td>Drug</td>
<td>Drug</td>
</tr>
<tr>
<td>Depl</td>
<td>Depl</td>
</tr>
</tbody>
</table>

The between-subjects analysis is produced first. This analysis is the same (except titling) as it would have been if **Sum** had been selected on the pop-up menu.

The within-subjects analysis is produced next. This analysis is the same (except titling) as it would have been if **Contrast** had been selected on the pop-up menu, though the within-subject effect name (Time) has been added to the effect names in the report. Note that the position formerly occupied by Intercept is Time, because the intercept term is estimating overall differences across the repeated measurements.
Example of a Compound Multivariate Model

JMP can handle data with layers of repeated measures. For example, see the Cholesterol.jmp data table. Groups of five participants belong to one of four treatment groups called A, B, Control, and Placebo. Cholesterol was measured in the morning and again in the afternoon once a month for three months (the data are fictional). In this example, the response columns are arranged chronologically with time of day within month.

1. Select Help > Sample Data Library and open Cholesterol.jmp.
2. Select Analyze > Fit Model.
3. Select April AM, April PM, May AM, May PM, June AM, and June PM and click Y.
4. Select treatment and click Add.
5. Next to Personality, select Manova.
6. Click Run.

**Figure 9.10** Treatment Graph

In the treatment graph, you can see that the four treatment groups began the study with very similar mean cholesterol values. The A and B treatment groups appear to have lower cholesterol values at the end of the trial period. The control and placebo groups remain unchanged.

7. Click the Choose Response menu and select Compound.

Complete this window to tell JMP how the responses are arranged in the data table and the number of levels of each response. In the cholesterol example, the time of day columns are arranged within month. Therefore, you name time of day as one factor and the month effect as the other factor. Testing the interaction effect is optional.

8. Use the options in Figure 9.11 to complete the window.
9. Click **OK**.

The tests for each effect appear. Parts of the report are shown in Figure 9.12. Note the following:

- The report for Time shows a $p$-value of 0.6038 for the interaction between Time and treatment, indicating that the interaction is not significant. This means that there is no evidence of a difference in treatment between AM and PM. Since Time has two levels (AM and PM), the exact $F$ test appears.

- The report for Month shows $p$-values of <.0001 for the interaction between Month and treatment, indicating that the interaction is significant. This suggests that the differences between treatment groups change depending on the month. The treatment graph in Figure 9.10 indicates no difference among the groups in April, but the difference between treatment types (A, B, Control, and Placebo) becomes large in May and even larger in June.

- The report for Time*Month shows no significant $p$-values for treatment. This indicates that the three-way interaction effect involving Time, Month, and treatment is not statistically significant.
Discriminant analysis is a method of predicting some level of a one-way classification based on known values of the responses. The technique is based on how close the measurement variables are to the multivariate means of the levels being predicted. Discriminant analysis is more fully implemented using the Discriminant Platform. See *Multivariate Methods*.

In JMP, you specify the measurement variables as $Y$ effects and the classification variable as a single $X$ effect. The multivariate fitting platform gives estimates of the means and the covariance matrix for the data, assuming that the covariances are the same for each group. You obtain discriminant information with the **Save Discrim** option in the pop-up menu next to the MANOVA platform name. This command saves distances and probabilities as columns in the current data table using the initial $E$ and $H$ matrices.
For a classification variable with \( k \) levels, JMP adds \( k \) distance columns, \( k \) classification probability columns, the predicted classification column, and two columns of other computational information to the current data table.

**Example of the Save Discrim Option**

Examine Fisher’s Iris data as found in Mardia et al. (1979). There are \( k = 3 \) levels of species and four measures on each sample.

1. Select **Help > Sample Data Library** and open Iris.jmp.
2. Select **Analyze > Fit Model**.
3. Select Sepal length, Sepal width, Petal length, and Petal width and click **Y**.
4. Select Species and click **Add**.
5. Next to Personality, select **Manova**.
6. Click **Run**.
7. Click the Manova Fit red triangle and select **Save Discrim**.

The following columns are added to the Iris.jmp sample data table:

- **SqDist[0]** Quadratic form needed in the Mahalanobis distance calculations.
- **SqDist[setosa]** Mahalanobis distance of the observation from the Setosa centroid.
- **SqDist[versicolor]** Mahalanobis distance of the observation from the Versicolor centroid.
- **SqDist[virginica]** Mahalanobis distance of the observation from the Virginica centroid.
- **Prob[0]** Sum of the negative exponentials of the Mahalanobis distances, used below.
- **Prob[setosa]** Probability of being in the Setosa category.
- **Prob[versicolor]** Probability of being in the Versicolor category.
- **Prob[virginica]** Probability of being in the Virginica category.
- **Pred Species** Species that is most likely from the probabilities.

Now you can use the new columns in the data table with other JMP platforms to summarize the discriminant analysis with reports and graphs. For example:

1. From the updated Iris.jmp data table (that contains the new columns) select **Analyze > Fit Y by X**.
2. Select Species and click **Y, Response**.
3. Select Pred Species and click **X, Factor**.
4. Click **OK**.
The Contingency Table summarizes the discriminant classifications. Three misclassifications are identified.

**Figure 9.13** Contingency Table of Predicted and Actual Species

**Statistical Details for the Manova Personality**

- “Multivariate Tests”
- “Approximate F-Tests”
- “Canonical Details”

**Multivariate Tests**

In the following, \( E \) is the residual cross product matrix and \( H \) is the model cross product matrix. Diagonal elements of \( E \) are the residual sums of squares for each variable. Diagonal elements of \( H \) are the sums of squares for the model for each variable. In the discriminant analysis literature, \( E \) is often called \( W \), where \( W \) stands for *within*.

Test statistics in the multivariate results tables are functions of the eigenvalues \( \lambda \) of \( E^{-1}H \). The following list describes the computation of each test statistic.

**Note:** After specification of a response design, the initial \( E \) and \( H \) matrices are premultiplied by \( M' \) and postmultiplied by \( M \).

- Wilks’ Lambda
Chapter 9
Multivariate Response Models

Fitting Linear Models Statistical Details for the Manova Personality

- Pillai’s Trace

\[ \Lambda = \frac{\det(E)}{\det(H + E)} = \prod_{i=1}^{n} \left( \frac{1}{1 + \lambda_i} \right) \]

- Hotelling-Lawley Trace

\[ V = \text{Trace}[H(H + E)^{-1}] = \sum_{i=1}^{n} \frac{\lambda_i}{1 + \lambda_i} \]

- Roy’s Max Root

\[ \Theta = \lambda_1, \text{ the maximum eigenvalue of } E^{-1}H. \]

E and H are defined as follows:

\[ E = Y'Y - b'(X'X)b \]
\[ H = (Lb)'(L(X'X)^{-1}L')^{-1}(Lb) \]

where b is the estimated vector for the model coefficients and \( A^{-1} \) denotes the generalized inverse of a matrix A.

The whole model L is a column of zeros (for the intercept) concatenated with an identity matrix having the number of rows and columns equal to the number of parameters in the model. L matrices for effects are subsets of rows from the whole model L matrix.

**Approximate F-Tests**

To compute F-values and degrees of freedom, let \( p \) be the rank of \( H + E \). Let \( q \) be the rank of \( L(X'X)^{-1}L' \), where the L matrix identifies elements of \( X'X \) associated with the effect being tested. Let \( v \) be the error degrees of freedom and \( s \) be the minimum of \( p \) and \( q \). Also let \( m = 0.5(|p - q| - 1) \) and \( n = 0.5(v - p - 1) \).

Table 9.2 on page 460, gives the computation of each approximate F from the corresponding test statistic.

Canonical Details

Details for the Test Details Option

When you select the Test Details option for a given test, eigenvalues, canonical correlations, and eigenvectors are shown in the report.

The canonical correlations produced by the Test Details option are computed as follows:

$$\rho_i = \sqrt{\frac{\lambda_i}{1 + \lambda_i}}$$

where $\lambda_i$ is the $i^{th}$ eigenvalue of the $E^{-1}H$ matrix used in computing the multivariate test statistics.

The matrix labeled Eigvec is the $V$ matrix, which is the matrix of eigenvectors of $E^{-1}H$ for the given test.

Note: The $E$ and $H$ matrices for the given test refer to $M'EM$ and $M'HM$ in terms of the original $E$ and $H$ matrices. The $M$ matrix is defined by the response design. The $E$ and $H$ used in this section are defined in “Multivariate Tests” on page 458.
Details for Centroid Plot Option

The total sample centroid and centroid values for effects are computed as follows:

\[ \text{Grand} = (c'_1 \tilde{y}, c'_2 \tilde{y}, \ldots, c'_g \tilde{y}) \]

\[ \text{Effect}_j = (c'_1 \tilde{x}_j, c'_2 \tilde{x}_j, \ldots, c'_g \tilde{x}_j) \]

where

\[ c_i = \left( v'_i \left( \frac{E}{N - r} \right) v_i \right)^{-1/2} v_i \]

\( N \) is the number of observations
\( v_i \) is the \( i^{th} \) column of \( V \), the eigenvector matrix of \( E^{-1}H \) for the given test
\( \tilde{x}_j \) is the multivariate least squares mean for the \( j^{th} \) effect
\( \tilde{y} \) is the overall mean of the responses
\( g \) is the number of eigenvalues of \( E^{-1}H \) greater than 0
\( r \) is the rank of the \( X \) matrix

**Note:** The \( E \) and \( H \) matrices for the given test refer to \( M'EM \) and \( M'HM \) in terms of the original \( E \) and \( H \) matrices. The \( M \) matrix is defined by the response design. The \( E \) and \( H \) used in this section are defined in “Multivariate Tests” on page 458.

The centroid radii for effects are calculated as follows:

\[ d = \sqrt{\frac{\chi^2_g(0.95)}{L(X'X)^{-1}L'}} \]

where \( g \) is the number of eigenvalues of \( E^{-1}H \) greater than 0 and the \( L \) matrices in the denominator are from the multivariate least squares means calculations.

Details for the Save Canonical Scores Option

The canonical \( Y \) values are calculated as follows:

\[ \tilde{Y} = YM'V \]

where

\( Y \) is the matrix of response variables
\( M' \) is the transpose of the response design matrix
\( V \) is the matrix of eigenvectors of \( E^{-1}H \) for the given test
Note: The \( E \) and \( H \) matrices for the given test refer to \( M'EM \) and \( M'HM \) in terms of the original \( E \) and \( H \) matrices. The \( M \) matrix is defined by the response design. The \( E \) and \( H \) used in this section are defined in “Multivariate Tests” on page 458.

Canonical Y values are saved for eigenvectors corresponding to eigenvalues larger than zero.
Chapter 10

Loglinear Variance Models
Model the Variance and the Mean of the Response

The Loglinear Variance personality of the Fit Model platform enables you to model both the expected value and the variance of a response using regression models. The log of the variance is fit to one linear model and the expected response is fit to a different linear model simultaneously.

Note: The estimates are demanding in their need for a lot of well-designed, well-fitting data. You need more data to fit variances than you do means.

For many engineers, the goal of an experiment is not to maximize or minimize the response itself, but to aim at a target response and achieve minimum variability. The loglinear variance model provides a very general and effective way to model variances, and can be used for unreplicated data, as well as data with replications.

Overview of the Loglinear Variance Model

The loglinear-variance model provides a way to model the variance simply through a linear model. See Harvey (1976), Cook and Weisberg (1983), Aitken (1987), and Carroll and Ruppert (1988). In addition to having regressor terms to model the mean response, there are regressor terms in a linear model to model the log of the variance:

mean model: \( E(y) = X\beta \)

variance model: \( \log(\text{Variance}(y)) = Z\lambda \),

or equivalently

\( \text{Variance}(y) = \exp(Z\lambda) \)

where the columns of \( X \) are the regressors for the mean of the response, and the columns of \( Z \) are the regressors for the variance of the response. The regular linear model parameters are represented by \( \beta \), and \( \lambda \) represents the parameters of the variance model.

Log-linear variance models are estimated using REML.

A dispersion or log-variance effect can model changes in the variance of the response. This is implemented in the Fit Model platform by a fitting personality called the Loglinear Variance personality.

Dispersion Effects

Modeling dispersion effects is not very widely covered in textbooks, with the exception of the Taguchi framework. In a Taguchi-style experiment, this is handled by taking multiple measurements across settings of an outer array, constructing a new response that measures the variability off-target across this outer array, and then fitting the model to find out the factors that produce minimum variability. This type of modeling requires a specialized design that is a complete Cartesian product of two designs. The method of this chapter models variances in a more flexible, model-based approach. The particular performance statistic that Taguchi recommends for variability modeling is \( STD = -\log(s) \). In the methodology used in JMP, the \( \log(s^2) \) is modeled and combined with a model that has a mean. The two are basically equivalent, since \( \log(s^2) = 2 \log(s) \).

Model Specification

Log-linear variance effects are specified in the Fit Model dialog by highlighting them and selecting LogVariance Effect from the Attributes drop-down menu. LogVariance appears at the end of the effect. When you use this attribute, it also changes the fitting Personality at the top to LogLinear Variance. If you want an effect to be used for both the mean and variance of the response, then you must specify it twice, once with the LogVariance option.
The effects that you specify with the log-variance attribute become the effects that generate the $Zs$ in the model, and the other effects become the $Xs$ in the model.

**Notes**

Every time another parameter is estimated for the mean model, at least one more observation is needed, and preferably more. But with variance parameters, several more observations for each variance parameter are needed to obtain reasonable estimates. It takes more data to estimate variances than it does means.

The log-linear variance model is a very flexible way to fit dispersion effects, and the method deserves much more attention than it has received so far in the literature.

**Launch the Loglinear Variance Personality**

Launch the Loglinear Variance personality by selecting **Analyze > Fit Model**, entering one or more columns for **Y**, and selecting **Loglinear Variance** from the **Personality** menu.

**Figure 10.1** Fit Model Launch Window with Loglinear Variance Selected

For more information about aspects of the Fit Model window that are common to all personalities, see the “**Model Specification**” chapter on page 29. For more information about the options in the Select Columns red triangle menu, see *Using JMP*. Information specific to the Loglinear Variance personality is presented here.
If your model effects have missing values, you can treat these missing values as informative categories. Select the Informative Missing option from the Model Specification red triangle menu.

**Example Using Loglinear Variance**

The data table InjectionMolding.jmp contains the experimental results from a 7-factor $2^{7-3}$ fractional factorial design with four added centerpoints (Montgomery 1991). Preliminary investigation determined that the mean response only seemed to vary with the first two factors, Mold Temperature, and Screw Speed, and the variance seemed to be affected by Holding Time.

**Figure 10.2 Injection Molding Data**

1. Select Help > Sample Data Library and open InjectionMolding.jmp.
2. Select Analyze > Fit Model.

Since the variables in the data table have been assigned preselected roles, the analysis runs automatically.
The Mean Model for Shrinkage report gives the parameters for the mean model, and the Variance Model for Shrinkage report gives the parameters for the variance model.
The Loglinear Report

The top portion of the resulting report shows the fitting of the Expected response. “Description of the Fit Statistics Report” on page 373 describes how the fit statistics are calculated. The Parameter Estimates and Fixed Effect Tests are similar to reports found in the standard least squares personality, though they are derived from restricted maximum likelihood (REML).

Figure 10.4  Mean Model Output

Figure 10.5  Variance Model Output

The second portion of the report shows the fit of the variance model. The Variance Parameter Estimates report shows the estimates and relevant statistics. Two hidden columns are provided:

- The hidden column exp(Estimate) is the exponential of the estimate. So, if the factors are coded to have +1 and -1 values, then the +1 level for a factor multiplies the variance by the
\(\exp(\text{Estimate})\) value. Likewise, the -1 level multiplies the variance by the reciprocal of this column. To see a hidden column, right-click the report and select the name of the column from the **Columns** menu that appears.

- The hidden column labeled \(\exp(2|\text{Estimate}|)\) is the ratio of the higher to the lower variance if the regressor has the range -1 to +1.

The report also shows the standard error, chi-square, \(p\)-value, and profile likelihood confidence limits of each estimate. The residual parameter is the overall estimate of the variance, given all other regressors are zero.

Does the variance model fit significantly better than the original model? The likelihood ratio test for this question compares the fitted model with the model where all parameters are zero except the intercept, the model of equal-variance. In this case the \(p\)-value is highly significant. Changes in **Hold Time** change the variance.

The **Variance Effect Likelihood Ratio Tests** refit the model without each term in turn to create the likelihood ratio tests. These are generally more trusted than Wald tests.

---

**Loglinear Platform Options**

The Loglinear Variance Fit menu contains the following options:

- **Save Columns**  Creates one or more columns in the data table. See “Save Columns” on page 471.

- **Row Diagnostics**  Plots row diagnostics. See “Row Diagnostics” on page 471.

- **Profiler**  Opens the Profiler, Contour Profiler, or Surface Profiler. See “Factor Profiling” on page 163 in the “Standard Least Squares Models” chapter.

- **Model Dialog**  Shows the completed launch window for the current analysis.

See *Using JMP* for more information about the following options:

- **Local Data Filter**  Shows or hides the local data filter that enables you to filter the data used in a specific report.

- **Redo**  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

- **Save Script**  Contains options that enable you to save a script that reproduces the report to several destinations.
Save By-Group Script  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.

Save Columns

The following Save Columns options are available:

Prediction Formula  Creates a new column called Mean. The new column contains the predicted values for the mean, as computed by the specified model.

Variance Formula  Creates a new column called Variance. The new column contains the predicted values for the variance, as computed by the specified model.

Std Dev Formula  Creates a new column called Std Dev. The new column contains the predicted values for the standard deviation, as computed by the specified model.

Residuals  Creates a new column called Residual that contains the residuals, which are the observed response values minus predicted values. See “Examining the Residuals” on page 472.

Studentized Residuals  Creates a new column called Studentized Resid. The new column values are the residuals divided by their standard error.

Std Error of Predicted  Creates a new column called Std Err Pred. The new column contains the standard errors of the predicted values.

Std Error of Individual  Creates a new column called Std Err Indiv. The new column contains the standard errors of the individual predicted values.

Mean Confidence Interval  Creates two new columns, Lower 95% Mean and Upper 95% Mean. The new columns contain the bounds for a confidence interval for the prediction mean.

Indiv Confidence Interval  Creates two new columns, Lower 95% Indiv and Upper 95% Indiv. The new columns contain confidence limits for individual response values.

Row Diagnostics

The following Row Diagnostics options are available:

Plot Actual by Predicted  Plots the observed values by the predicted values of Y. This is the leverage plot for the whole model.

Plot Studentized Residual by Predicted  Plots the Studentized residuals by the predicted values of Y.
Examining the Residuals

To see the dispersion effect, follow these steps:

1. Select Help > Sample Data Library and open InjectionMolding.jmp.
2. Select Analyze > Fit Model.
   Since the variables in the data table have been assigned preselected roles, the analysis runs automatically.
3. Click the Loglinear Variance Fit red triangle and select Save Columns > Residuals.
4. In the InjectionMolding.jmp sample data table, right-click the continuous icon next to Hold Time in the Columns panel, and select Nominal.
5. Select Analyze > Fit Y by X.
7. Select Hold Time and click X, Factor.
8. Click OK.

Figure 10.6  Residual by Dispersion Effect

In this plot it is easy to see the variance go up as the Hold Time increases. This is done by treating Hold Time as a nominal factor.
Profiling the Fitted Model

Use the Profiler, Contour Profiler, or Surface Profiler to gain further insight into the fitted model. To select a profiler option, click the Loglinear Variance Fit red triangle and select one of the options under the Profilers menu.

Example of Profiling the Fitted Model

For example, suppose that the goal was to find the factor settings that achieved a target of 35 for the response, but at the smallest variance. Fit the models and choose Profiler from the report menu. For example, Figure 10.7 shows the Profiler set up to match a target value for a mean and to minimize variance.

1. Select Help > Sample Data Library and open InjectionMolding.jmp.
2. Select Analyze > Fit Model.
   Since the variables in the data table have been assigned preselected roles, the analysis runs automatically.
3. Click the Loglinear Variance Fit red triangle and select Profilers > Profiler.
4. Click the Prediction Profiler red triangle and select Optimization and Desirability > Set Desirabilities.
5. In the Response Goal window that appears, change Maximize to Match Target.
6. Click OK.
7. In the second Response Goal window, click OK.
8. Click the Prediction Profiler red triangle and select Optimization and Desirability > Maximize Desirability.
9. Click the Prediction Profiler red triangle and select Prediction Intervals.
One of the best ways to see the relationship between the mean and the variance (both modeled with the LogVariance personality) is through looking at the individual prediction confidence intervals about the mean. Regular confidence intervals (those shown by default in the Profiler) do not show information about the variance model as well as individual prediction confidence intervals do. Prediction intervals show both the mean and variance model in one graph.

If $Y$ is the modeled response, and you want a prediction interval for a new observation at $x_n$, then:

$$s^2|x_n = s^2_Y|x_n + s^2_Y|x_n$$

where:

- $s^2|x_n$ is the variance for the individual prediction at $x_n$
- $s^2_Y|x_n$ is the variance of the distribution of $Y$ at $x_n$
- $s^2_Y|x_n$ is the variance of the sampling distribution of $\hat{Y}$, and is also the variance for the mean.

Because the variance of the individual prediction contains the variance of the distribution of $Y$, the effects of the changing variance for $Y$ can be seen. Not only are the individual prediction intervals wider, but they can change shape with a change in the variance effects.
When your response variable has discrete values, you can use the Fit Model platform to fit a logistic regression model. The Fit Model platform provides two personalities for fitting logistic regression models. The personality that you use depends on the modeling type (Nominal or Ordinal) of your response column.

For nominal response variables, the Nominal Logistic personality fits a linear model to a multi-level logistic response function.

For ordinal response variables, the Ordinal Logistic personality fits the cumulative response probabilities to the logistic distribution function of a linear model.

Both personalities provide likelihood ratio tests for the model, a confusion matrix, and ROC and lift curves. When the response is binary, the Nominal Logistic personality also provides odds ratios (with corresponding confidence intervals).

Overview of the Nominal and Ordinal Logistic Personalities

Logistic regression models the probabilities of the levels of a categorical $Y$ response variable as a function of one or more $X$ effects. The Fit Model platform provides two personalities for fitting logistic regression models. The personality that you use depends on the modeling type (Nominal or Ordinal) of your response column.

For more information about fitting logistic regression models, see Walker and Duncan (1967), Nelson (1976), Harrell (1986), and McCullagh and Nelder (1989).

For more information about the parameterization of the logistic regression model, see “Logistic Regression Model” on page 502.

Nominal Logistic Regression

When the response variable has a nominal modeling type, the platform fits a linear model to a multi-level logistic response function using maximum likelihood. Therefore, all but one response level is modeled by a logistic curve that represents the probability of the response level given the value of the $X$ effects. The probability of the final response level is 1 minus the sum of the other fitted probabilities. As a result, at all values of the $X$ effects, the fitted probabilities for the response levels sum to 1.

If the response variable is binary, you can set the Target Level in the Fit Model window to specify the level whose probability you want to model. By default, the model estimates the probability of the higher level of the response variable.

For more information about fitting models for nominal response variables, see “Nominal Responses” on page 532 in the “Statistical Details” chapter.

Ordinal Logistic Regression

When the response variable has an ordinal modeling type, the platform fits the cumulative response probabilities to the logistic function of a linear model using maximum likelihood. Therefore, the cumulative probability of being at or below each response level is modeled by a curve. The curves are the same for each level except that they are shifted to the right or left.

Tip: If there are many response levels, the ordinal model is much faster to fit and uses less memory than the nominal model.

For more information about fitting models with ordinal response variables, see “Ordinal Responses” on page 533 in the “Statistical Details” chapter.
Other JMP Platforms That Fit Logistic Regression Models

There are many other places in JMP where you can fit logistic regression models:

- To fit logistic regression models with a single continuous main effect, you can use the Fit Y by X platform to see a cumulative logistic probability plot for each effect. See Basic Analysis.
- To perform variable selection in logistic regression models, you can use the Stepwise personality of the Fit Model platform. See the “Stepwise Regression Models” chapter on page 249.
- To fit logistic regression models that use a link function other than the Logit link, you can use the Generalized Linear Model personality of the Fit Model platform. See the “Generalized Linear Models” chapter on page 505.
- To perform variable selection in logistic regression models and fit penalized logistic regression models, you can use the Generalized Regression personality of the Fit Model platform. See the “Generalized Regression Models” chapter on page 283.

Examples of Logistic Regression

This section contains two examples, one for each of the logistic regression personalities in the Fit Model platform (Nominal and Ordinal):

- “Example of Nominal Logistic Regression” on page 478
- “Example of Ordinal Logistic Regression” on page 480

Example of Nominal Logistic Regression

An experiment was performed on metal ingots that were prepared with different heating and soaking times and then tested for readiness to roll. See Cox and Snell (1989). The data are contained in the Ingots.jmp sample data table. In this example, the Fit Model platform fits the probability of the Ready response using a logistic regression model with regressors heat and soak.

1. Select Help > Sample Data Library and open Ingots.jmp.
   The values of the categorical variable ready, Ready and Not Ready, indicate whether an ingot is ready to roll.
2. Select Analyze > Fit Model.
3. Select ready and click Y.
   Because you selected a column with the Nominal modeling type, the Fit Model Personality updates to Nominal Logistic.
Because ready is a Nominal column with only two levels, the Target Level option appears. This option enables you to specify the response level whose probability you want to model.

4. From the Target Level list, select Ready.
   In this model, the Target Level is Ready, so you are modeling the probability of the Ready response.

5. Select heat and soak and click Add.

6. Select count and click Freq.

7. Click Run.
   When the fitting process converges, the nominal regression report appears.

</tr>
</tbody>
</table>
In the Whole Model Test report, the chi-square statistic (11.64) has a small \( p \)-value (0.0030), which indicates that the overall model is significant. However, the parameter estimate for soak has a \( p \)-value of 0.8639, which indicates that soaking time is not statistically significant.

8. Click the red triangle next to Nominal Logistic Fit for ready and select **Profiler**.

**Figure 11.3** Prediction Profiler

When heat is set at 45 and soak is set at 2 the probability of ready is 0.85.

At this point, you might also be interested in using inverse prediction to find the heating time at a specific soaking time and given a particular probability of readiness to roll. See “Example of Inverse Prediction” on page 493 for a continuation of this example.

**Example of Ordinal Logistic Regression**

An experiment was conducted to test whether various cheese additives (A to D) had an effect on cheese taste. Taste was measured by a tasting panel and recorded on an ordinal scale from 1 (strong dislike) to 9 (excellent taste). See McCullagh and Nelder (1989). The data are in the Cheese.jmp sample data table.

1. Select **Help > Sample Data Library** and open Cheese.jmp.
2. Select **Analyze > Fit Model**.
3. Select **Response** and click **Y**.
   
   Because you selected a column with the Ordinal modeling type, the Fit Model Personality updates to Ordinal Logistic.
4. Select **Cheese** and click **Add**.
5. Select **Count** and click **Freq**.
6. Click **Run**.
The model fit in this example reduces the $-\text{LogLikelihood}$ of 429.9 for the intercept-only model to 355.67 for the full model. This reduction yields a likelihood ratio chi-square statistic for the whole model of 148.45 with 3 degrees of freedom. Therefore, the difference in perceived cheese taste is highly significant.

The most preferred cheese additive is the one with the most negative parameter estimate. Cheese[D] does not appear in the Parameter Estimates report, because it does not have its own column of the design matrix. However, Cheese D’s effect can be computed as the negative sum of the others, and is shown in Table 11.1.

**Table 11.1 Preferences for Cheese Additives in Cheese.jmp**

<table>
<thead>
<tr>

</tr>
<tr>
<td>C</td>
<td>0.8477</td>
<td>3rd place</td>
</tr>
</tbody>
</table>
Comparison to Nominal Logistic Model

The Lack of Fit report shows a test of whether the model fits the data well.

As an ordinal problem, each of the first eight response levels has an intercept, but there are only three parameters for the four levels of Cheese. As a result, there are 3 degrees of freedom in the ordinal model. The ordinal model is the Fitted model in the Lack of Fit test.

As a nominal problem, each of the first eight response levels has an intercept as well as three parameters for the four levels of Cheese. As a result, there are $8 \times 3 = 24$ degrees of freedom in the nominal model. Therefore, the nominal model is the Saturated model in the Lack of Fit test.

In this example, the Lack of Fit test for the ordinal model happens to be testing the ordinal response model against the nominal model. The nonsignificance of Lack of Fit leads one to believe that the ordinal model is reasonable.
Launch the Nominal and Ordinal Logistic Personalities

Launch the Nominal Logistic and Ordinal Logistic personalities by selecting **Analyze > Fit Model** and entering one or more non-continuous columns for $Y$. If multiple columns are entered for $Y$, a model for each response is fit.

**Figure 11.5** Fit Model Launch Window with Nominal Logistic Selected

For more information about aspects of the Fit Model window that are common to all personalities, see the “**Model Specification**” chapter on page 29. For more information about the options in the Select Columns red triangle menu, see *Using JMP*. Information specific to the Nominal Logistic and Ordinal Logistic personalities is presented here.

If your model effects have missing values, you can treat these missing values as informative categories. Select the Informative Missing option from the Model Specification red triangle menu.

To specify a model without an intercept term, select the No Intercept option in the Construct Model Effects panel of the Fit Model window. The No Intercept option is not available for the Ordinal Logistic personality.

The event of interest in the logistic regression model is defined by the Target Level option in the Fit Model window. This option is available only when you specify a binary response column in the Nominal Logistic personality.
**Note:** The Logistic personalities in the Fit Model platform require that your data be in a stacked format such that all of the responses are in one column. Sometimes, your data are formatted in multiple columns. See “Example of Stacking Counts in Multiple Columns” on page 500 for an example of converting responses in multiple columns into a single column response.

---

**Validation in Logistic Regression Models**

Validation is the process of using part of a data set to estimate model parameters, and using the other part to assess the predictive ability of the model.

- The *training* set is used to estimate model parameters.
- The *validation* set is used in the model fitting to assess or validate the predictive ability of the model.
- The *test* set is a final, independent assessment of the model’s predictive ability. The test set is available only when using a validation column.

The training, validation, and test sets are created as subsets of the original data. This is done through the use of a validation column in the Fit Model launch window.

The validation column’s values determine how the data is split, and what method is used for validation:

- If the column has two distinct values, then training and validation sets are created.
- If the column has three distinct values, then training, validation, and test sets are created.
- If the column has more than three distinct values, or only one, then no validation is performed.

When a validation column is used, model fit statistics are given for the training, validation, and test sets in the Fit Details report. There is also a separate ROC curve, lift curve, and confusion matrix for each of the Training, Validation, and Test sets.

For more information about how a Validation column is used in JMP modeling platforms, see *Predictive and Specialized Modeling.*
The Logistic Fit Report

When you fit a model using the Nominal Logistic or Ordinal Logistic personality, you obtain a Nominal Logistic Fit report or an Ordinal Logistic Fit report, respectively. By default, these reports contain the following reports:

Effect Summary An interactive report that enables you to add or remove effects from the model. See “Effect Summary Report” on page 182 in the “Standard Least Squares Models” chapter.

Logistic Plot (Available only if the model consists of a single continuous effect.) The logistic probability plot illustrates what the logistic model is fitting. At each value on the horizontal axis, the probability scale in the vertical direction is partitioned into probabilities for each response category. The probabilities are measured as the vertical distance between the curves, with the total across all response category probabilities summing to 1.

The points in the logistic plot represent the observations from the data table. The horizontal position of each point is determined by its value of continuous factor. The vertical position of each point is randomly chosen to be between curves that correspond to the value of its response category. Because a fixed random seed is used, the vertical positions do not differ across multiple fits of the same model.

Iterations (Available only in the Nominal Logistic personality.) After launching Fit Model, an iterative estimation process begins and is reported iteration by iteration. After the fitting process completes, you can open the Iteration History report and see the iteration steps.

Whole Model Test Shows tests that compare the whole-model fit to the model that omits all the regressor effects except the intercept parameters. The test is analogous to the Analysis of Variance table for continuous responses. For more information about the Whole Model Test report, see “Whole Model Test” on page 486.

Fit Details Shows various measures of fit for the model. See “Fit Details” on page 487.

Lack of Fit (Available only when there are replicated points with respect to the X effects and the model is not saturated.) Shows a lack of fit test, also called a goodness of fit test, that addresses whether more terms are needed in the model. See “Lack of Fit Test” on page 488.

Parameter Estimates Shows the parameter estimates, standard errors, and associated hypothesis tests. The Covariance of Estimates report gives the variances and covariances of the parameter estimates.
**Note:** The Covariance of Estimates report appears only for nominal response variables, not for ordinal response variables.

**Singularity Details**  (Appears only when there are linear dependencies among the model terms.) Shows a report that contains the linear functions that the model terms satisfy.

**Effect Likelihood Ratio Tests**  The likelihood ratio chi-square tests are calculated as twice the difference of the log-likelihoods between the full model and the model constrained by the hypothesis to be tested. The constrained model is the model that does not contain the effect. These tests can take time to do because each test requires a separate set of iterations.

**Note:** Likelihood ratio tests are the platform default if they are projected to take less than 20 seconds to complete. Otherwise, the default effect tests are Wald tests.

### Whole Model Test

The Whole Model Test table shows tests that compare the whole-model fit to the model that omits all the regression parameters except the intercept parameters. The test is analogous to the Analysis of Variance table for continuous responses. The negative log-likelihood corresponds to the sums of squares, and the chi-square test corresponds to the $F$ test.

The Whole Model Test table shows these quantities:

- **Model**  Lists the model labels.

  - **Difference**  The difference between the Full model and the Reduced model. This model is used to measure the significance of the regressors as a whole to the fit.

  - **Full**  The complete model that includes the intercepts and all effects.

  - **Reduced**  The model that includes only the intercept parameters.

- **–LogLikelihood**  The negative log-likelihood for the respective models. See “Likelihood, AICc, and BIC” on page 559 in the “Statistical Details” appendix.

- **DF**  The degrees of freedom (DF) for the Difference between the Full and Reduced model.

- **Chi-Square**  The likelihood ratio chi-square test statistic for the hypothesis that all regression parameters are zero. The test statistic is computed by taking twice the difference in negative log-likelihoods between the fitted model and the reduced model that has only intercepts.

- **Prob>ChiSq**  The probability of obtaining a greater chi-square value if the specified model fits no better than the model that includes only intercepts.
RSquare (U)  The proportion of the total uncertainty that is attributed to the model fit, defined as the ratio of the Difference to the Reduced negative log-likelihood values. RSquare ranges from zero for no improvement in fit to 1 for a perfect fit. An RSquare (U) value of 1 indicates that the predicted probabilities for events that occur are equal to one: There is no uncertainty in predicted probabilities. Because certainty in the predicted probabilities is rare for logistic models, RSquare (U) tends to be small.

RSquare (U) is sometimes referred to as $U$, the uncertainty coefficient, or as McFadden’s pseudo $R^2$.

AICc  The corrected Akaike Information Criterion. See “Likelihood, AICc, and BIC” on page 559 in the “Statistical Details” appendix.

BIC  Bayesian Information Criterion. See “Likelihood, AICc, and BIC” on page 559 in the “Statistical Details” appendix.

Observations (or Sum Weights)  Total number of observations in the sample. If a Freq or Weight column is specified in the Fit Model window, this value is the sum of the values of a column assigned to the Freq or Weight role.

Fit Details

The Fit Details report contains the following statistics:

Entropy RSquare  Equivalent to RSquare (U). See “Whole Model Test” on page 486.

Generalized RSquare  A measure that can be applied to general regression models. It is based on the likelihood function $L$ and is scaled to have a maximum value of 1. The Generalized RSquare measure simplifies to the traditional RSquare for continuous normal responses in the standard least squares setting. Generalized RSquare is also known as the Nagelkerke or Craig and Uhler $R^2$, which is a normalized version of Cox and Snell’s pseudo $R^2$. See Nagelkerke (1991).

Mean -Log $p$  The average of $-\log(p)$, where $p$ is the fitted probability associated with the event that occurred.

RASE  The root average square error, where the differences are between the response and $p$ (the fitted probability for the event that actually occurred).

Mean Abs Dev  The average of the absolute values of the differences between the response and $p$ (the fitted probability for the event that actually occurred).

Misclassification Rate  The rate for which the response category with the highest fitted probability is not the observed category.

$N$  The number of observations.
For Entropy RSquare and Generalized RSquare, values closer to 1 indicate a better fit. For Mean -Log p, RASE, Mean Abs Dev, and Misclassification Rate, smaller values indicate a better fit.

To test that the effects as a whole are significant (the Whole Model test), a chi-square statistic is computed by taking twice the difference in negative log-likelihoods between the fitted model and the reduced model that has only intercepts.

If you specified a validation column, the Fit Details report contains columns for each of the Training, Validation, and Test sets.

**Lack of Fit Test**

The Lack of Fit test addresses whether there is enough information in the current model or whether more complex terms are needed. This test is sometimes called a goodness-of-fit test. The lack of fit test calculates a pure-error negative log-likelihood by constructing categories for every combination of the model effect values in the data. The Saturated row in the Lack Of Fit table contains this log-likelihood. The Lack of Fit report also contains a test of whether the Saturated log-likelihood is significantly better than the Fitted model.

The Saturated degrees of freedom is \( m-1 \), where \( m \) is the number of unique populations. The Fitted degrees of freedom is the number of parameters not including the intercept.

The Lack of Fit table contains the negative log-likelihood for error due to Lack of Fit, error in a Saturated model (pure error), and the total error in the Fitted model. The chi-square statistic tests for lack of fit.

**Logistic Fit Platform Options**

- “Options for Nominal and Ordinal Fits”
- “Options for Nominal Fits”
- “Options for Ordinal Fits”

**Options for Nominal and Ordinal Fits**

The following options are available in both the Nominal Logistic Fit and Ordinal Logistic Fit red triangle menus:

**Logistic Plot**  (Available only if the model consists of a single continuous effect.) Shows or hides the Logistic Plot report. See “The Logistic Fit Report” on page 485.
Likelihood Ratio Tests  Shows or hides the Effect Likelihood Ratio Tests report. The likelihood ratio chi-square tests are calculated as twice the difference of the log-likelihoods between the full model and the model constrained by the hypothesis to be tested. The constrained model is the model that does not contain the effect. These tests can take time to do because each test requires a separate set of iterations. Therefore, they could take a long time for large problems.

Note: Likelihood ratio tests are the platform default if they are projected to take less than 20 seconds to complete. This default option is highly recommended.

Wald Tests  Shows or hides the Effect Wald Tests report. The Wald chi-square is a quadratic approximation to the likelihood ratio test, and it is a by-product of the calculations. Though Wald tests are considered less trustworthy, they do provide an adequate significance indicator for screening effects. Each parameter estimate and effect is shown with a Wald test. This is the default test if the likelihood ratio tests are projected to take more than 20 seconds to complete.

Confidence Intervals  Shows or hides profile-likelihood confidence intervals for the model parameters. You can change the confidence level by selecting Set Alpha Level in the Model Specification red triangle menu in the Fit Model window. Each confidence limit requires a set of iterations in the model fit and can take a long time to compute. Furthermore, the effort does not always succeed in finding limits.

ROC Curve  Shows or hides an ROC curve for the model. Receiver Operating Characteristic (ROC) curves measure the sorting efficiency of the model’s fitted probabilities to sort the response levels. ROC curves can also aid in setting criterion points in diagnostic tests. The higher the curve from the diagonal, the better the fit. An introduction to ROC curves is found in Basic Analysis.

If the logistic fit has more than two response levels, it produces a generalized ROC curve (identical to the one in the Partition platform). In such a plot, there is a curve for each response level, which is the ROC curve of that level versus all other levels. See Predictive and Specialized Modeling.

If you specified a validation column, an ROC curve is shown for each of the Training, Validation, and Test sets.

Lift Curve  Shows or hides a lift curve for the model. A lift curve shows the same information as an ROC curve, but in a way to dramatize the richness of the ordering at the beginning. The vertical axis shows the ratio of how rich that portion of the population is in the chosen response level compared to the rate of that response level as a whole. If you specified a validation column, a lift curve is shown for each of the Training, Validation, and Test sets. See Predictive and Specialized Modeling for more information about lift curves.
Confusion Matrix  Shows or hides a report of confusion statistics, which contains a Confusion Matrix report and a Confusion Rates report. Both reports are two-way classifications of the actual response levels and the predicted response levels. The predicted response level is the Target Level specified in the launch window. The Confusion Rates report is equal to the Confusion Matrix report, with the numbers divided by the row totals.

For a good model, predicted response levels should be the same as the actual response levels. The Confusion Matrix report provides a way to assess how the predicted responses align with the actual responses. If you specified a validation column, a confusion matrix is shown for each of the Training, Validation, and Test sets.

If the response is nominal and has a Profit Matrix column property, a Decision Matrix report also appears when this option is selected. For more information about the Decision Matrix report, see *Predictive and Specialized Modeling*.

Profiler  Shows or hides the prediction profiler, showing the fitted values for a specified response probability as the values of the factors in the model are changed. This feature is available for both nominal and ordinal responses. For more information about the options in the red triangle menu, see *Profiler*.

Contour Profiler  (Available only when the model contains more than one continuous factor.) Shows or hides the Contour Profiler. For more information about the options in the red triangle menu, see *Profiler*.

Model Dialog  Shows the completed launch window for the current analysis.

Effect Summary  Shows or hides the Effect Summary report, which enables you to interactively update the effects in the model. See “The Logistic Fit Report” on page 485.

See *Using JMP* for more information about the following options:

Local Data Filter  Shows or hides the local data filter that enables you to filter the data used in a specific report.

Redo  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

Save Script  Contains options that enable you to save a script that reproduces the report to several destinations.

Save By-Group Script  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.
Options for Nominal Fits

The following options are available in the Nominal Logistic Fit red triangle menu:

**Plot Options** (Available only if the model consists of a single continuous effect.) The Plot Options menu contains the following options:

- **Show Points** Toggles the points in the Logistic Plot on or off.
- **Show Rate Curve** Enables you to compare the rate at various values of the effect variable with the fitted logistic curve. This option is useful only if you have several points for each value of the effect. In these cases, you get reasonable estimates of the rate at each value, and compare this rate with the fitted logistic curve. To prevent too many degenerate points, usually at zero or one, JMP shows only the rate value if there are at least three points at the x-value.
- **Line Color** Specifies the color of the plot curves.
- **Odds Ratios** Shows or hides an Odds Ratios report that contains Unit Odds Ratios and Range Odds Ratios.

**Figure 11.6 Odds Ratios**

![Odds Ratios Table]

**Inverse Prediction** (Available only for two-level nominal responses.) Finds the x value that results in a specified probability. See the appendix “Statistical Details” on page 529 for more information about inverse prediction.

**Save Probability Formula** Creates columns in the current data table that contain formulas for linear combinations of the response levels, prediction formulas for the response levels, and a prediction formula giving the most likely response.

For a nominal response model with r levels, JMP creates the following columns:

- columns called Lin[j] that contain a linear combination of the regressors for response levels \( j = 1, 2, \ldots, r - 1 \)
- a column called Prob[r], with a formula for the fit to the last level, \( r \)
- columns called Prob[j] for \( j < r \) with a formula for the fit to level \( j \)
– a column called Most Likely response name that selects the most likely level of each row based on the computed probabilities.

**Publish Probability Formulas** Creates probability formulas and saves them as formula column scripts in the Formula Depot platform. If a Formula Depot report is not open, this option creates a Formula Depot report. See *Predictive and Specialized Modeling*.

**Indicator Parameterization Estimates** (Available only when there are nominal columns among the model effects.) Shows or hides the Indicator Function Parameterization report, which gives parameter estimates for the model where nominal columns are coded using indicator (SAS GLM) parameterization and are treated as continuous. Ordinal columns remain coded using the usual JMP coding scheme. The SAS GLM and JMP coding schemes are described in “The Factor Models” on page 534 in the “Statistical Details” appendix.

**Caution:** Standard errors and chi-square values given in the Indicator Function Parameterization report differ from those in the Parameter Estimates report. This is because the estimates are estimating different model parameters.

### Options for Ordinal Fits

The following options are available in the Ordinal Logistic Fit red triangle menu:

**Save** Contains the following Save options:

**Save Probability Formula** Creates columns in the current data table that contain formulas for linear combinations of the response levels, prediction formulas for the response levels, and a prediction formula giving the most likely response.

For an ordinal response model with $r$ levels, JMP creates the following columns:

– a column called Linear that contains the formula for a linear combination of the regressors without an intercept term

– columns called Cum[$j$] that each contain a formula for the cumulative probability that the response is less than or equal to level $j$, for levels $j = 1, 2, \ldots r - 1$. There is no Cum[1, 2, \ldots r - 1] that is 1 for all rows

– columns called Prob[$j = 1, 2, \ldots r - 1$], for $1 < j < r$ that each contain the formula for the probability that the response is level $j$. Prob[1] is Cum[1], and Prob[r] is 1 – Cum[r – 1].

– a column called Most Likely response name that selects the most likely level of each row based on the computed probabilities.
Publish Probability Formulas  Creates probability formulas and saves them as formula column scripts in the Formula Depot platform. If a Formula Depot report is not open, this option creates a Formula Depot report. See Predictive and Specialized Modeling.

Save Quantiles  (Available only when the response is numeric and has the ordinal modeling type.) Creates columns in the current data table named OrdQ.05, OrdQ.50, and OrdQ.95 that fit the quantiles for these three probabilities.

Save Expected Value  (Available only when the response is numeric and has the ordinal modeling type.) Creates a column in the current data table called Ord Expected. This column contains the linear combination of the response values with the fitted response probabilities for each row and gives the expected value.

Additional Examples of Logistic Regression

This section contains additional examples using logistic regression in the Fit Model platform.

- “Example of Inverse Prediction”
- “Example of Using Effect Summary for a Nominal Logistic Model”
- “Example of a Quadratic Ordinal Logistic Model”
- “Example of Stacking Counts in Multiple Columns”

Example of Inverse Prediction

Inverse prediction enables you to predict the value for one independent variable at a specified probability of the response. If there is more than one independent variable, you must specify values for all of them except the one you are predicting.

An experiment was performed on metal ingots. The ingots were prepared with different heating and soaking times and then tested for readiness to roll. See Cox and Snell (1989). In JMP, the data are contained in the Ingots.jmp sample data table.

You are interested in predicting the heating time at a soaking time of 2 for probabilities of readiness to roll of 0.8 and 0.9.

1. For the analysis, follow the steps in “Example of Nominal Logistic Regression” on page 478.
2. Click the red triangle next to Nominal Logistic Fit for ready and select Inverse Prediction.
3. Delete the value for heat.

You want to find the predicted value of heat, so you leave the heat value empty.
4. Enter 2 for soak.
   You want to predict heating time when soak is 2.

5. Under Probability, enter 0.9 and 0.8 in the first two rows.

**Figure 11.7 The Inverse Prediction Specification Window**

6. Click OK.

**Figure 11.8 Inverse Prediction Report**

When soak is 2, the predicted value of heat for which there is a 90% chance of an ingot being ready to roll is 39.60 with a 95% confidence interval from 32.09 to 57.29. When soak is 2, the predicted value for heat for which there is an 80% chance of an ingot being ready to roll is 49.49 with a 95% confidence interval from 39.90 to 78.71.
Example of Using Effect Summary for a Nominal Logistic Model

A market research study was undertaken to evaluate preference for a brand of detergent. See Ries and Smith (1963). The results of the study are in the Detergent.jmp sample data table. The model is defined by the following:

- the response variable, brand, with values m and x
- an effect called softness (water softness) with values soft, medium, and hard
- an effect called previous use with values yes and no
- an effect called temperature with values high and low
- a count variable, count, which gives the frequency counts for each combination of effect categories

The study begins by specifying the full three-factor factorial model.

1. Select Help > Sample Data Library and open Detergent.jmp.
2. Select Analyze > Fit Model.
3. Select brand from the Select Columns list and click Y.
   
   Because you specified a nominal response variable, the Personality changes to Nominal Logistic.
   
   Because brand is a Nominal column with only two levels, the Target Level option appears. This option enables you to specify the response level whose probability you want to model.

4. From the Target Level list, select m.
5. Select count and click Freq.
6. Select softness through temperature and click Macros > Full Factorial.
7. Click Run.
Figure 11.9 Nominal Logistic Fit for Three-Factor Factorial Model

The Whole Model Test report shows that the three-factor full factorial model as a whole is significant (Prob>ChiSq = 0.0006).

The Effect Likelihood Ratio Tests report shows that the effects that include softness do not contribute significantly to the model fit. This leads you to consider removing softness from the model. You can do this from the Effect Summary report.

8. In the Effect Summary report, select softness*previous use through softness under Source and click **Remove**.

The report updates to show the two-factor factorial model (Figure 11.10). The Whole Model Test report shows that the two-factor model is also significant as a whole.
Chapter 11
Fitting Linear Models

Logistic Regression Models
Additional Examples of Logistic Regression

Figure 11.10 Nominal Logistic Fit for Two-Factor Factorial Model

You conclude that previous use of a detergent brand and water temperature have an effect on detergent preference. You also note that the interaction between temperature and previous use is not statistically significant, so there is no evidence that temperature depends on previous use.

Example of a Quadratic Ordinal Logistic Model

The Ordinal Logistic Personality can fit a quadratic surface to optimize the probabilities of higher or lower levels of an ordinal response.

In this example, a microwave popcorn manufacturer wants to find out how much salt consumers like in their popcorn. To do this, the manufacturer looks for the maximum probability of a favorable response as a function of how much salt is added to the popcorn package. In this experiment, the salt amounts are controlled at 0, 1, 2, and 3 teaspoons. Respondents rate the taste on a scale of 1 (low) to 5 (high). The optimal amount of salt is the amount that maximizes the probability of more favorable responses. The ten observations for each of the salt levels are shown in Table 11.2.
Table 11.2 Salt in Popcorn

<table>
<thead>
<tr>
<th>Salt Amount</th>
<th>Salt Rating Responses</th>
</tr>
</thead>
<tbody>
<tr>
<td>no salt</td>
<td>1, 3, 2, 4, 2, 1, 4, 3, 4</td>
</tr>
<tr>
<td>1 tsp.</td>
<td>4, 5, 3, 4, 5, 4, 5, 4, 5</td>
</tr>
<tr>
<td>2 tsp.</td>
<td>4, 3, 5, 1, 4, 2, 5, 4, 3, 2</td>
</tr>
<tr>
<td>3 tsp.</td>
<td>3, 1, 2, 3, 1, 2, 1, 2, 1, 2</td>
</tr>
</tbody>
</table>

1. Select Help > Sample Data Library and open Salt in Popcorn.jmp.
2. Select Analyze > Fit Model.
3. Select Taste Test from the Select Columns list and click Y.
4. Select Salt from the Select Columns list and click Macros > Response Surface.
5. Click Run.
6. Click the disclosure icon next to Response Surface to open the report.
The report shows how the quadratic model fits the response probabilities. The curves, instead of being shifted logistic curves, become stacked U-shaped curves where each curve achieves its minimum at the same point. The critical value is at Mean(X) – 0.5 * (b1/b2) where b1 is the linear coefficient and b2 is the quadratic coefficient. This formula is for centered X. From the Parameter Estimates table, you can compute that the optimal amount of salt is 1.5 - 0.5 * (0.5637/1.3499) = 1.29 teaspoons.
The vertical distance at a specific amount of salt between each curve measures the probability of each of the five response levels for the specific amount of salt. The probability for the highest response level is the distance from the top curve to the top of the plot rectangle. This distance reaches a maximum when the amount of salt is about 1.3 teaspoons. All curves share the same critical point.

The parameter estimates for Salt and Salt\*Salt are the coefficients used to find the critical value. Although the critical value appears on the logistic plot as a minimum, it is a maximum in the sense of maximizing the probability of the highest response. The Solution portion of the report is shown under Response Surface in Figure 11.11, where 1.29 is shown under Critical Value.

### Example of Stacking Counts in Multiple Columns

When data that are frequencies (counts) are listed in several columns of your data table, you must transform the data into the form that you need for logistic regression. For example, the Ingots2.jmp data table (Figure 11.12) has columns Nready and Nnotready. These columns give the number of ingots that are ready to roll and ingots that are not ready to roll for each combination of Heat and Soak values.

**Figure 11.12  Ingots2.jmp Sample Data Table**

<table>

</table>

Before fitting a logistic regression model, use the following steps to stack the Nready and Nnotready columns into a single column:

1. Select Help > Sample Data Library and open Ingots2.jmp.
2. Select Tables > Stack.
3. Select Nready and NNotReady from the Select Columns list and click Stack Columns.
4. Click OK. 

This creates the new table in Figure 11.13. Label is the response (Y) column and Data is the frequency column.

This stacked data table is equivalent to the Ingots.jmp sample data table used in “Example of Nominal Logistic Regression” on page 478.

Statistical Details for the Nominal and Ordinal Logistic Personalities

- “Logistic Regression Model”
- “Odds Ratios”
- “Relationship of Statistical Tests”
Logistic Regression Model

Logistic regression fits nominal Y responses to a linear model of X terms. To be more precise, it fits probabilities for the response levels using a logistic function. For two response levels, the function is:

\[ P(Y = r_1) = (1 + e^{-Xb})^{-1} \]

where \( r_1 \) is the first response level

or equivalently:

\[ \log \left( \frac{P(Y = r_1)}{P(Y = r_2)} \right) = Xb \]

where \( r_1 \) and \( r_2 \) are the two responses levels, respectively

**Note:** When Y is binary and has a nominal modeling type, you can set the Target Level in the Fit Model window to specify the level whose probability you want to model. In this section, the target level is designated as \( r_1 \).

For \( r \) nominal response levels, where \( r > 2 \), the model is defined by \( r - 1 \) linear model parameters of the following form:

\[ \log \left( \frac{P(Y = i)}{P(Y = r)} \right) = Xb_i \]

The fitting principal of maximum likelihood means that the \( \beta \)s are chosen to maximize the joint probability attributed by the model to the responses that did occur. This fitting principal is equivalent to minimizing the negative log-likelihood (\( -\text{LogLikelihood} \)):

\[ \text{Loss} = -\text{logLikelihood} = \sum_{i=1}^{n} -\log(\text{Prob}(i\text{th row has the } y_j\text{th response})) \]

**Odds Ratios**

For two response levels, the logistic regression model is specified as follows:

\[ \log \left( \frac{\text{Prob}(Y = r_1)}{\text{Prob}(Y = r_2)} \right) = Xb \]

where \( r_1 \) and \( r_2 \) are the two response levels

Therefore, the *odds* are defined as follows:

\[ \frac{\text{Prob}(Y = r_1)}{\text{Prob}(Y = r_2)} = \exp(X\beta) = \exp(\beta_0) \cdot \exp(\beta_1X_1) \cdots \exp(\beta_iX_i) \]
Note that \( \exp(\beta_i(X_i + 1)) = \exp(\beta_i X_i) \exp(\beta_i) \). This shows that if \( X_i \) changes by a unit amount, the odds is multiplied by \( \exp(\beta_i) \), which we label the *unit odds ratio*. As \( X_i \) changes over its whole range, the odds are multiplied by \( \exp((X_{\text{high}} - X_{\text{low}})\beta_i) \), which we label the *range odds ratio*. For binary responses, the log odds ratio for flipped response levels involves only changing the sign of the parameter. Therefore, you might want the reciprocal of the reported value to focus on the last response level instead of the first.

Two-level nominal effects are coded 1 and -1 for the first and second levels, so range odds ratios or their reciprocals would be of interest.

If no confidence intervals for the parameter estimates have been calculated when you select the Odds Ratio option, selecting the Odds Ratio option produces Wald-based confidence intervals for the odds ratio.

Selecting the Odds Ratio option produces profile likelihood-based confidence intervals for the odds ratios when all of the following conditions are met:

- the Likelihood Ratio Tests option has been selected
- the Confidence Intervals option has been selected
- the number of parameters for each response is less than 8
- the number of rows is less than 1000.

The method used for computing confidence intervals for the odds ratios is noted at the bottom of the Odds Ratios report.

### Relationship of Statistical Tests

All of the statistical tests in the Logistic Regression reports compare the fit of the specified model with subset or superset models, as illustrated in Figure 11.14. If a test shows significance, then the higher order model is justified.

- Whole model tests: if the specified model is significantly better than a reduced model without any effects except the intercepts.
- Lack of Fit tests: if a saturated model is significantly better than the specified model.
- Effect tests: if the specified model is significantly better than a model without a given effect.
Statistical Details for the Nominal and Ordinal Logistic Personalities

Figure 11.14 Relationship of Statistical Tests

Tests are a comparison of model fits

- **Whole Model Test**
  - Reduced model (with only intercepts)

- **Lack-of-Fit Test**
  - Saturated model (a parameter for each unique combination of $x$ values)

- **specified model**
  - Wald Effect Tests (optional)

- **Likelihood Ratio Effect Tests** (default)
  - Model without $i^{th}$ effect

### Summary

- **Whole Model Test** compares the saturated model to the specified model.
- **Lack-of-Fit Test** assesses the goodness of fit of the saturated model.
- **Wald Effect Tests** are performed to evaluate the significance of individual effects in the specified model.
- **Likelihood Ratio Effect Tests** compare the specified model to a model without a specific effect, providing an alternative way to assess the significance of that effect.
Generalized linear models provide a unified way to fit responses that do not fit the usual requirements of traditional linear models. For example, frequency counts are often characterized as having a Poisson distribution and fit using a generalized linear model.

The Generalized Linear Model personality of the Fit Model platform enables you to fit generalized linear models for responses with binomial, normal, Poisson, or exponential distributions. The platform provides reports similar to those that are provided for traditional linear models. The platform also accommodates separation in logistic regression models using the Firth correction.

Overview of the Generalized Linear Model Personality

Traditional linear models are used extensively in statistical data analysis. However, there are situations that violate the assumptions of traditional linear models. In these situations, traditional linear models are not appropriate. Traditional linear models assume that the responses are continuous and normally distributed with constant variance across all observations. These assumptions might not be reasonable. For example, these assumptions are not reasonable if you want to model counts, or if the variance of the observed responses increases as the response increases. Another example of violating the assumptions of traditional linear models is when the mean of the response is restricted to a specific range of values, such as proportions that fall between 0 and 1.

For situations such as these that fall into a wider range of data analysis problems, generalized linear models can be applied. Generalized linear models are an extension of traditional linear models. A generalized linear model consists of a linear component, a link function, and a variance function. The link function, \( g(\mu_i) = x_i'\beta \), is a monotonic and differentiable function that describes how the expected value of \( Y_i \) is related to the linear predictors. An example of generalized linear regression is Poisson regression, where \( \log(\mu_i) \) is the link function. For a complete list of the generalized linear regression models available using the Generalized Linear Models personality of the Fit Model platform, see “Statistical Details for the Generalized Linear Model Personality” on page 523.

Fitted generalized linear models can be summarized and evaluated using the same statistics as traditional linear models. The Fit Model platform provides parameter estimates, standard errors, goodness-of-fit statistics, confidence intervals, and hypothesis tests for generalized linear models. It should be noted that exact distribution theory is not always available or practical for generalized linear models. Therefore, some inference procedures are based on asymptotic results.

An important aspect of fitting generalized linear models is the selection of explanatory variables in the model. Changes in goodness-of-fit statistics are often used to evaluate the contribution of subsets of explanatory variables to a particular model. The deviance is defined as twice the difference between the maximum attainable value of the log-likelihood function and the value of the log-likelihood function at the maximum likelihood estimates of the regression parameters. The deviance is often used as a measure of goodness of fit. The maximum attainable log-likelihood is achieved with a model that has a parameter for every observation.

For variable selection and penalized methods in generalized linear modeling, you can use the Generalized Regression personality of the Fit Model platform in JMP Pro. See the “Generalized Regression Models” chapter on page 283.
Example of a Generalized Linear Model

This example uses Poisson regression to model count data from a study of nesting horseshoe crabs. Each female crab had a male crab resident in her nest. The study investigated whether there were other males, called satellites, residing nearby. The data table CrabSatellites.jmp contains a response variable listing the number of male satellites, as well as variables that describe the color, spine condition, weight, and carapace width of the female crab. You are interested in the relationship between the number of satellites and the variables that describe the female crabs.

To fit the Poisson regression model, follow these steps:

1. Select Help > Sample Data Library and open CrabSatellites.jmp.
2. Select Analyze > Fit Model.
3. Select satell and click Y.
4. Select color, spine, width, and weight and click Add.
5. From the Personality list, select Generalized Linear Model.
6. From the Distribution list, select Poisson.
   In the Link Function list, Log should be selected for you automatically.
7. Click Run.
The Whole Model Test shows that the difference between log-likelihoods for the full and reduced models is 41.6. The Prob>ChiSq value is equivalent to the *p*-value for a whole model *F* test. A *p*-value less than 0.0001 indicates that the model as a whole is significant. The report also contains the corrected Akaike Information Criterion (AICc), 921.7613. This value can be compared with other models to determine the best-fitting model for the data. Smaller AICc values indicate better fitting models.

The Effects Tests report shows that weight is a significant factor in the model. Note that the *p*-value for weight, 0.0026, is the same in the Parameter Estimates table as well, since weight is a continuous variable.

The Effect Tests report also shows that the categorical variable color is significant. Color has four levels, Light Med, Medium, Dark Med, and Dark. The parameter estimates for the first three levels are shown in the Parameter Estimates table. The parameter estimate for Dark is the negative of the sum of the parameter estimates for the first three levels.

You can use the Prediction Profiler to further explore the model.

8. Click the red triangle next to Generalized Linear Model Fit and select Profilers > Profiler.
The confidence band on weight indicates that there is less variability in the model for smaller weight values than there is for larger weight values. The profiler enables you to easily explore the levels of the categorical variables. From the profiler, you can see that the predicted number of satellite crabs decreases as the color of the crab changes from light to dark.
Launch the Generalized Linear Model Personality

Launch the Generalized Linear Model personality by selecting Analyze > Fit Model, entering one or more columns for $Y$, and selecting Generalized Linear Model from the Personality menu.

Figure 12.4 Fit Model Launch Window with Generalized Linear Model Selected

For more information about aspects of the Fit Model window that are common to all personalities, see the “Model Specification” chapter on page 29. For more information about the options in the Select Columns red triangle menu, see Using JMP. Information specific to the Generalized Linear Model personality is presented here.

If your model effects have missing values, you can treat these missing values as informative categories. Select the Informative Missing option from the Model Specification red triangle menu.

Tip: The No Intercept option is not available in the Generalized Linear Model personality of the Fit Model platform.

When you select Generalized Linear Model for Personality, the Fit Model launch window changes to include additional options. The following additional options are available in the Generalized Linear Model personality:

**Distribution**  Specifies a probability distribution for the response variable.

**Link Function**  Specifies a link function that relates the linear model to the response variable.
**Overdispersion Tests and Intervals**  Specifies that an overdispersion parameter should be included in the model. Overdispersion occurs when the variance of the response is greater than would be expected by the theoretical variance of the response distribution. This can arise in Poisson and binomial response models. McCullagh and Nelder (1989) state that overdispersion is not uncommon in practice.

*Note:* This option adds a column for Overdispersion to the Goodness-of-Fit Statistics table in the Whole Model Test report.

**Firth Bias-Adjusted Estimates**  Specifies that the Firth bias-adjusted method is used to fit the model. This maximum likelihood-based method has been shown to produce better estimates and tests than maximum likelihood-based models that do not use bias correction. In addition, bias-corrected MLEs ameliorate separation problems that tend to occur in logistic-type models. For more information about the separation problem in logistic regression, see Firth (1993) and Heinze and Schemper (2002).

**Offset**  (Appears as a Pick Role Variables button.) Specifies a variable for the offset. An offset variable is one that is treated like a regression covariate whose parameter is fixed to be 1.0. Offset variables are most often used to scale the modeling of the mean in Poisson regression situations with a log link.

**Response Specification for the Binomial Response Distribution**

When you select Binomial as the Distribution, the response variable must be specified in one of the following ways:

- If your data are not summarized as frequencies of events, specify a single binary column as the response. The response column must be nominal.
- If your data are summarized as frequencies of events, specify a single binary column as the response and a frequency variable in the Freq role. The response column must be nominal, and the frequency variable contains the count of each response level.
- If your data are summarized as frequencies of events and number of trials, specify two continuous columns in this order: a count of the number of successes, and a count of the number of trials. Alternatively, you can specify the number of failures instead of the number of successes.
Generalized Linear Model Fit Report

By default, the Generalized Linear Model Fit report contains details about the model specification as well as the following reports:

**Singularity Details**  (Appears only when there are linear dependencies among the model terms.) Shows a report that contains the linear functions that the model terms satisfy.

**Regression Plot**  (Appears only when there is one continuous predictor and no more than one categorical predictor.) Shows a plot of the response on the vertical axis and the continuous predictor on the horizontal axis. A regression line is shown over the points. If there is a categorical predictor in the model, each level of the categorical predictor has a separate regression line and a legend appears next to the plot.

**Whole Model Test**  Shows tests that compare the whole-model fit to the model that omits all the effects except the intercept parameters. This report also contains goodness-of-fit statistics and the corrected Akaike’s Information Criterion (AICc) value. See “Whole Model Test” on page 514.

**Effect Summary**  An interactive report that enables you to add or remove effects from the model. See “Effect Summary Report” on page 182 in the “Standard Least Squares Models” chapter.

**Effect Tests**  The Effect Tests are joint tests that all the parameters for an individual effect are zero. If an effect has only one parameter, as with continuous effects, then the tests are the same as the tests in the Parameter Estimates table.

*Note:* Even if the Firth adjustment is used, the Effect Tests are based on the non-penalized likelihood function.

**Parameter Estimates**  Shows the parameter estimates, standard errors, and associated hypothesis tests and confidence limits. Simple continuous effects have only one parameter. Models with complex classification effects have a parameter for each anticipated degree of freedom.

*Note:* If there are more than 1,000 observations, Wald-based confidence intervals are shown. Otherwise, profile-likelihood confidence intervals are shown.

**Studentized Deviance Residual by Predicted**  Shows a plot of studentized deviance residuals on the vertical axis and the predicted response values on the horizontal axis.
Whole Model Test

The Whole Model Test table shows tests that compare the whole-model fit to the model that omits all the regression parameters except the intercept parameter. It also contains two goodness-of-fit statistics and the AICc value to assess model adequacy.

The Whole Model Test table shows these quantities:

- **Model**: Lists the model labels.
  - **Difference**: The difference between the Full model and the Reduced model. This model is used to measure the significance of the regressors as a whole to the fit.
  - **Full**: The complete model that includes the intercepts and all effects.
  - **Reduced**: The model that includes only the intercept parameters.

- **–LogLikelihood**: The negative log-likelihood for the respective models. See “Likelihood, AICc, and BIC” on page 559 in the “Statistical Details” appendix.

- **L-R ChiSquare**: The likelihood ratio chi-square test statistic for the hypothesis that all regression parameters are zero. The test statistic is computed by taking twice the difference in negative log-likelihoods between the fitted model and the reduced model that has only an intercept.

- **DF**: The degrees of freedom (DF) for the Difference between the Full and Reduced model.

- **Prob>ChiSq**: The probability of obtaining a greater chi-square value if the specified model fits no better than the model that includes only an intercept.

- **Goodness of Fit Statistic**: Lists the two goodness-of-fit statistics: Pearson and Deviance.
  - **ChiSquare**: The chi-square test statistic for the respective goodness-of-fit statistics.
  - **DF**: The degrees of freedom for the respective goodness-of-fit statistics.
  - **Prob>ChiSq**: The *p*-value for the respective goodness-of-fit statistics.

- **Overdispersion**: (Appears only when the Overdispersion Tests and Intervals option is selected in the launch window.) An estimate of the overdispersion parameter. See “Statistical Details for the Generalized Linear Model Personality” on page 523.

- **AICc**: The corrected Akaike Information Criterion. See “Likelihood, AICc, and BIC” on page 559 in the “Statistical Details” appendix.
Generalized Linear Model Fit Report Options

The Generalized Linear Model Fit red triangle menu contains the following options:

**Custom Test**  Enables you to test a custom hypothesis. For more information about custom tests, see “Custom Test” on page 124 in the “Standard Least Squares Models” chapter.

**Contrast**  Enables you to test for differences in levels within a variable. If a contrast involves a covariate, you can specify the value of the covariate at which to test the contrast. For an example of the Contrast option, see “Using Contrasts to Compare Differences in the Levels of a Variable” on page 518.

**Inverse Prediction**  (Available only for continuous X variables.) Enables you to predict an X value, given specific values for Y and the other X variables. For more information about the Inverse Prediction option, see “Inverse Prediction” on page 142 in the “Standard Least Squares Models” chapter.

**Covariance of Estimates**  Shows or hides a covariance matrix for all the effects in a model. The estimated covariance matrix of the parameter estimator is defined as follows:

\[
\Sigma = -H^{-1}
\]

where \( H \) is the Hessian (or second derivative) matrix evaluated using the parameter estimates on the last iteration. Note that the dispersion parameter, whether estimated or specified, is incorporated into \( H \). Rows and columns corresponding to aliased parameters are not included in \( \Sigma \).

**Correlation of Estimates**  Shows or hides a correlation matrix for all the effects in a model. The correlation matrix is the normalized covariance matrix. For each \( \sigma_{ij} \) element of \( \Sigma \), the corresponding element of the correlation matrix is \( \frac{\sigma_{ij}}{\sigma_i \sigma_j} \) where \( \sigma_i = \sqrt{\sigma_{ii}} \).

**Profilers**  Shows a submenu of the following profilers:

- **Profiler**  Shows or hides a prediction profiler for examining prediction traces for each X variable. For more information about the prediction profiler, see “Profiler” on page 164 in the “Standard Least Squares Models” chapter.

- **Contour Profiler**  Shows or hides an interactive contour profiler. For more information about the contour profiler, see Profilers.

- **Surface Profiler**  Shows or hides a 3-D surface profiler. For more information about the surface profiler, see Profilers.

**Diagnostic Plots**  Shows a submenu of plots of residuals, predicted values, and actual values. These plots enable you to search for outliers and determine the adequacy of your model. For more information about deviance, see “Model Selection and Deviance” on page 525. The following plots are available:
**Studentized Deviance Residuals by Predicted**  Shows or hides a plot of studentized deviance residuals on the vertical axis and the predicted response values on the horizontal axis.

**Studentized Pearson Residuals by Predicted**  Shows or hides a plot of the studentized Pearson residuals on the vertical axis and the predicted response values on the horizontal axis.

**Deviance Residuals by Predicted**  Shows or hides a plot of the deviance residuals on the vertical axis and the predicted response values on the horizontal axis.

**Pearson Residuals by Predicted**  Shows or hides a plot of the Pearson residuals on the vertical axis and the predicted response values on the horizontal axis.

**Regression Plot**  (Available only when there is one continuous predictor and no more than one categorical predictor.) Shows or hides a plot of the response on the vertical axis and the continuous predictor on the horizontal axis. A regression line is shown over the points. If there is a categorical predictor in the model, each level of the categorical predictor has a separate regression line and a legend appears next to the plot.

**Linear Predictor Plot**  (Available only when there is one continuous predictor and no more than one categorical predictor.) Shows or hides a plot of responses transformed by the inverse link function on the vertical axis and the continuous predictor on the horizontal axis. A transformed regression line is shown over the points. If there is a categorical predictor in the model, each level of the categorical predictor has a separate transformed regression line and a legend appears next to the plot.

**Save Columns**  Shows a submenu of options that enable you to save certain quantities as new columns in the current data table. For more information about the residual formulas, see “Residual Formulas” on page 526.

**Prediction Formula**  Creates a formula column in the current data table that predicts the model.

**Predicted Values**  Creates a column in the current data table that contains the values predicted by the model.

**Mean Confidence Interval**  Creates columns in the current data table that contain the 95% confidence limits for the prediction equation for the model. These confidence limits reflect the variation in the parameter estimates.

**Note:** You can change the $\alpha$ level for the confidence limits in the Fit Model window by selecting Set Alpha Level from the Model Specification red triangle menu.
Save Indiv Confid Limits  Creates columns in the current data table that contain the 95% confidence limits for a given individual value for the model. These confidence limits reflect variation in the error and variation in the parameter estimates.

Note: You can change the $\alpha$ level for the confidence limits in the Fit Model window by selecting Set Alpha Level from the Model Specification red triangle menu.

Deviance Residuals  Creates a column in the current data table that contains the deviance residuals.

Pearson Residuals  Creates a column in the current data table that contains the Pearson residuals.

Studentized Deviance Residuals  Creates a column in the current data table that contains the studentized deviance residuals.

Studentized Pearson Residuals  Creates a column in the current data table that contains the studentized Pearson residuals.

Model Dialog  Shows the completed launch window for the current analysis.

Effect Summary  Shows or hides the Effect Summary report, which enables you to interactively update the effects in the model. See “Effect Summary Report” on page 182 in the “Standard Least Squares Models” chapter.

See Using JMP for more information about the following options:

Local Data Filter  Shows or hides the local data filter that enables you to filter the data used in a specific report.

Redo  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

Save Script  Contains options that enable you to save a script that reproduces the report to several destinations.

Save By-Group Script  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.
**Additional Examples of the Generalized Linear Models Personality**

- “Using Contrasts to Compare Differences in the Levels of a Variable”
- “Poisson Regression with Offset”
- “Normal Regression with a Log Link”

**Using Contrasts to Compare Differences in the Levels of a Variable**

This example continues the crab satellite example in “Example of a Generalized Linear Model” on page 508. Suppose that you want to test whether female crabs with good spines attracted a different number of male crabs (satellites) than female crabs with worn or broken spines.

1. Complete step 1 through step 7 of “Example of a Generalized Linear Model” on page 508.
2. Click the red triangle next to Generalized Linear Model Fit and select **Contrast**. The Choose effects for contrast window appears.
3. Select **spine**, the variable of interest, and click **Go**.
4. To compare the crabs with good spines to crabs with worn or broken spines, click the + button beside Both Good and the - button beside both One Worn/Broken and Both Worn/Broken.
   
   This creates a contrast specification that compares the female crabs with good spines against the female crabs with worn or broken spines.

**Figure 12.5  Contrast Specification Window**

5. Click **Done**.
The Prob>Chisq, 0.8242, is much greater than 0.05, so we cannot conclude that there is a difference in satellite attraction based on spine condition.

**Poisson Regression with Offset**

The sample data table Ship Damage.JMP is adapted from data found in McCullagh and Nelder (1989). The data table contains information about a certain type of damage caused by waves to the forward section of the hull. Hull construction engineers are interested in the risk of damage associated with three variables: ship type (Type), the year in which the ship was constructed (Yr Made), and the block of years the ship was in service (Yr Used).

In this analysis we use the variable Service, the log of the aggregate months of service, as an *offset variable*. An offset variable is one that is treated like a regression covariate whose parameter is fixed to be 1.0. Offset variables are most often used to scale the modeling of the mean in Poisson regression situations with a log link. In this example, we use log(months of service) since one would expect that the number of repairs be proportional to the number of months in service.

To see how an offset variable is used, assume the linear component of the GLM is called $\eta$. Then, with a log link function, the model for the mean with the offset included is specified as follows:

$$\exp[\text{Log(months of service)} + \eta] = [(\text{months of service}) \times \exp(\eta)].$$

To run this example, follow these steps:

1. Select **Help > Sample Data Library** and open Ship Damage.jmp.
2. Select **Analyze > Fit Model**.
3. From the Personality list, select **Generalized Linear Model**.
4. From the Distribution list, select **Poisson**.
   - In the Link Function list, **Log** should be selected for you automatically.
5. Select N and click Y.
6. Select Service and click Offset.
7. Select Type, Yr Made, Yr Used and click Add.
8. Click the check mark box for Overdispersion Tests and Intervals.
9. Click Run.

From the report, notice that all three effects (Type, Yr Made, Yr Used) are significant.

Figure 12.7 Partial Report for a Poisson with Offset Model

Normal Regression with a Log Link

This example uses the Nor.jmp data table, where X is an explanatory variable and Y is the response variable. First, you explore the relationship between X and Y to determine the appropriate link function to use in the Generalized Linear Model personality of the Fit Model platform.

1. Select Help > Sample Data Library and open Nor.jmp.
2. Select Analyze > Fit Y By X.
4. Select X, click **Factor**, and then click **OK**.

**Figure 12.8** Y by X Results for Nor.jmp

You can see that $Y$ varies nonlinearly with $X$ and that the variance is approximately constant. Therefore, a normal distribution with a log link function is appropriate to model these data; that is, $\log(\mu_i) = \mathbf{x}_i'\beta$ so that $\mu_i = \exp(\mathbf{x}_i'\beta)$.

5. Select **Analyze > Fit Model**.

6. In the Personality list, select the **Generalized Linear Model**.

7. In the Distribution list, select **Normal**.

8. In the Link Function list, select **Log**.

9. Select Y and click **Y**.

10. Select X and click **Add**.

11. Click **Run**.

Statistical Details for the Generalized Linear Model Personality

To construct a generalized linear model, you must select response and explanatory variables for your data. You then must choose an appropriate link function and probability distribution for your response. Explanatory variables can be any combination of continuous variables, classification variables, and interactions. Some common examples of generalized linear models are listed in Table 12.1.

The platform fits a generalized linear model to the data by maximum likelihood estimation of the parameter vector. In general, there is no closed-form solution for the maximum likelihood estimates of the parameters. Therefore, the platform estimates the parameters of the model numerically through an iterative fitting process using a technique pioneered by Nelder and Wedderburn (1972). The overdispersion parameter \( \phi \) is estimated by dividing the Pearson goodness-of-fit statistic by its degrees of freedom. Covariances, standard errors, and confidence limits are computed for the estimated parameters based on the asymptotic normality of maximum likelihood estimators.

A number of link functions and probability distributions are available in the Generalized Linear Model personality of the Fit Model platform. Table 12.2 lists the built-in link functions.

Model Selection and Deviance

An important aspect of generalized linear modeling is the selection of explanatory variables in the model. Changes in goodness-of-fit statistics are often used to evaluate the contribution of subsets of explanatory variables to a particular model. The deviance is defined to be twice the difference between the maximum attainable log-likelihood and the log-likelihood at the maximum likelihood estimates of the regression parameters. The deviance is often used as a measure of goodness of fit. The maximum attainable log-likelihood is achieved with a model that has a parameter for every observation. Table 12.4 lists the deviance formula for each of the available distributions for the response variable.

Table 12.4 Deviance Formulas for Response Distributions

<table>
<thead>
<tr>

</tr>
</thead>
<tbody>
<tr>
<td>Normal</td>
<td>( \sum_i w_i (y_i - \mu_i)^2 )</td>
</tr>
<tr>
<td>Binomial</td>
<td>( 2 \sum_i w_i m_i \left[ y_i \log\left(\frac{y_i}{\mu_i}\right) + (1 - y_i) \log\left(\frac{1 - y_i}{1 - \mu_i}\right) \right] )</td>
</tr>
<tr>
<td>Poisson</td>
<td>( 2 \sum_i w_i \left[ y_i \log\left(\frac{y_i}{\mu_i}\right) - (y_i - \mu_i) \right] )</td>
</tr>
<tr>
<td>Exponential</td>
<td>( 2 \sum_i w_i \left[ -\log\left(\frac{y_i}{\mu_i}\right) + \left(\frac{y_i - \mu_i}{\mu_i}\right) \right] )</td>
</tr>
</tbody>
</table>

The Pearson chi-square statistic is defined as follows:

\[
X^2 = \sum_i \frac{w_i (y_i - \mu_i)^2}{V(\mu_i)}
\]

where

- \( y_i \) is the \( i^{th} \) response
- \( \mu_i \) is the corresponding predicted mean
- \( V(\mu_i) \) is the variance function
- \( w_i \) is a known weight for the \( i^{th} \) observation
One strategy for variable selection is to fit a sequence of models. You start with a simple model that contains only an intercept term, and then include one additional explanatory variable in each successive model. You can measure the importance of the additional explanatory variable by the difference in deviance or fitted log-likelihood values between successive models. Asymptotic tests enable you to assess the statistical significance of the additional term.

When the distribution is non-normal, a normal critical value is used instead of a $t$-distribution critical value in inverse prediction.

**Residual Formulas**

**Deviance**

$$r_{Di} = \sqrt{d_i}(\text{sign}(y_i - \mu_i))$$

**Studentized Deviance**

$$r_{Di} = \frac{\text{sign}(y_i - \mu_i)\sqrt{d_i}}{\sqrt{\phi(1 - h_i)}}$$

**Pearson**

$$r_{Pi} = \frac{y_i - \mu_i}{\sqrt{V(\mu_i)}}$$

**Studentized Pearson**

$$r_{Pi} = \frac{y_i - \mu_i}{\sqrt{V(\mu_i)(1 - h_i)}}$$

where

$(y_i - \mu_i)$ is the raw residual

$\text{sign}(y_i - \mu_i)$ is 1 if $(y_i - \mu_i)$ is positive and -1 if $(y_i - \mu_i)$ is negative

$d_i$ is the contribution to the total deviance from observation $i$

$\phi$ is the dispersion parameter

$V(\mu_i)$ is the variance function

$h_i$ is the $i^{th}$ diagonal element of the matrix $W_e^{(1/2)}X(W_eX)^{-1}X'W_e^{(1/2)}$, where $W_e$ is the weight matrix used in computing the expected information matrix.
For more information about residuals and generalized linear models, see the GENMOD Procedure chapter in SAS Institute Inc. (2020a).
This appendix discusses the different types of response models, their factors, their design coding, and parameterization. It also includes many other details of methods described in the main text.

The JMP system fits linear models to three different types of response models that are labeled continuous, ordinal, and nominal. Many details about the factor side are the same for the different response models, but JMP supports graphics and marginal profiles only for continuous responses—not for ordinal and nominal.

Different computer programs use different design-matrix codings, and thus parameterizations, to fit effects and construct hypothesis tests. JMP uses a different coding than the GLM procedure in the SAS system, although in most cases JMP and SAS GLM procedure produce the same results. The following sections describe the details of JMP coding and highlight those cases when it differs from that of the SAS GLM procedure.

The Response Models

JMP fits linear models to three different types of responses: continuous, nominal, and ordinal. The models and methods available in JMP are practical, are widely used, and suit the need for a general approach in a statistical software tool. As with all statistical software, you are responsible for learning the assumptions of the models that you choose to use, and the consequences if the assumptions are not met. See “The Usual Assumptions” on page 552 in this chapter.

- “Continuous Responses”
- “Nominal Responses”
- “Ordinal Responses”

Continuous Responses

When the response column (the column assigned the Y role) is continuous, JMP fits the value of the response directly. The basic model is that for each observation,

\[ Y = (\text{some function of the } X\text{'s and parameters}) + \text{error} \]

Statistical tests are based on the assumption that the error term in the model is normally distributed.

Fitting Principle for Continuous Response

The Fitting principle is called least squares. The least squares method estimates the parameters in the model to minimize the sum of squared errors. The errors in the fitted model, called residuals, are the difference between the actual value of each observation and the value predicted by the fitted model.

The least squares method is equivalent to the maximum likelihood method of estimation if the errors have a normal distribution. This means that the analysis estimates the model that gives the most likely residuals. The log-likelihood is a scale multiple of the sum of squared errors for the normal distribution.

Base Model for Continuous Responses

The simplest model for continuous measurement fits just one value to predict all the response values. This value is the estimate of the mean. The mean is just the arithmetic average of the response values. All other models are compared to this base model.
Nominal Responses

Nominal responses are analyzed with a straightforward extension of the logit model. For a binary (two-level) response, a logit response model is specified as follows:

\[
\log \left( \frac{P(y = 1)}{P(y = 2)} \right) = X\beta
\]

The above can also be written as follows:

\[ P(y = 1) = F(X\beta) \]

where \( F(x) \) is the cumulative distribution function of the standard logistic distribution:

\[
F(x) = \frac{1}{1 + e^{-x}} = \frac{e^x}{1 + e^x}
\]

For \( r \) response levels, JMP fits the probabilities that the response is one of \( r \) different response levels given by the data values. The probability estimates must all be positive. For a given configuration of \( Xs \), the probability estimates must sum to 1 over the response levels. The function that JMP uses to predict probabilities is a composition of a linear model and a multi-response logistic function. This is sometimes called a log-linear model because the logs of ratios of probabilities are linear models. JMP relates each response probability to the \( r \)th probability and fit a separate set of design parameters to these \( r - 1 \) models.

\[
\log \left( \frac{P(y = j)}{P(y = r)} \right) = X\beta_{(j)} \text{ for } j = 1, \ldots, r - 1
\]

Fitting Principle for Nominal Response

The fitting principle is called maximum likelihood. It estimates the parameters such that the joint probability for all the responses given by the data is the greatest obtainable by the model. Rather than reporting the joint probability (likelihood) directly, it is more manageable to report the total of the negative logs of the likelihood.

The uncertainty (negative log-likelihood) is the sum of the negative logs of the probabilities attributed by the model to the responses that actually occurred in the sample data. For a sample of size \( n \), it is often denoted as \( H \) and written

\[
H = \sum_{i=1}^{n} -\log(P(y = y_i))
\]

If you attribute a probability of 1 to each event that did occur, then the sum of the negative logs is zero for a perfect fit.
The nominal model can take a lot of time and memory to fit, especially if there are many response levels. JMP tracks the progress of its calculations with an iteration history, which shows the negative log-likelihood values becoming smaller as they converge to the estimates.

**Base Model for Nominal Responses**

The simplest model for a nominal response is a set of constant response probabilities fitted as the occurrence rates for each response level across the whole data table. In other words, the probability that \( y \) is response level \( j \) is estimated by dividing the total sample count \( n \) into the total of each response level \( n_j \). This probability is specified as follows:

\[
    p_j = \frac{n_j}{n}
\]

All other models are compared to this base model. The base model serves the same role for a nominal response as the sample mean does for continuous models.

The \( R^2 \) statistic measures the portion of the uncertainty accounted for by the model, which is

\[
    1 - \frac{H(\text{full model})}{H(\text{base model})}
\]

However, it is rare in practice to get an \( R^2 \) near 1 for categorical models.

**Ordinal Responses**

With an ordinal response \( (Y) \), as with nominal responses, JMP fits probabilities that the response is one of \( r \) different response levels given by the data.

Ordinal data have an order like continuous data. The order is used in the analysis but the spacing or distance between the ordered levels is not used. If you have a numeric response but want your model to ignore the spacing of the values, you can assign the ordinal level to that response column. If you have a classification variable and the levels are in some natural order such as low, medium, and high, you can use the ordinal modeling type.

Ordinal responses are modeled by fitting a series of parallel logistic curves to the cumulative probabilities. Each curve has the same design parameters but a different intercept and is specified as follows:

\[
    P(y \leq j) = F(a_j + X\beta) \quad \text{for} \quad j = 1, \ldots, r - 1
\]

where \( r \) response levels are present and \( F(x) \) is the standard logistic cumulative distribution function

\[
    F(x) = \frac{1}{1 + e^{-x}} = \frac{e^x}{1 + e^x}
\]
Another way to write this is in terms of an unobserved continuous variable, $z$, that causes the ordinal response to change as it crosses various thresholds:

$$
y = \begin{cases} 
  r & \alpha_{r-1} \leq z \\
  j & \alpha_{j-1} \leq z < \alpha_j \\
  1 & z \leq \alpha_1 
\end{cases}
$$

where $z$ is an unobservable function of the linear model and error $\varepsilon$

$$z = X\beta + \varepsilon$$

and $\varepsilon$ has the logistic distribution.

These models are attractive because they recognize the ordinal character of the response, they need far fewer parameters than nominal models, and the computations are fast.

A different but mathematically equivalent way to envision an ordinal model is to think of a nominal model where, instead of modeling the odds, you model the cumulative probability. Instead of fitting functions for all but the last level, you fit only one function and slide it to fit each cumulative response probability.

**Fitting Principle for Ordinal Response**

The maximum likelihood fitting principle for an ordinal response model is the same as for a nominal response model. It estimates the parameters such that the joint probability for all the responses that occur is the greatest obtainable by the model. It uses an iterative method that is faster and uses less memory than nominal fitting.

**Base Model**

The simplest model for an ordinal response, like a nominal response, is a set of response probabilities fitted as the occurrence rates of the response in the whole data table.

**The Factor Models**

The way the $x$-variables (factors) are modeled to predict an expected value or probability is the subject of the factor side of the model.

The factors enter the prediction equation as a linear combination of $x$ values and the parameters to be estimated. For a continuous response model, where $i$ indexes the observations and $j$ indexes the parameters, the assumed model for a typical observation, $y_{ij}$, is written

$$y_i = \beta_0 + \beta_1 x_{1i} + \ldots + \beta_k x_{ki} + \varepsilon_i$$
where

\[ y_i \text{ is the response} \]
\[ x_{ij} \text{ are functions of the data} \]
\[ \epsilon_i \text{ is an unobservable realization of the random error} \]
\[ b_j \text{ are unknown parameters to be estimated.} \]

The way the \( x \)'s in the linear model are formed from the factor terms is different for each modeling type. The linear model \( x \)'s can also be complex effects such as interactions or nested effects. Complex effects are discussed in detail later.

**Continuous Factors**

Continuous factors are placed directly into the design matrix as regressors. If a column is a linear function of other columns, then the parameter for this column is marked *zeroed* or *nonestimable*. Continuous factors are centered by their mean when they are crossed with other factors (interactions and polynomial terms). Centering is suppressed if the factor has a Column Property of *Mixture* or *Coding*, or if the centered polynomials option is turned off when specifying the model. If there is a coding column property, the factor is coded before fitting.

**Nominal Factors**

Nominal factors are transformed into indicator variables for the design matrix. SAS GLM constructs an indicator column for each nominal level. JMP constructs the same indicator columns for each nominal level except the last level. When the last nominal level occurs, a one is subtracted from all the other columns of the factor. For example, consider a nominal factor A with three levels coded for GLM and for JMP as shown below.

**Table A.1  Nominal Factor A**

<table>
<thead>
<tr>
<th></th>
<th>GLM</th>
<th></th>
<th>JMP</th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>A1</td>
<td>A2</td>
<td>A3</td>
<td>A13</td>
</tr>
<tr>
<td>A1</td>
<td>1</td>
<td>0</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>A2</td>
<td>0</td>
<td>1</td>
<td>0</td>
<td>0</td>
</tr>
<tr>
<td>A3</td>
<td>0</td>
<td>0</td>
<td>1</td>
<td>-1</td>
</tr>
</tbody>
</table>
In GLM, the linear model design matrix has linear dependencies among the columns, and the least squares solution uses a generalized inverse. The solution chosen happens to be such that the A3 parameter is set to zero.

In JMP, the linear model design matrix is coded so that it achieves full rank unless there are missing cells or other incidental collinearity. The parameter for the A effect for the last level is the negative sum of the other levels, which makes the parameters sum to zero over all the effect levels.

**Interpretation of Parameters**

**Note:** The parameter for a nominal level is interpreted as the differences in the predicted response for that level from the average predicted response over all levels.

The design column for a factor level is constructed as the zero-one indicator of that factor level minus the indicator of the last level. This is the coding that leads to the parameter interpretation above.

<table>
<thead>
<tr>
<th>JMP Parameter Report</th>
<th>How to Interpret</th>
<th>Design Column Coding</th>
</tr>
</thead>
<tbody>
<tr>
<td>Intercept</td>
<td>mean over all levels</td>
<td>1'</td>
</tr>
<tr>
<td>A[1]</td>
<td>( \alpha_1 - 1/3(\alpha_1 + \alpha_2 + \alpha_3) )</td>
<td>(A==1) - (A==3)</td>
</tr>
<tr>
<td>A[2]</td>
<td>( \alpha_2 - 1/3(\alpha_1 + \alpha_2 + \alpha_3) )</td>
<td>(A==2) - (A==3)</td>
</tr>
</tbody>
</table>

**Interactions and Crossed Effects**

Interaction effects with both GLM and JMP are constructed by taking a direct product over the rows of the design columns of the factors being crossed. For example, the GLM code

```plaintext
PROC GLM;
    CLASS A B;
    MODEL A B A*B;
```

yields this design matrix:

<table>
<thead>
<tr>
<th></th>
<th>A</th>
<th>B</th>
<th>AB</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>1</td>
<td>2</td>
<td>3</td>
</tr>
<tr>
<td>B</td>
<td>1</td>
<td>2</td>
<td>3</td>
</tr>
<tr>
<td>AB</td>
<td>11</td>
<td>12</td>
<td>13</td>
</tr>
</tbody>
</table>
Using the JMP **Fit Model** command and requesting a factorial model for columns A and B produces the following design matrix. Note that A13 in this matrix is A1–A3 in the previous matrix. However, A13B13 is A13*B13 in the current matrix.

### Table A.3 Design Matrix (Continued)

</tr>
</tbody>
</table>

Nested Effects

Nested effects in GLM are coded the same as interaction effects because GLM determines the right test by what is not in the model. Any effect not included in the model can be soaked up by a containing interaction (or, equivalently, nested) effect.

Nested effects in JMP are coded differently. JMP uses the terms inside the parentheses as grouping terms for each group. For each combination of levels of the nesting terms, JMP constructs the effect on the outside of the parentheses. The levels of the outside term do not need to line up across the levels of the nesting terms. Each level of nest is considered separately with regard to the construction of design columns and parameters.

Least Squares Means across Nominal Factors

Least squares means are the predicted values corresponding to some combination of levels, after setting all the other factors to some neutral value. The neutral value for direct continuous regressors is defined as the sample mean. The neutral value for an effect with uninvolved nominal factors is defined as the average effect taken over the levels (which happens to result in all zeros in our coding). Ordinal factors use a different neutral value in “Ordinal Least Squares Means” on page 549. The least squares means might not be estimable, and if not, they are marked nonestimable. The least squares means in JMP agree with those in SAS PROC GLM (Goodnight and Harvey 1978) in all cases except when a weight is used. When a weight variable is used, JMP uses a weighted mean and SAS PROC GLM uses an unweighted mean for its neutral values.

Effective Hypothesis Tests

Generally, the hypothesis tests produced by JMP agree with the hypothesis tests of most other trusted programs, such as SAS PROC GLM (Hypothesis types III and IV). The following two sections describe where there are differences.

In SAS PROC GLM, the hypothesis tests for Types III and IV are constructed using the general form of estimable functions and finding functions that involve only the effects of interest and effects contained by the effects of interest (Goodnight 1978).

The same tests are constructed in JMP. However, because there is a different parameterization, an effect can be tested (assuming full rank for now) by doing a joint test on all the parameters for that effect. The tests do not involve containing interaction parameters because the coding has made them uninvolved with the tests on their contained effects.

If there are missing cells or other singularities, the JMP tests are different from GLM tests. There are several ways to describe them:

- JMP tests are equivalent to testing that the least squares means are different, at least for main effects. If the least squares means are nonestimable, then the test cannot include some comparisons and therefore loses degrees of freedom. For interactions, JMP is testing that the least squares means differ by more than just the marginal pattern described by the containing effects in the model.
- JMP tests an effect by comparing the SSE for the model with that effect to the SSE for the model without that effect. JMP parameterizes the model so that this method makes sense.
• JMP implements the *effective hypothesis tests* described by Hocking (1985, pp. 80–89, 163–166), although JMP uses structural rather than cell-means parameterization. Effective hypothesis tests start with the hypothesis desired for the effect and include “as much as possible” of that test. Of course, if there are containing effects with missing cells, then this test has to drop part of the hypothesis because the complete hypothesis would not be estimable. The effective hypothesis drops as little of the complete hypothesis as possible.

• The differences among hypothesis tests in JMP and GLM (and other programs) that relate to the presence of missing cells are not considered interesting tests anyway. If an interaction is significant, the test for the contained main effects is not interesting. If the interaction is not significant, then it can always be dropped from the model. Some tests are not even unique. If you relabel the levels in a missing cell design, then the GLM Type IV tests can change.

The following section continues this topic in finer detail.

**Singularities and Missing Cells in Nominal Effects**

Consider the case of linear dependencies among the design columns. With JMP coding, this does not occur unless there is insufficient data to fill out the combinations that need estimating, or unless there is some type of confounding or collinearity of the effects.

With linear dependencies, a least squares solution for the parameters might not be unique and some tests of hypotheses cannot be tested. The strategy chosen for JMP is to set parameter estimates to zero in sequence as their design columns are found to be linearly dependent on previous effects in the model. A special column in the report shows what parameter estimates are zeroed and which parameter estimates are estimable. A separate *singularities* report shows what the linear dependencies are.

In cases of singularities the hypotheses tested by JMP can differ from those selected by GLM. Generally, JMP finds fewer degrees of freedom to test than GLM because it holds its tests to a higher standard of marginality. In other words, JMP tests always correspond to tests across least squares means for that effect, but GLM tests do not always have this property.

For example, consider a two-way model with interaction and one missing cell where A has three levels, B has two levels, and the A3B2 cell is missing.

| Table A.7  Two-Way Model with Interaction |
|-----------------|---|---|---|
| A B  | A1 | A2 | B1 | A1B1 | A2B1 |
| A1 B1 | 1  | 0  | 1  | 1    | 0    |
| A2 B1 | 0  | 1  | 1  | 0    | 1    |
| A3 B1 | -1 | -1 | 1  | -1   | -1   |
The expected values for each cell are:

\[
\begin{array}{c|ccc|cc}
A1 & B2 & 1 & 0 & -1 & -1 & 0 \\
A2 & B2 & 0 & 1 & -1 & 0 & -1 \\
A3 & B2 & -1 & -1 & -1 & 1 & 1 \\
\end{array}
\]

Suppose this interaction is missing.

The expected values for each cell are:

\[
\begin{array}{c|c|c}
B1 & A1 & A2 \\
\mu + \alpha_1 + \beta_1 + \alpha\beta_{11} & \mu + \alpha_1 - \beta_1 - \alpha\beta_{11} \\
\mu + \alpha_2 + \beta_1 + \alpha\beta_{21} & \mu + \alpha_2 - \beta_1 - \alpha\beta_{21} \\
\mu - \alpha_1 - \alpha_2 + \beta_1 - \alpha\beta_{11} - \alpha\beta_{21} & \mu - \alpha_1 - \alpha_2 - \beta_1 + \alpha\beta_{11} + \alpha\beta_{21} \\
\end{array}
\]

Obviously, any cell with data has an expectation that is estimable. The cell that is missing has an expectation that is nonestimable. In fact, its expectation is precisely that linear combination of the design columns that is in the singularity report

\[
\mu - \alpha_1 - \alpha_2 - \beta_1 + \alpha\beta_{11} + \alpha\beta_{21}
\]

Suppose that you want to construct a test that compares the least squares means of B1 and B2. In this example, the average of the rows in the above table give these least squares means.

\[
\text{LSM}(B1) = \frac{1}{3}(\mu + \alpha_1 + \beta_1 + \alpha\beta_{11} + \\
\mu + \alpha_2 + \beta_1 + \alpha\beta_{21} + \\
\mu - \alpha_1 - \alpha_2 + \beta_1 - \alpha\beta_{11} - \alpha\beta_{21}) \\
= \mu + \beta_1
\]

\[
\text{LSM}(B2) = \frac{1}{3}(\mu + \alpha_1 - \beta_1 - \alpha\beta_{11} + \\
\mu + \alpha_2 - \beta_1 - \alpha\beta_{21} + \\
\mu - \alpha_1 - \alpha_2 - \beta_1 + \alpha\beta_{11} + \alpha\beta_{21}) \\
= \mu - \beta_1
\]

\[
\text{LSM}(B1) - \text{LSM}(B2) = 2\beta_1
\]

Note that this shows that a test on the \(\beta_1\) parameter is equivalent to testing that the least squares means are the same. But because \(\beta_1\) is not estimable, the test is not testable, meaning there are no degrees of freedom for it.
Now, construct the test for the least squares means across the A levels.

\[
\text{LSM}(A1) = \frac{1}{2}(\mu + \alpha_1 + \beta_1 + \alpha_\beta_{11} + \mu + \alpha_1 - \beta_1 - \alpha_\beta_{11}) = \mu + \alpha_1 \\
\text{LSM}(A2) = \frac{1}{2}(\mu + \alpha_2 + \beta_1 + \alpha_\beta_{21} + \mu + \alpha_2 - \beta_1 - \alpha_\beta_{21}) = \mu + \alpha_2 \\
(1/2)(\mu - \alpha_1 - \alpha_2 + \beta_1 - \alpha_\beta_{11} - \alpha_\beta_{21}) \\
\text{LSM}(A3) = \mu - \alpha_1 - \alpha_2 - \beta_1 + \alpha_\beta_{11} + \alpha_\beta_{21}) = \mu - \alpha_1 - \alpha_2 \\
\text{LSM}(A1) - \text{LSM}(A3) = 2\alpha_1 + \alpha_2 \\
\text{LSM}(A2) - \text{LSM}(A3) = 2\alpha_2 + \alpha_1
\]

Neither of these turn out to be estimable, but there is another comparison that is estimable; namely comparing the two A columns that have no missing cells.

\[
\text{LSM}(A1) - \text{LSM}(A2) = \alpha_1 - \alpha_2
\]

This combination is indeed tested by JMP using a test with 1 degree of freedom, although there are two parameters in the effect.

The estimability can be verified by taking its inner product with the singularity combination, and checking that it is zero:

<table>

</tbody>
</table>

It turns out that the design columns for missing cells for any interaction always knocks out degrees of freedom for the main effect (for nominal factors). Thus, there is a direct relation between the non-estimability of least squares means and the loss of degrees of freedom for testing the effect corresponding to these least squares means.
How does this compare with what GLM does? GLM and JMP do the same test when there are no missing cells. That is, they effectively test that the least squares means are equal. But when GLM encounters singularities, it focuses out these cells in different ways, depending on whether they are Type III or Type IV. For Type IV, it looks for estimable combinations that it can find. These might not be unique, and if you reorder the levels, you might get a different result. For Type III, it does some orthogonalization of the estimable functions to obtain a unique test. But the test might not be very interpretable in terms of the cell means.

The JMP approach has several points in its favor, although at first it might seem distressing that you might lose more degrees of freedom than with GLM:

1. The tests are philosophically linked to LSMs.
2. The tests are easy computationally, using reduction sum of squares for reparameterized models.
3. The tests agree with Hocking’s “Effective Hypothesis Tests”.
4. The tests are whole marginal tests, meaning they always go completely across other effects in interactions.

The last point needs some elaboration: Consider a graph of the expected values of the cell means in the previous example with a missing cell for A3B2.

**Figure A.1 Expected Values of the Cell Means**

The graph shows expected cell means with a missing cell. The means of the A1 and A2 cells are profiled across the B levels. The JMP approach says you cannot test the B main effect with a missing A3B2 cell, because the mean of the missing cell could be anything, as allowed by the interaction term. If the mean of the missing cell was the higher value shown, the B effect would likely test significant. If it were the lower, it would likely test nonsignificant. The point is that you do not know. That is what the least squares means are saying when they are declared nonestimable. That is what the hypotheses for the effects should be saying too—that you do not know.

If you want to test hypotheses involving margins for subsets of cells, then that is what GLM Type IV does. In JMP, you would have to construct these tests yourself by partitioning the effects with a lot of calculations or by using contrasts.
JMP and GLM Hypotheses

GLM works differently than JMP and produces different hypothesis tests in situations where there are missing cells. In particular, GLM does not recognize any difference between a nesting and a crossing in an effect, but JMP does. Suppose that you have a three-layer nesting of A, B(A), and C(A B) with different numbers of levels as you go down the nested design.

Figure A.10 shows the test of the main effect A in terms of the GLM parameters. The first set of columns is the test done by JMP. The second set of columns is the test done by GLM Type IV. The third set of columns is the test equivalent to that by JMP; it is the first two columns that have been multiplied by a matrix:

\[
\begin{bmatrix}
2 & 1 \\
1 & 2
\end{bmatrix}
\]

to be comparable to the GLM test. The last set of columns is the GLM Type III test. The difference is in how the test distributes across the containing effects. In JMP, it seems more top-down hierarchical. In GLM Type IV, the test seems more bottom-up. In practice, the test statistics are often similar.

</tbody>
</table>

So from the JMP perspective, the GLM test looks a little strange, putting a coefficient on the a1b24 parameter.
Ordinal Factors

Factors marked with the ordinal modeling type are coded differently than nominal factors. The parameter estimates are interpreted differently, the tests are different, and the least squares means are different.

For ordinal factors, the first level of the factor is a control or baseline level, and the parameters measure the effect on the response as the ordinal factor is set to each succeeding level. The ordinal factor coding is appropriate for factors that contain levels that represent various doses, where the first dose is zero. The following table shows an example of a three-level ordinal factor:

<table>
<thead>
<tr>
<th>Term</th>
<th>Coded Column</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>a2</td>
</tr>
<tr>
<td></td>
<td>a3</td>
</tr>
<tr>
<td>A1</td>
<td>0</td>
</tr>
<tr>
<td></td>
<td>0</td>
</tr>
<tr>
<td>A2</td>
<td>1</td>
</tr>
<tr>
<td></td>
<td>0</td>
</tr>
<tr>
<td>A3</td>
<td>1</td>
</tr>
<tr>
<td></td>
<td>1</td>
</tr>
</tbody>
</table>

The pattern for the design is such that the lower triangle is ones with zeros elsewhere.

For a simple main-effects model, this can be specified as follows:

\[ y = \mu + \alpha_2 X_{(a \leq 2)} + \alpha_3 X_{(a \leq 3)} + \epsilon \]

noting that \( \mu \) is the expected response at \( A = 1 \), \( \mu + \alpha_2 \) is the expected response at \( A = 2 \), and \( \mu + \alpha_2 + \alpha_3 \) is the expected response at \( A = 3 \). Thus, \( \alpha_2 \) estimates the effect moving from \( A = 1 \) to \( A = 2 \) and \( \alpha_3 \) estimates the effect moving from \( A = 2 \) to \( A = 3 \).

If all the parameters for an ordinal main effect have the same sign, then the response effect is monotonic across the ordinal levels.

Ordinal Interactions

The ordinal interactions, as with nominal effects, are produced with a horizontal direct product of the columns of the factors. Consider an example with two ordinal factors A and B, where each factor has three levels. The ordinal coding in JMP produces the design matrix shown next. The pattern for the interaction is a block lower-triangular matrix of lower-triangular matrices of ones.
Table A.13  Ordinal Interactions

<table>
<thead>
<tr>
<th>A</th>
<th>B</th>

<td>1</td>
<td>1</td>
<td>0</td>
<td>1</td>
<td>0</td>
</tr>
<tr>
<td>A3</td>
<td>B3</td>
<td>1</td>
<td>1</td>
<td>1</td>
<td>1</td>
<td>1</td>
<td>1</td>
</tr>
</tbody>
</table>

Note: When you test to see whether there is no effect, there is not much difference between nominal and ordinal factors for simple models. However, there are major differences when interactions are specified. We recommend that you use nominal rather than ordinal factors for most models.

Hypothesis Tests for Ordinal Crossed Models

To see what the parameters mean, examine this table of the expected cell means in terms of the parameters, where $\mu$ is the intercept, $\alpha_2$ is the parameter for level A2, and so on.

<td>$\mu + \alpha_2 + \beta_2 + \beta_3 + \alpha_\beta_{22} + \alpha_\beta_{23}$</td>
</tr>
</tbody>
</table>
Fitting Linear Models

The Factor Models

Note that the main effect test for A is really testing the A levels holding B at the first level. Similarly, the main effect test for B is testing across the top row for the various levels of B holding A at the first level. This is the appropriate test for an experiment where the two factors are both doses of different treatments. The main question is the efficacy of each treatment by itself, and fewer points are devoted to looking for *drug interactions* when doses of both drugs are applied. In some cases, it might even be dangerous to apply large doses of each drug.

Note that each cell’s expectation can be obtained by adding all the parameters associated with each cell that is to the left and above it, inclusive of the current row and column. The expected value for the last cell is the sum of all the parameters.

Though the hypothesis tests for effects contained by other effects differs with ordinal and nominal codings, the test of effects not contained by other effects is the same. In the crossed design above, the test for the interaction would be the same no matter whether A and B were fit nominally or ordinally.

**Ordinal Least Squares Means**

As stated previously, least squares means are the predicted values corresponding to some combination of levels, after setting all the other factors to some neutral value. JMP defines the neutral value for an effect with uninvolved ordinal factors as the effect at the first level, meaning the control, or *baseline* level.

This definition of least squares means for ordinal factors maintains the idea that the hypothesis tests for contained effects are equivalent to tests that the least squares means are equal.

**Singularities and Missing Cells in Ordinal Effects**

With the ordinal coding, you are saying that the first level of the ordinal effect is the baseline. It is thus possible to get good tests on the main effects even when there are missing cells in the interactions—even if you have no data for the interaction.

**Example with Missing Cell**

The example is the same as above, with two observations per cell except that the A3B2 cell has no data. You can now compare the results when the factors are coded nominally with results when they are coded ordinally. The model fit is the same, as seen in Figure A.2.

Figure A.2  Summary Information for Nominal Fits (Left) and Ordinal Fits (Right)

The parameter estimates are very different because of the different coding. Note that the missing cell affects estimability for some nominal parameters but for none of the ordinal parameters.

Figure A.3  Parameter Estimates for Nominal Fits (Left) and Ordinal Fits (Right)
The singularity details show the linear dependencies (and also identify the missing cell by examining the values).

**Figure A.4** Singularity Details for Nominal Fits (Left) and Ordinal Fits (Right)

The effect tests lose degrees of freedom for nominal. In the case of B, there is no test. For ordinal, there is no loss because there is no missing cell for the *base* first level.

**Figure A.5** Effects Tests for Nominal Fits (Left) and Ordinal Fits (Right)

The least squares means are also different. The nominal LSMs are not all estimable, but the ordinal LSMs are. You can verify the values by looking at the cell means. Note that the A*B LSMs are the same for the two. Figure A.6 shows least squares means for nominal and ordinal fits.

**Figure A.6** Least Squares Means for Nominal Fits (Left) and Ordinal Fits (Right)
Frequencies

The impact of frequencies, including those with non-integer values, on an analysis is explained by their effect on the loss function. Suppose that you want to estimate the parameter $\theta$ using response values $y_i$ and predictors $x_{i1}, x_{i2}, \ldots, x_{in}$. Suppose that the loss function, assuming no frequency variable, is given by the following:

$$L(\theta|y) = \sum_{i=1}^{n} L(\theta|y_i, x_{i1}, x_{i2}, \ldots, x_{in})$$

If frequencies $f_i$ are defined, then the loss function is:

$$L(\theta|y, f) = \sum_{i=1}^{n} f_i L(\theta|y_i, x_{i1}, x_{i2}, \ldots, x_{in})$$

Calculations for all inference-base quantities, such as parameter estimates, standard errors, hypothesis tests, and confidence intervals, are based on this form of the loss function.

The Usual Assumptions

Before you put your faith in statistics, reassure yourself that you know both the value and the limitations of the techniques that you use. Statistical methods are just tools—they cannot guard you from incorrect science (invalid statistical assumptions) or bad data.

Assumed Model

Most statistics are based on the assumption that the model is correct. To the extent that your model might not be correct, you must attenuate your credibility in the statistical reports that result from the model.

Relative Significance

Many statistical tests do not evaluate the model in an absolute sense. Significant test statistics might be saying only that the model fits better than some reduced model, such as the mean. The model can appear to fit the data but might not describe the underlying physical model well at all.
Multiple Inferences

Often the value of the statistical results is not that you believe in them directly, but rather that they provide a key to some discovery. To confirm the discovery, you might need to conduct further studies. Otherwise, you might just be sifting through the data.

For example, if you conduct enough analyses, you can find 5% significant effects in 5% of your studies, even if the factors have no predictive value. Similarly, to the extent that you use your data to shape your model (instead of testing the correct model for the data), you are corrupting the significance levels in your report. The random error then influences your model selection and leads you to believe that your model is better than it really is.

Validity Assessment

There are a variety of techniques and patterns to assess the validity of the model:

- Model validity can be checked against a saturated version of the factors with Lack of Fit tests. The Fit Model platform presents these tests automatically if your contain replicated x values in a non-saturated model.

- You can check the distribution assumptions for a continuous response by looking at plots of residuals and studentized residuals from the Fit Model platform. Or, use the Save commands in the platform pop-up menu to save the residuals in data table columns. Then use the Analyze > Distribution on these columns to look at a histogram with its normal curve and the normal quantile plot. The residuals are not quite independent, but you can informally identify severely non-normal distributions.

- The best all-around diagnostic tool for continuous responses is the leverage plot because it shows the influence of each point on each hypothesis test. If you suspect that there is a mistaken value in your data, this plot helps determine whether a statistical test is heavily influenced by a single point.

- It is a good idea to scan your data for outlying values and examine them to see whether they are valid observations. You can spot univariate outliers in the Distribution platform reports and plots. Bivariate outliers appear in Fit Y by X scatterplots and in the Multivariate scatterplot matrix. You can see trivariate outliers in a three-dimensional plot produced by the Graph > Scatterplot 3D. Higher dimensional outliers can be found with Principal Components or Scatterplot 3D, and with Mahalanobis and jack-knifed distances computed and plotted in the Multivariate platform.
Alternative Methods

The statistical literature describes special nonparametric and robust methods, but JMP implements only a few of them at this time. These methods require fewer distributional assumptions (nonparametric), and then are more resistant to contamination (robust). However, they are less conducive to a general methodological approach, and the small sample probabilities on the test statistics can be time consuming to compute.

If you are interested in linear rank tests and need only normal large sample significance approximations, you can analyze the ranks of your data to perform the equivalent of a Wilcoxon rank-sum or Kruskal-Wallis one-way test.

If you are uncertain that a continuous response adequately meets normal assumptions, you can change the modeling type from continuous to ordinal and then analyze safely, even though this approach sacrifices some richness in the presentations and some statistical power as well.

Key Statistical Concepts

There are two key concepts that unify classical statistics and encapsulate statistical properties and fitting principles into forms that you can visualize:

- a unifying concept of uncertainty
- two basic fitting machines

These two ideas help unlock the understanding of statistics with intuitive concepts that are based on the foundation laid by mathematical statistics.

Statistics is to science what accounting is to business. It is the craft of weighing and balancing observational evidence. Statistical tests are like credibility audits. But statistical tools can do more than that. They are instruments of discovery that can show unexpected things about data and lead to interesting new ideas. Before using these powerful tools, you need to understand a bit about how they work.

Uncertainty, a Unifying Concept

When you do accounting, you total money amounts to get summaries. When you look at scientific observations in the presence of uncertainty or noise, you need some statistical measurement to summarize the data. Just as money is additive, uncertainty is additive if you choose the right measure for it.
The best measure is not the direct probability because to get a joint probability, you have to assume that the observations are independent and then multiply probabilities rather than add them. It is easier to take the log of each probability because then you can sum them and the total is the log of the joint probability.

However, the log of a probability is negative because it is the log of a number between 0 and 1. In order to keep the numbers positive, JMP uses the negative log of the probability. As the probability becomes smaller, its negative log becomes larger. This measure is called uncertainty, and it is measured in reverse fashion from probability.

In business, you want to maximize revenues and minimize costs. In science, you want to minimize uncertainty. Uncertainty in science plays the same role as cost plays in business. All statistical methods fit models such that uncertainty is minimized.

It is not difficult to visualize uncertainty. Just think of flipping a series of coins where each toss is independent. The probability of tossing a head is 0.5, and -log(0.5) is 1 for base 2 logarithms. The probability of tossing $h$ heads in a row is defined as follows:

$$ p = \left(\frac{1}{2}\right)^h $$

Solving for $h$ produces the following:

$$ h = -\log_2 p $$

You can think of the uncertainty of some event as the number of consecutive “head” tosses you have to flip to get an equally rare event.

Almost everything we do statistically has uncertainty, -$\log p$, at the core. Statistical literature refers to uncertainty as negative log-likelihood.

The Two Basic Fitting Machines

An amazing fact about statistical fitting is that most of the classical methods reduce to using two simple machines, the spring and the pressure cylinder.

Springs

First, springs are the machine of fit for a continuous response model (Farebrother 1987). Suppose that you have $n$ points and that you want to know the expected value (mean) of the points. Envision what happens when you lay the points out on a scale and connect them to a common junction with springs (Figure A.7). When you let go, the springs wiggle the junction point up and down and then bring it to rest at the mean. This is what must happen according to physics.
If the data are normally distributed with a mean at the junction point where springs are attached, then the physical energy in each point’s spring is proportional to the uncertainty of the data point. All you have to do to calculate the energy in the springs (the uncertainty) is to compute the sum of squared distances of each point to the mean.

To choose an estimate that attributes the least uncertainty to the observed data, the spring settling point is chosen as the estimate of the mean. That is the point that requires the least energy to stretch the springs and is equivalent to the least squares fit.

**Figure A.7 Connect Springs to Data Points**

That is how you fit one mean or fit several means. That is how you fit a line, or a plane, or a hyperplane. That is how you fit almost any model to continuous data. You measure the energy or uncertainty by the sum of squares of the distances that you must stretch the springs.

Statisticians put faith in the normal distribution because it is the one that requires the least faith. It is, in a sense, the most random. It has the most non-informative shape for a distribution. It is the one distribution that has the most expected uncertainty for a given variance. It is the distribution whose uncertainty is measured in squared distance. In many cases it is the limiting distribution when you have a mixture of distributions or a sum of independent quantities. It is the distribution that leads to test statistics that can be measured fairly easily.

When the fit is constrained by hypotheses, you test the hypotheses by measuring this same spring energy. Suppose you have responses from four different treatments in an experiment, and you want to test if the means are significantly different. First, envision your data plotted in groups as shown in Figure A.8, but with springs connected to a separate mean for each treatment. Then exert pressure against the spring force to move the individual means to the common mean. Presto! The amount of energy that constrains the means to be the same is the test statistic that you need. That energy is the main ingredient in the $F$ test for the hypothesis that tests whether the means are the same.
Pressure Cylinders

What if your response is categorical instead of continuous? For example, suppose that the response is the country of origin for a sample of cars. For your sample, there are probabilities for the three response levels, American, European, and Japanese. You can set these probabilities for country of origin to some estimate and then evaluate the uncertainty in your data. This uncertainty is found by summing the negative logs of the probabilities of the responses given by the data. It is defined as follows:

\[ H = \sum h_y(i) = -\sum \log p_y(i) \]

The idea of springs illustrates how a mean is fit to continuous data. When the response is categorical, statistical methods estimate the response probabilities directly and choose the estimates that minimize the total uncertainty of the data. The probability estimates must be nonnegative and sum to 1. You can picture the response probabilities as the composition along a scale whose total length is 1. For each response observation, load into its response area a gas pressure cylinder, such as a tire pump. Let the partitions between the response levels vary until an equilibrium of lowest potential energy is reached. The sizes of the partitions that result then estimate the response probabilities.

Figure A.9 shows what the situation looks like for a single category such as the medium size cars (see the mosaic column from Carpoll.jmp labeled medium in Figure A.10). Suppose there are thirteen responses (cars). The first level (American) has six responses, the next has two, and the last has five responses. The response probabilities become 6/13, 2/13, and 5/13, respectively, as the pressure against the response partitions balances out to minimize the total energy.
As with springs for continuous data, you can divide your sample by some factor and fit separate sets of partitions. Then test that the response rates are the same across the groups by measuring how much additional energy you need to push the partitions to be equal. Imagine the pressure cylinders for car origin probabilities grouped by the size of the car. The energy required to force the partitions in each group to align horizontally tests whether the variables have the same probabilities. Figure A.10 shows these partitions.

**Figure A.10** A Mosaic Plot for Categorical Data
Likelihood, AICc, and BIC

Many statistical models in JMP are fit using a technique called maximum likelihood. This technique seeks to estimate the parameters of a model, which we denote generically by \( \beta \), by maximizing the likelihood function. The likelihood function, denoted \( L(\beta) \), is the product of the probability density functions (or probability mass functions for discrete distributions) evaluated at the observed data values. Given the observed data, maximum likelihood estimation seeks to find values for the parameters, \( \beta \), that maximize \( L(\beta) \).

Rather than maximize the likelihood function \( L(\beta) \), it is more convenient to work with the negative of the natural logarithm of the likelihood function, \(-\log L(\beta)\). The problem of maximizing \( L(\beta) \) is reformulated as a minimization problem where you seek to minimize the negative log-likelihood \((-\log L(\beta) = -\log L(\beta))\). Therefore, smaller values of the negative log-likelihood or twice the negative log-likelihood \((-2\log L(\beta))\) indicate better model fits.

You can use the value of negative log-likelihood to choose between models and to conduct custom hypothesis tests that compare models fit using different platforms in JMP. This is done through the use of likelihood ratio tests. One reason that \(-2\log L(\beta)\) is reported in many JMP platforms is that the distribution of the difference between the full and reduced model \(-2\log L(\beta)\) values is asymptotically Chi-square. The degrees of freedom associated with this likelihood ratio test are equal to the difference between the numbers of parameters in the two models (Wilks 1938).

The corrected Akaike's Information Criterion (AICc) and the Bayesian Information Criterion (BIC) are information-based criteria that assess model fit. Both are based on \(-2\log L(\beta)\).

AICc is defined as follows:

\[
AICc = -2\log L(\beta) + 2k + 2k(k + 1)/(n - k - 1)
\]

where \( k \) is the number of estimated parameters in the model and \( n \) is the number of observations used in the model. This value can be used to compare various models for the same data set to determine the best-fitting model. The model having the smallest value, as discussed in Akaike (1974), is usually the preferred model.

BIC is defined as follows:

\[
BIC = -2\log L(\beta) + k \ln(n)
\]

where \( k \) is the number of estimated parameters in the model and \( n \) is the number of observations used in the model. When comparing the BIC values for two models, the model with the smaller BIC value is considered better.

In general, BIC penalizes models with more parameters more than AICc does. For this reason, it leads to choosing more parsimonious models, that is, models with fewer parameters, than does AICc. For a detailed comparison of AICc and BIC, see Burnham and Anderson (2004).
Simplified Formulas for AICc and BIC in Least Squares Regression

In the case of least squares regression, the AICc and BIC can also be calculated based on the sum of squared errors (SSE). In terms of SSE, AICc and BIC are defined as follows:

\[
\text{AICc} = n \ln \left( \frac{\text{SSE}}{n} \right) + 2k + 2(k+1)/(n-k-1) + n \ln(2\pi) + n
\]

\[
\text{BIC} = n \ln \left( \frac{\text{SSE}}{n} \right) + k \ln(n) + n \ln(2\pi) + n
\]

where \( k \) is the number of estimated parameters in the model, \( n \) is the number of observations used in the model, and \( \text{SSE} \) is the error sum of squares in the model.

Power Calculations

The next sections give formulas for computing the least significant number (LSN), least significant value (LSV), power, and adjusted power. With the exception of LSV, these computations are provided for each effect, and for a collection of user-specified contrasts (under Custom Test and LS Means Contrast). LSV is computed only for a single linear contrast. In the details below, the \textit{hypothesis} refers to the collection of contrasts of interest.

- “Computations for the LSN”
- “Computations for the LSV”
- “Computations for the Power”
- “Computations for the Adjusted Power”

Computations for the LSN

The least significant number (LSN) solves for \( N \) in the equation:

\[
\alpha = 1 - \text{FDist} \left[ \frac{N\delta^2}{df_{Hyp}\sigma^2}, df_{Hyp}, N - df_{Hyp} - 1 \right]
\]

where

- \( \text{FDist} \) is the cumulative distribution function of the central \( F \) distribution
- \( df_{Hyp} \) represents the degrees of freedom for the hypothesis
- \( \sigma^2 \) is the error variance
- \( \delta^2 \) is the squared effect size
For retrospective analyses, \( \delta^2 \) is estimated by the sum of squares for the hypothesis divided by \( n \), the size of the current sample. If the test is for an effect, then \( \delta^2 \) is estimated by the sum of squares for that effect divided by the number of observations in the current study. For retrospective studies, the error variance \( \sigma^2 \) is estimated by the mean square error. These estimates, along with an \( \alpha \) value of 0.05, are entered into the Power Details window as default values.

When you are conducting a prospective analysis to plan a future study, consider determining the sample size that will achieve a specified power (see “Computations for the Power” on page 562).

**Computations for the LSV**

The least significant value (LSV) is computed only for a single linear contrast.

**Test of a Single Linear Contrast**

Consider the one-degree-freedom test \( L\beta = 0 \), where \( L \) is a row vector of constants. The test statistic for a \( t \) test for this hypothesis is:

\[
\frac{Lb}{s\sqrt{L(X'X)^{-1}L'}}
\]

where \( s \) is the root mean square error. We reject the hypothesis at significance level \( \alpha \) if the absolute value of the test statistic exceeds the \( 1 - \alpha/2 \) quantile of the \( t \) distribution, \( t_{1-\alpha/2} \), with degrees of freedom equal to those for error.

To find the least significant value, denoted \( (Lb)^{LSV} \), we solve for \( Lb \):

\[
(Lb)^{LSV} = t_{1-\alpha/2}s\sqrt{L(X'X)^{-1}L'}
\]

**Test of a Single Parameter**

In the special case where the linear contrast tests a hypothesis setting a single \( \beta_i \) equal to 0, this reduces to the following:

\[
b_i^{LSV} = t_{1-\alpha/2}s\sqrt{(X'X)_{ii}} = t_{1-\alpha/2}StdError(b_i)
\]
Test of a Difference in Means

In a situation where the test of interest is a comparison of two group means, the literature talks about the least significant difference (LSD). In the special case where the model contains only one nominal variable, the formula for testing a single linear contrast reduces to the formula for the LSD:

\[
LSD = t_{1 - \alpha/2} \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}
\]

However, in JMP, the parameter associated with a level for a nominal effect measures the difference between the mean of that level and the mean for all levels. So, the LSV for such a comparison is half the LSD for the differences of the means.

Note: If you are testing a contrast across the levels of a nominal effect, keep in mind how JMP codes nominal effects. Namely, the parameter associated with a given level measures the difference to the average for all levels.

Computations for the Power

Suppose that you are interested in computing the power of a test of a linear hypothesis, based on significance level \( \alpha \) and a sample size of \( N \). You want to detect an effect of size \( \delta \).

To calculate the power, begin by finding the critical value for an \( \alpha \)-level \( F \) test of the linear hypothesis. This is given by solving for \( F_C \) in the equation

\[
\alpha = 1 - \text{FDist}[F_C, df_{Hyp}, N - df_{Model} - 1] \]

Here, \( df_{Hyp} \) represents the degrees of freedom for the hypothesis, \( df_{Model} \) represents the degrees of freedom for the model, and \( N \) is the proposed (or actual) sample size.

Then calculate the noncentrality parameter associated with the desired effect size. The noncentrality parameter is defined as follows:

\[
\lambda = (N\delta^2) / \sigma^2
\]

where \( \sigma^2 \) is a proposed (or estimated) value of the error variance.

Given an effect of size \( \delta \), the test statistic has a non-central \( F \) distribution, where the distribution function is denoted \( FDist \) below, with noncentrality parameter \( \lambda \). To obtain the power of your test, calculate the probability that the test statistic exceeds the critical value:

\[
\text{Power} = 1 - \text{FDist} \left[ F_C, df_{Hyp}, N - df_{Model} - 1, \frac{N\delta^2}{\sigma^2} \right]
\]
In obtaining retrospective power for a study with $n$ observations, JMP estimates the noncentrality parameter $\lambda = (n\bar{\delta}^2)/\sigma^2$ by $\hat{\lambda} = SS_{Hyp}/\hat{\sigma}^2$, where $SS_{Hyp}$ represents the sum of squares due to the hypothesis.

**Computations for the Adjusted Power**

The adjusted power calculation (Wright and O’Brien 1988) is relevant only for retrospective power analysis. Adjusted power calculates power using a noncentrality parameter estimate that has been adjusted to remove the positive bias that occurs when parameters are simply replaced by their sample estimates.

The estimate of the noncentrality parameter, $\lambda$, obtained by estimating $\delta$ and $\sigma$ by their sample estimates, is calculated as follows:

$$\hat{\lambda} = SS_{Hyp}/MSE$$

Wright and O’Brien (1988) explain that an unbiased estimate of the noncentrality parameter is given by the following:

$$[\hat{\lambda}(df_{Error} - 2)/df_{Error}] - df_{Hyp} = \frac{\hat{\lambda}(N - df_{Model} - 1 - 2)}{N - df_{Model} - 1} - df_{Hyp}$$

The expression on the right illustrates the calculation of the unbiased noncentrality parameter when a sample size $N$, different from the study size $n$, is proposed for a retrospective power analysis. Here, $df_{Hyp}$ represents the degrees of freedom for the hypothesis and $df_{Model}$ represents the degrees of freedom for the whole model.

Unfortunately, this adjustment to the noncentrality estimate can lead to negative values. Negative values are set to zero, reintroducing some slight bias. The adjusted noncentrality estimate is

$$\hat{\lambda}_{adj} = \max\left[0, \frac{\hat{\lambda}(N - df_{Model} - 1 - 2)}{N - df_{Model} - 1} - df_{Hyp}\right]$$

The adjusted power is

$$Power_{adj} = 1 - FDist[F_C, df_{Hyp}N - df_{Model} - 1, \hat{\lambda}_{adj}]$$

Confidence limits for the noncentrality parameter are constructed as described in Dwass (1955):

Lower CL for $\lambda = \max\left[0, [(\sqrt{SS_{Hyp}/MSE}) - \sqrt{df_{Hyp}F_C}]^2\right]$

Upper CL for $\lambda = [(\sqrt{SS_{Hyp}/MSE}) - \sqrt{df_{Hyp}F_C}]^2$
Confidence limits for the power are obtained by substituting these confidence limits for $\lambda$ into the following equation:

$$\text{Power} = 1 - \text{FDist}\left[F_{C, \text{df}_{Hyp}^*, \text{N} - \text{df}_{Model}^* - 1}, \lambda\right]$$

---

**Inverse Prediction with Confidence Limits**

Inverse prediction estimates a value of an independent variable from a response value. In bioassay problems, inverse prediction with confidence limits is especially useful. In JMP, you can request inverse prediction estimates for continuous and binary response models. If the response is continuous, you can request confidence limits for an individual response or an expected response.

The confidence limits are computed using Fieller’s theorem (1954), which is based on the following logic. The goal is predicting the value of a single regressor and its confidence limits given the values of the other regressors and the response.

- Let $b$ estimate the parameters $\beta$ so that we have $b$ distributed as $N(\beta, V)$.
- Let $x$ be the regressor values of interest, with the $i^{\text{th}}$ value to be estimated.
- Let $y$ be the response value.

We desire a confidence region on the value of $x[i]$ such that $\beta'x = y$ with all other values of $x$ given.

The inverse prediction is

$$x[i] = \frac{y - \beta'(i)x(i)}{\beta[i]}$$

where the subscript $(i)$ in parentheses indicates that the $i^{\text{th}}$ component is omitted. A confidence interval can be formed from the relation

$$(y - b'x)^2 < t^2 x'Vx$$

where $t$ is the $t$ value for the specified confidence level.

The equation

$$(y - b'x)^2 - t^2 x'Vx = 0$$

can be written as a quadratic in terms of $z = x[i]$:

$$gz^2 + hz + f = 0$$
where

\[ g = b[i]^2 - t^2 V[i, i] \]

\[ h = -2y b[i] + 2b[i] b'(i) x(i) - 2t^2 V[i, (i)] x(i) \]

\[ f = y^2 - 2y b'(i) x(i) + (b'(i) x(i))^2 - t^2 x(i) V(i) x(i) \]

Depending on the values of \( g, h, \) and \( f, \) the set of values satisfying the inequality, and hence the confidence interval for the inverse prediction, can have a number of forms:

- an interval of the form \((\phi_1, \phi_2)\), where \(\phi_1 < \phi_2\)
- two disjoint intervals of the form \((-\infty, \phi_1) \cup (\phi_2, \infty)\), where \(\phi_1 < \phi_2\)
- the entire real line, \((-\infty, \infty)\)
- only one of \(-\infty, \phi)\) or \((\phi, \infty)\)

In the case where the Fieller confidence interval is the entire real line, Wald intervals are presented.

**Note:** The Fit Y by X logistic platform and the Fit Model Nominal Logistic personalities use \(t\) values when computing confidence intervals for inverse prediction. The Fit Model Generalized Linear Model personality, as well as PROC PROBIT in SAS/STAT, use \(z\) values, which give different results.

Get the Most from JMP

Whether you are a first-time or a long-time user, there is always something to learn about JMP.

Visit JMP.com to find the following:

• live and recorded webcasts about how to get started with JMP
• video demos and webcasts of new features and advanced techniques
• details on registering for JMP training
• schedules for seminars being held in your area
• success stories showing how others use JMP
• the JMP user community, resources for users including examples of add-ins and scripts, a forum, blogs, conference information, and so on

Statistical Details for the Partition Platform ............................................................................................ 86
  Responses and Factors ........................................................................................................................ 86
  Splitting Criterion ............................................................................................................................... 87
  Predicted Probabilities in Decision Tree and Bootstrap Forest ........................................................... 87

5 Bootstrap Forest .................................................................................................................................. 89

Fit a Model By Averaging Many Trees
Overview of the Bootstrap Forest Platform ............................................................................................ 91
Example of Bootstrap Forest with a Categorical Response .................................................................. 92
  Bootstrap Forest Model ....................................................................................................................... 92
  Missing Values .................................................................................................................................... 94
Example of Bootstrap Forest with a Continuous Response ........................................ 95
Launch the Bootstrap Forest Platform ...................................................................... 97
  Launch Window .................................................................................................... 97
  Specification Window ......................................................................................... 99
The Bootstrap Forest Report .................................................................................. 101
  Model Validation-Set Summaries ...................................................................... 102
  Specifications ..................................................................................................... 102
  Overall Statistics ............................................................................................... 102
  Cumulative Validation ....................................................................................... 104
  Per-Tree Summaries ......................................................................................... 105
Bootstrap Forest Platform Options ...................................................................... 106

6  Boosted Tree ........................................................................................................ 109
  Fit Many Layers of Trees, Each Based on the Previous Layer
  Overview of the Boosted Tree Platform ............................................................ 111
  Example of Boosted Tree with a Categorical Response .................................. 111
  Example of Boosted Tree with a Continuous Response .................................. 113
Launch the Boosted Tree Platform ........................................................................ 115
  Specification Window ......................................................................................... 117
The Boosted Tree Report ...................................................................................... 119
  Model Validation-Set Summaries ...................................................................... 120
  Specifications ..................................................................................................... 121
  Overall Statistics ............................................................................................... 121
  Cumulative Validation ....................................................................................... 122
Boosted Tree Platform Options ........................................................................... 123
Statistical Details for the Boosted Tree Platform .................................................. 125
  Overfit Penalty .................................................................................................... 125

7  K Nearest Neighbors ............................................................................................ 127
  Predict Response Values Using Nearby Observations
  Overview of the K Nearest Neighbors Platform ................................................. 129
  Example of K Nearest Neighbors with Categorical Response ......................... 130
  Example of K Nearest Neighbors with Continuous Response ....................... 132
Launch the K Nearest Neighbors Platform ............................................................. 134
The K Nearest Neighbors Report .......................................................................... 135
  Continuous Responses ....................................................................................... 136
  Categorical Responses ....................................................................................... 136
K Nearest Neighbors Platform Options ................................................................ 137
  Model Fit Options .............................................................................................. 138
8 Naive Bayes
Classify Observations Using Probabilistic Assumptions
Overview of the Naive Bayes Platform .......................................................... 143
Example of Naive Bayes ................................................................................. 144
Launch the Naive Bayes Platform ................................................................. 146
The Naive Bayes Report .................................................................................. 148
  Fit Details Report ......................................................................................... 148
  Response Column Report ........................................................................... 148
  Confusion Matrix Report ............................................................................ 149
  ROC Curves ............................................................................................... 149
Naive Bayes Platform Options ..................................................................... 149
Additional Example of Naive Bayes .............................................................. 151
Statistical Details for the Naive Bayes Platform .......................................... 152
  Algorithm .................................................................................................. 152
  Saved Probability Formulas ..................................................................... 153

9 Support Vector Machines
Predict Response Categories Using Support Vectors
Overview of Support Vector Machines ......................................................... 157
Example of Support Vector Machines ......................................................... 157
Launch the Support Vector Machines Platform ........................................... 159
  The Support Vector Machines Launch Window ........................................ 160
  Model Launch Control Panel .................................................................... 161
The Support Vector Machine Report ............................................................ 163
  Model Comparison Report ...................................................................... 164
  Support Vector Machine Model Report ................................................... 165
Support Vector Machines Platform Options .............................................. 167
  Support Vector Machine Model Report Options ..................................... 168
Additional Example of the SVM Platform .................................................. 170
  Example of Support Vector Regression for Continuous Response .......... 170

10 Model Screening
Fit and Compare Multiple Prediction Models
Example of Model Screening for Continuous Response ......................... 175
Launch the Model Screening Platform ......................................................... 177
The Model Screening Report ....................................................................... 180
  Summary Across the Folds Report ............................................................ 181
  Training, Validation, and Test Measures of Fit .......................................... 182
Model Screening Platform Options .............................................................. 183
Decision Thresholds Report ........................................................................ 185
11 Model Comparison

Compare the Predictive Ability of Fitted Models

Example of Model Comparison .................................................. 191
Launch the Model Comparison Platform .................................. 194
The Model Comparison Report .................................................. 195
Model Comparison Platform Options ........................................ 197
  Continuous and Categorical Responses ................................. 197
  Continuous Responses .......................................................... 197
  Categorical Responses ......................................................... 197
Additional Example of Model Comparison ............................... 198

12 Make Validation Column

Divide Data into Training, Validation, and Test Sets

Overview of the Make Validation Column Platform ................... 203
Example of Make Validation Column ........................................ 203
Launch the Make Validation Column Platform ............................ 205
Make Validation Column Report ................................................ 208
  Specify Rates or Relative Rates ........................................ 208
  Set Cutpoints .......................................................................... 208
  Options .................................................................................... 209
  Go ......................................................................................... 209
Make Validation Column Platform Options ............................... 209
Additional Example of the Make Validation Column Platform ....... 210

13 Formula Depot

Manage Models and Generate Scoring Code

Overview of the Formula Depot Platform .................................. 215
Example of Formula Depot ....................................................... 215
Launch the Formula Depot Platform .......................................... 216
  Platforms That Publish Prediction Formulas to the Formula Depot 217
Formula Depot Platform Options .............................................. 217
  Formula Depot Model Options ............................................... 219
Generating Scoring Code from the Formula Depot Platform ....... 219

14 Fit Curve

Fit Built-In Nonlinear Models to Your Data

Overview of the Fit Curve Platform .......................................... 225
Example Using the Fit Curve Platform ...................................... 226
Launch the Fit Curve Platform .................................................. 229
The Fit Curve Report ............................................................... 230
Fit Curve Options ................................................................. 230
15 **Nonlinear Regression**

*Fit Custom Nonlinear Models to Your Data*

- Example of Fitting a Custom Model .................................................. 249
- Launch the Nonlinear Platform .......................................................... 251
- The Nonlinear Fit Report ................................................................. 252
- Nonlinear Platform Options ............................................................. 256
- Create a Formula Using the Model Library ........................................... 260
- Additional Examples ........................................................................... 263
  - Example of Maximum Likelihood: Logistic Regression ......................... 263
  - Example of a Probit Model with Binomial Errors: Numerical Derivatives .... 265
  - Example of a Poisson Loss Function .................................................. 266
  - Example of Setting Parameter Limits ............................................... 268
- Statistical Details for the Nonlinear Platform ...................................... 271
  - Profile Likelihood Confidence Limits ............................................... 272
  - How Custom Loss Functions Work ................................................... 273
  - Notes Concerning Derivatives .......................................................... 274
  - Notes on Effective Nonlinear Modeling ........................................... 275

16 **Functional Data Explorer**

*Perform Functional Data Analysis*

- Overview of the Functional Data Explorer Platform .............................. 279
- Example of Functional Data Explorer ............................................... 280
- Launch the Functional Data Explorer Platform .................................. 283
- The Functional Data Explorer Report .............................................. 286
  - Model Reports ................................................................................. 287
- Functional Data Explorer Platform Options ....................................... 292
  - Functional Data Explorer Group Options ....................................... 293
  - Data Processing Report Options ................................................... 294
  - Model Report Options ................................................................. 297
- Additional Examples of the Functional Data Explorer Platform ............. 298
  - Example for Multiple Functional Processes ................................... 298
  - Example of Functional DOE .......................................................... 302
17 **Gaussian Process** .......................................................... 307
   **Fit Data Using Smoothing Models**
   Example of Gaussian Process .............................................. 309
   Launch the Gaussian Process Platform ................................. 311
   The Gaussian Process Report ............................................ 312
       Actual by Predicted Plot ............................................. 312
       Model Report .......................................................... 312
       Marginal Model Plots ................................................. 313
   Gaussian Process Platform Options ................................... 313
   Additional Examples of the Gaussian Process Platform ............ 314
       Example of a Gaussian Process Model ............................... 315
       Example of Gaussian Process Model with Categorical Predictors 316
   Statistical Details for the Gaussian Process Platform ............ 318
       Models with Continuous Predictors ................................ 318
       Models with Categorical Predictors ................................. 319
       Variance Formula Parameterization .................................. 320
       Model Fit Details ..................................................... 320

18 **Time Series Analysis** .................................................... 321
   **Fit Time Series Models and Transfer Functions**
   Overview of the Time Series Platform .................................. 323
   Example of the Time Series Platform .................................... 324
   Launch the Time Series Platform ......................................... 326
   The Time Series Analysis Report ....................................... 328
       Time Series Graph .................................................... 328
       Time Series Basic Diagnostics Chart ............................... 329
   Time Series Platform Options .......................................... 331
       Time Series Diagnostics .............................................. 331
       Differencing and Decomposition ................................... 332
       ARIMA and Seasonal ARIMA Models ................................. 335
       Smoothing Models .................................................... 336
       State Space Smoothing Models ..................................... 337
       Transfer Function Models ........................................... 338
       Smoothing Model Specification Windows .......................... 341
   Reports ................................................................. 343
       Difference Report .................................................... 343
       Decomposition Reports ............................................... 344
19 Time Series Forecast

Forecast Multiple Time Series

Example of Time Series Forecast .................................................. 375
Launch the Time Series Forecast Platform .................................... 377
  Data Format .............................................................................. 377
The Time Series Forecast Report ..................................................... 379
  Analysis of Time Pattern ............................................................ 379
  Group Summary of Time .............................................................. 379
  Group Summary of Y ................................................................. 380
  Modeling Specifications ............................................................... 380
Time Series Forecast Platform Options ............................................. 383
Model Reports ............................................................................ 384

20 Matched Pairs Analysis

Compare Measurements on the Same Subject

Overview of the Matched Pairs Platform .......................................... 389
Example of Comparing Matched Pairs .............................................. 389
Launch the Matched Pairs Platform .................................................. 391
  Multiple Y Columns ................................................................. 391
The Matched Pairs Report ............................................................... 392
  Difference Plot and Report .......................................................... 393
  Across Groups .......................................................................... 393
Matched Pairs Platform Options ...................................................... 394
Example Comparing Matched Pairs across Groups ............................... 395
Statistical Details for the Matched Pairs Platform ................................. 396
  Graphics for Matched Pairs ......................................................... 397
21 **Modeling Utilities** ................................................................. 399

*Exploring Data for Outliers, Missing Values, and Patterns*

- Explore Outliers Utility ......................................................... 401
  - Example of the Explore Outliers Utility .............................. 401
  - Launch the Explore Outliers Utility ................................. 405
  - Quantile Range Outliers ............................................... 406
  - Robust Fit Outliers ..................................................... 409
  - Robust PCA Outliers .................................................. 411
  - K Nearest Neighbor Outliers ........................................ 414
  - Explore Outliers Utility Options .................................. 416
  - Additional Examples of the Explore Outliers Utility .......... 417

- Explore Missing Values Utility ........................................... 419
  - Example of the Explore Missing Values Utility .................. 420
  - The Missing Value Report ............................................ 422
  - Explore Missing Values Utility Options ......................... 428

- Explore Patterns Utility .................................................... 429
  - Example of the Explore Patterns Utility ............................ 429
  - Launch the Explore Patterns Utility ............................... 432
  - Explore Patterns Report ............................................. 433
  - Explore Patterns Utility Options .................................. 434
  - Additional Example of the Explore Patterns Utility .......... 438
  - Statistical Details for the Explore Patterns Utility .......... 440

22 **Response Screening** ........................................................... 443

*Test Many Responses in Large-Scale Data*

- Overview of the Response Screening Platform ....................... 445
- Example of Response Screening ........................................ 446
- Launch the Response Screening Platform ............................. 449
- The Response Screening Report ....................................... 451
  - Result Table .......................................................... 451
  - FDR PValue Plot .................................................... 453
  - FDR LogWorth by Effect Size .................................... 454
  - FDR LogWorth by RSquare ......................................... 455
- The PValues Data Table ................................................... 455
  - PValues Data Table Scripts ........................................ 456
- Response Screening Platform Options ................................ 456
  - Means Data Table ................................................... 458
  - Compare Means Data Table ......................................... 459
- The Response Screening Personality in Fit Model .................. 461

Launch Response Screening in Fit Model ........................................... 462
The Fit Response Screening Report ................................................. 463
Fit Response Screening Options ..................................................... 464
PValues Data Table ........................................................................ 465
Y Fits Data Table ........................................................................... 466
Additional Examples of Response Screening .................................... 467
Example of Tests of Practical Significance and Equivalence .......... 467
Example of the MaxLogWorth Option ............................................. 469
Example of Robust Fit ..................................................................... 470
Response Screening Personality ....................................................... 473
Statistical Details for the Response Screening Platform .................. 474
The False Discovery Rate ................................................................. 474

23 Process Screening ........................................................................ 477
Screen Many Processes for Stability and Capability ....................... 479
Overview of the Process Screening Platform ................................ 479
Example of Process Screening ......................................................... 479
Launch the Process Screening Platform ......................................... 482

Overview of Modeling Techniques

*Predictive and Specialized Modeling* provides details about more technical modeling techniques, such as Response Screening, Partitioning, and Neural Networks.

- The Neural platform implements a fully connected multi-layer perceptron with one or two layers. Use neural networks to predict one or more response variables using a flexible function of the input variables. See Chapter 3, “Neural Networks”.

- The Partition platform recursively partitions data according to a relationship between the \( X \) and \( Y \) values, creating a decision tree of partitions. See Chapter 4, “Partition Models”.

- The Bootstrap Forest platform enables you to fit an ensemble model by averaging many decision trees each of which is fit to a random subset of the training data. See Chapter 5, “Bootstrap Forest”.

- The Boosted Tree platform produces an additive decision tree model that consists of many smaller decision trees that are constructed in layers. The tree in each layer consists of a small number of splits, typically five or fewer. Each layer is fit using the recursive fitting methodology. See Chapter 6, “Boosted Tree”.

- The K Nearest Neighbors platform predicts a response value for a given observation using the responses of the observations in that observation’s local neighborhood. It can be used with a categorical response for classification and with a continuous response for prediction. See Chapter 7, “K Nearest Neighbors”.

- The Naive Bayes platform classifies observations into groups that are defined by the levels of a categorical response variable. The variables (or factors) that are used for classification are often called features in the data mining literature. See Chapter 8, “Naive Bayes”.

- The Support Vector Machines platform classifies observations into groups that are defined by levels of a categorical response variable. The model classifies data by optimizing a hyperplane that separates the classes. See Chapter 9, “Support Vector Machines”.

- The Model Screening platform enables you to quickly run multiple predictive models and compare the results. Measures of fit are provided for each model along with overlaid diagnostic plots. See Chapter 10, “Model Screening”.

- The Model Comparison platform enables you to compare the predictive ability of different models. Measures of fit are provided for each model along with overlaid diagnostic plots. See Chapter 11, “Model Comparison”.

- The Make Validation Column platform lets you partition the data into two or three sets, using one of five different methods to create these partitions. See Chapter 12, “Make Validation Column”.
• The Formula Depot platform enables you to organize, compare, profile, and score models for deployment. For model exploration work, you can use the Formula Depot to store candidate models outside of your JMP data table. See Chapter 13, “Formula Depot”.

• The Fit Curve platform provides predefined models, such as polynomial, logistic, Gompertz, exponential, peak, and pharmacokinetic models. Compare different groups or subjects using a variety of analytical and graphical techniques. See Chapter 14, “Fit Curve”.

• The Nonlinear platform lets you fit custom nonlinear models, which include a model formula and parameters to be estimated. See Chapter 15, “Nonlinear Regression”.

• The Gaussian Process platform models the relationship between a continuous response and one or more continuous predictors. These models are common in areas like computer simulation experiments, such as the output of finite element codes, and they often perfectly interpolate the data. See Chapter 17, “Gaussian Process”.

• The Functional Data Explorer platform enables you to convert functional data into a form that can be analyzed in another JMP platform. See Chapter 16, “Functional Data Explorer”.

• The Time Series platform lets you explore, analyze, and forecast univariate time series. See Chapter 18, “Time Series Analysis”.

• The Time Series Forecast platform lets you model and forecast multiple time series. The best fitting model is automatically selected from a set of up to 30 exponential smoothing models. See Chapter 19, “Time Series Forecast”.

• The Matched Pairs platform compares the means between two or more correlated variables and assesses the differences. See Chapter 20, “Matched Pairs Analysis”.

• The Modeling Utilities assist in the data cleaning and pre-processing stages of data analysis. Each utility has exploratory tools to give you a more thorough understanding of your data. See Chapter 21, “Modeling Utilities”.

• The Response Screening platform automates the process of conducting tests across a large number of responses. Your test results and summary statistics are presented in data tables, rather than reports, to enable data exploration. See Chapter 22, “Response Screening”.

• The Process Screening platform enables you to explore a large number of processes across time. The platform calculates control chart, process stability, and process capability metrics, and detects large process shifts. See Chapter 23, “Process Screening”.

• The Predictor Screening platform enables you to screen a data set for significant predictors. See Chapter 24, “Predictor Screening”.

• The Association Analysis platform enables you to identify items that have an affinity for each other. It is frequently used to analyze transactional data (also called market baskets) to identify items that often appear together in transactions. See Chapter 25, “Association Analysis”.
The Process History Explorer platform enables you to identify problem components in complex process histories. See Chapter 26, “Process History Explorer”.
Most features in this platform are available only in JMP Pro and noted with this icon.

The Neural platform implements a fully connected multi-layer perceptron with one or two layers. Use neural networks to predict one or more response variables using a flexible function of the input variables. Neural networks can be very good predictors when it is not necessary to describe the functional form of the response surface, or to describe the relationship between the inputs and the response.

Overview of the Neural Platform

Think of a neural network as a function of a set of derived inputs, called hidden nodes. The hidden nodes are nonlinear functions of the original inputs. You can specify up to two layers of hidden nodes, where each layer can contain as many hidden nodes as you want.

Figure 3.2 shows a two-layer neural network with three X variables and one Y variable. In this example, the first layer has two nodes, and each node is a function of all three nodes in the second layer. The second layer has three nodes, and all nodes are a function of the three X variables. The predicted Y variable is a function of both nodes in the first layer.

Figure 3.2 Neural Network Diagram

The functions applied at the nodes of the hidden layers are called activation functions. The activation function is a transformation of a linear combination of the X variables. For more information about the activation functions, see “Hidden Layer Structure” on page 41.

The function applied at the response is a linear combination (for continuous responses), or a logistic transformation (for nominal or ordinal responses).

The main advantage of a neural network model is that it can efficiently model different response surfaces. Given enough hidden nodes and layers, any surface can be approximated to any accuracy. The main disadvantage of a neural network model is that the results are not easily interpretable. This is because there are intermediate layers rather than a direct path from the X variables to the Y variables, as in the case of regular regression.

Launch the Neural Platform

To launch the Neural platform, select **Analyze > Predictive Modeling > Neural**.

Launching the Neural platform is a two-step process. First, enter your variables on the Neural launch window. Second, specify your options in the Model Launch control panel.
The Neural Launch Window

Use the Neural launch window to specify X and Y variables, a validation column, and to enable Informative Missing value coding.

Figure 3.3 The Neural Launch Window

For more information about the options in the Select Columns red triangle menu, see Using JMP.

Y, Response The response variable or variables that you want to analyze. When multiple responses are specified, the models for the responses share all parameters in the hidden layers (those parameters not connected to the responses).

X, Factor The predictor variables.

Freq A column whose numeric values assign a frequency to each row in the analysis.

Validation A numeric column that defines the validation sets. See “Validation Methods for Neural” on page 40. If you click the Validation button with no columns selected in the Select Columns list, you can add a validation column to your data table. For more information about the Make Validation Column utility, see the “Make Validation Column” chapter on page 201.

By A column or columns whose levels define separate analyses. For each level of the specified column, the corresponding rows are analyzed using the other variables that you have specified. The results are presented in separate reports. If more than one By variable is assigned, a separate report is produced for each possible combination of the levels of the By variables.

Informative Missing Check this box to enable informative coding of missing values. This coding allows estimation of a predictive model despite the presence of missing
values. It is useful in situations where missing data are informative. If this option is not checked, rows with missing values are ignored.

For a continuous variable, missing values are replaced by the mean of the variable. Also, a missing value indicator, named `<colname> Is Missing`, is created and included in the model. If a variable is transformed using the Transform Covariates fitting option on the Model Launch control panel, missing values are replaced by the mean of the transformed variable.

For a categorical variable, missing values are treated as a separate level of that variable.

**Set Random Seed**  Sets the seed for the starting values used in the fitting procedure. Set Random Seed is useful if you want to reproduce an analysis. If you set a random seed and save the script, the seed is automatically saved in the script.

**The Model Launch Control Panel**

Use the Model Launch control panel to specify the validation method, the structure of the hidden layer, whether to use gradient boosting, and other fitting options.

**Figure 3.4 The Model Launch Control Panel**
**Validation Method**  
Select the method that you want to use for model validation. See “Validation Methods for Neural” on page 40.

**Random Seed**  
Specify a nonzero numeric random seed if you want to reproduce the validation assignment for future launches of the Neural platform. By default, the Random Seed is set to zero, which does not produce reproducible results. When you save the analysis to a script, the random seed that you enter is saved to the script.

**Hidden Layer Structure or Hidden Nodes**  
Specify the number of hidden nodes of each type in each layer. See “Hidden Layer Structure” on page 41.

**Note**: The standard edition of JMP uses only the TanH activation function, and can fit only neural networks with one hidden layer.

**Boosting**  
Specify options for gradient boosting. See “Boosting” on page 42.

**Fitting Options**  
Specify options for variable transformation and model fitting. See “Fitting Options” on page 43.

**Go**  
Fits the neural network model and shows the model reports.

After you click Go to fit a model, you can reopen the Model Launch Control Panel and change the settings to fit another model.

**Validation Methods for Neural**

Neural utilizes a validation method in its fitting routine. Choices of validation method include holdback, K-fold, or (in JMP Pro) the use of a validation column. To fit a model, the Neural platform does the following:

- applies a penalty on the model parameters
- uses the validation set to tune the penalties on the parameters.

Select one of the following validation methods:

**Excluded Rows Holdback**  
Uses row states to subset the data. Rows that are unexcluded are used as the training set, and excluded rows are used as the validation set.

For more information about using row states and how to exclude rows, see Using JMP.

**Holdback**  
Randomly divides the original data into the training and validation sets. You specify the proportion of the original data to use as the validation set (holdback). The random selection is based on stratified sampling across the model factors to attempt to create training and validation sets that are more balanced than ones based on simple random sampling.
**KFold**  Divides the data into K subsets, or folds. In turn, each of the K folds is used to validate the model fit on the rest of the data, fitting a total of K models. The final model is for the fold that resulted in the model with the best validation statistic.

This method is useful for small data sets, because it makes efficient use of limited amounts of data.

**Validation Column**  Uses a numeric column that defines the validation sets. The column’s values determine how the data is split:

- If the validation column has two levels, the smaller value defines the training set and the larger value defines the validation set.
- If the validation column has three levels, the values, in order of increasing size, define the training, validation, and test sets.
- If the validation column has more than three unique values, then K-Fold validation is performed. The number of folds is determined by the number of values in the validation column.

The Neural platform uses the validation column to train and tune the model or to train, tune, and evaluate the model. For more information about validation, see “Validation in JMP Modeling” on page 541 in the “Statistical Details” appendix.

### Hidden Layer Structure

**Note:** The standard edition of JMP uses only the TanH activation function, and can fit only neural networks with one hidden layer.

The Neural platform can fit one or two-layer neural networks. Increasing the number of nodes in the first layer, or adding a second layer, makes the neural network more flexible. You can add an unlimited number of nodes to either layer. The second layer nodes are functions of the X variables. The first layer nodes are functions of the second layer nodes. The Y variables are functions of the first layer nodes.

**Caution:** You cannot use boosting with a two-layer neural network. If you specify any non-zero values in the second layer and also specify boosting, the second layer is ignored.

The functions applied at the nodes of the hidden layers are called activation functions. An activation function is a transformation of a linear combination of the X variables. The following activation functions are available:

**TanH**  The hyperbolic tangent function is a sigmoid function. TanH transforms values to be between -1 and 1, and is the centered and scaled version of the logistic function. The hyperbolic tangent function is:
where \( x \) is a linear combination of the X variables.

**Linear**  The identity function. The linear combination of the X variables is not transformed.

The Linear activation function is most often used in conjunction with one of the non-linear activation functions. In this case, the Linear activation function is placed in the second layer, and the non-linear activation functions are placed in the first layer. This is useful if you want to first reduce the dimensionality of the X variables, and then have a nonlinear model for the Y variables.

For a continuous Y variable, if only Linear activation functions are used, the model for the Y variable reduces to a linear combination of the X variables. For a nominal or ordinal Y variable, the model reduces to a logistic regression.

**Gaussian**  The Gaussian function. Use this option for radial basis function behavior, or when the response surface is Gaussian (normal) in shape. The Gaussian function is:

\[
\frac{e^{2x} - 1}{e^{2x} + 1}
\]

where \( x \) is a linear combination of the X variables.

**Boosting**

Boosting is the process of building a large additive neural network model by fitting a sequence of smaller models. Each of the smaller models is fit on the scaled residuals of the previous model. The models are combined to form the larger final model. The process uses validation to assess how many component models to fit, not exceeding the specified number of models.

Boosting is often faster than fitting a single large model. However, the base model should be a 1 to 2 node single-layer model. The benefit of faster fitting can be lost if a large number of models is specified.

Use the Boosting panel in the Model Launch control panel to specify the number of component models and the learning rate. Use the Hidden Layer Structure panel in the Model Launch control panel to specify the structure of the base model.

The learning rate must be \( 0 < r \leq 1 \). Learning rates close to 1 result in faster convergence on a final model, but also have a higher tendency to overfit data. Use learning rates close to 1 when a small Number of Models is specified.
As an example of how boosting works, suppose you specify a base model consisting of one layer and two nodes, with the number of models equal to eight. The first step is to fit a one-layer, two-node model. The predicted values from that model are scaled by the learning rate, then subtracted from the actual values to form a scaled residual. The next step is to fit a different one-layer, two-node model, where the response values are the scaled residuals of the previous model. This process continues until eight models are fit, or until the addition of another model fails to improve the validation statistic. The component models are combined to form the final, large model. In this example, if six models are fit before stopping, the final model consists of one layer and $2 \times 6 = 12$ nodes.

**Caution:** You cannot use boosting with a two-layer neural network. If you specify any non-zero values in the second layer and also specify boosting, the second layer is ignored.

**Fitting Options**

The following model fitting options are available:

**Transform Covariates**  Transforms all continuous variables to near normality using either the Johnson Su or Johnson Sb distribution. Transforming the continuous variables helps mitigate the negative effects of outliers or heavily skewed distributions. See the Save Transformed Covariates option in “Neural Model Options” on page 47.

**Robust Fit**  Trains the model using least absolute deviations instead of least squares. This option is useful if you want to minimize the impact of response outliers. This option is available only for continuous responses.

**Penalty Method**  Choose the penalty method. To mitigate the tendency neural networks have to overfit data, the fitting process incorporates a penalty on the likelihood. See “Penalty Method” on page 44.

**Number of Tours**  Specify the number of times to restart the fitting process, with each iteration using different random starting points for the parameter estimates. The iteration with the best validation statistic is chosen as the final model.
Penalty Method

The penalty is $\lambda p(\beta_i)$, where $\lambda$ is the penalty parameter, and $p(\ )$ is a function of the parameter estimates, called the penalty function. Validation is used to find the optimal value of the penalty parameter.

Table 3.1  Descriptions of Penalty Methods

<table>
<thead>
<tr>
<th>Method</th>
<th>Penalty Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Squared</td>
<td>$\sum \beta_i^2$</td>
<td>Use this method if you think that most of your X variables are contributing to the predictive ability of the model.</td>

<td>NoPenalty</td>
<td>none</td>
<td>Does not use a penalty. You can use this option if you have a large amount of data and you want the fitting process to go quickly. However, this option can lead to models with lower predictive performance than models that use a penalty.</td>
</tr>
</tbody>
</table>
Model Reports

A model report is created for every neural network model. Measures of fit appear for the training and validation sets. In addition, confusion statistics appear when the response is nominal or ordinal.

Figure 3.5 Example of a Neural Model Report

Training and Validation Measures of Fit

Measures of fit appear for the training and validation sets (Figure 3.5).

**Generalized RSquare**  A measure that can be applied to general regression models. It is based on the likelihood function $L$ and is scaled to have a maximum value of 1. The value is 1 for a perfect model, and 0 for a model no better than a constant model. The Generalized RSquare measure simplifies to the traditional RSquare for continuous normal responses in the standard least squares setting. Generalized RSquare is also known as the Nagelkerke or Craig and Uhler $R^2$, which is a normalized version of Cox and Snell’s pseudo $R^2$. See Nagelkerke (1991).

**Entropy RSquare**  (Appears only when the response is nominal or ordinal.) A measure of fit that compares the log-likelihoods from the fitted model and the constant probability model. Entropy RSquare ranges from 0 to 1, where values closer to 1 indicate a better fit. See “Entropy RSquare” on page 541 in the “Statistical Details” chapter.

**RSquare**  Gives the RSquare for the model.
**RASE**  Gives the root average squared error. When the response is nominal or ordinal, the differences are between 1 and p (the fitted probability for the response level that actually occurred).

**Mean Abs Dev**  The average of the absolute values of the differences between the response and the predicted response. When the response is nominal or ordinal, the differences are between 1 and p (the fitted probability for the response level that actually occurred).

**Misclassification Rate**  The rate for which the response category with the highest fitted probability is not the observed category. Appears only when the response is nominal or ordinal.

**-LogLikelihood**  Gives the negative of the log-likelihood. See *Fitting Linear Models*.

**SSE**  Gives the error sums of squares. Available only when the response is continuous.

**Sum Freq**  Gives the number of observations that are used. If you specified a Freq variable in the Neural launch window, Sum Freq gives the sum of the frequency column.

If there are multiple responses, fit statistics are given for each response, and an overall Generalized RSquare and negative Log-Likelihood is given.

### Confusion Statistics

For nominal or ordinal responses, a Confusion Matrix report and Confusion Rates report is given (Figure 3.5). The Confusion Matrix report shows a two-way classification of the actual response levels and the predicted response levels. For a categorical response, the predicted level is the one with the highest predicted probability. The Confusion Rates report is equal to the Confusion Matrix report, with the numbers divided by the row totals.

### Neural Platform Options

The Neural red triangle menu contains the following options:

See *Using JMP* for more information about the following options:

**Local Data Filter**  Shows or hides the local data filter that enables you to filter the data used in a specific report.

**Redo**  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

**Save Script**  Contains options that enable you to save a script that reproduces the report to several destinations.
Save By-Group Script Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.

Neural Model Options

Each model report has a red triangle menu that contains options for producing additional output or saving results. The model report red triangle menu contains the following options:

Diagram Shows a diagram representing the hidden layer structure.

Show Estimates Shows the parameter estimates in a report.

Profiler Launches the Prediction Profiler. For nominal or ordinal responses, each response level is represented by a separate row in the Prediction Profiler. For more information about the options in the red triangle menu, see Profilers.

Categorical Profiler Launches the Prediction Profiler. Similar to the Profiler option, except that all categorical probabilities are combined into a single profiler row. Available only for nominal or ordinal responses. For more information about the options in the red triangle menu, see Profilers.

Contour Profiler Launches the Contour Profiler. This is available only when the model contains more than one continuous factor. For more information about the options in the red triangle menu, see Profilers.

Surface Profiler Launches the Surface Profiler. This is available only when the model contains more than one continuous factor. For more information about the options in the red triangle menu, see Profilers.

ROC Curve Creates an ROC curve. Available only for nominal or ordinal responses. For more information about ROC Curves, see “ROC Curve” on page 72 in the “Partition Models” chapter.

Lift Curve Creates a lift curve. Available only for nominal or ordinal responses. For more information about Lift Curves, see “Lift Curve” on page 73 in the “Partition Models” chapter.

Plot Actual by Predicted Plots the actual versus the predicted response. Available only for continuous responses.

Plot Residual by Predicted Plots the residuals versus the predicted responses. Available only for continuous responses.

Save Formulas Creates new columns in the data table containing formulas for the predicted response and the hidden layer nodes.
**Save Profile Formulas**  Creates new columns in the data table containing formulas for the predicted response. Formulas for the hidden layer nodes are embedded in this formula. This option produces formulas that can be used by the Interactive HTML version of the Profiler.

**Save Fast Formulas**  Creates new columns in the data table containing formulas for the predicted response. Formulas for the hidden layer nodes are embedded in this formula. This option produces formulas that evaluate faster than the other options, but cannot be used in the Interactive version of the Profiler.

**Publish Prediction Formula**  Creates prediction formulas and saves them as formula column scripts in the Formula Depot platform. If a Formula Depot report is not open, this option creates a Formula Depot report. See the “Formula Depot” chapter on page 213.

**Make SAS Data Step**  Creates SAS code that you can use to score a new data set.

**Save Validation**  Creates a new column in the data table that identifies which rows were used in the training and validation sets. This option is not available when a Validation column is specified on the Neural launch window. See “The Neural Launch Window” on page 38.

**Save Transformed Covariates**  Creates new columns in the data table showing the transformed covariates. The columns contain formulas that show the transformations. This option is available only when the Transform Covariates option is checked on the Model Launch control panel. See “Fitting Options” on page 43.

**Remove Fit**  Removes the entire model report.

---

**Example of a Neural Network**

This example uses the Boston Housing.jmp data table. Suppose you want to create a model to predict the median home value as a function of several demographic characteristics. Follow the steps below to build the neural network model:

1. Select Help > Sample Data Library and Boston Housing.jmp.
2. Launch the Neural platform by selecting Analyze > Predictive Modeling > Neural.
3. Assign mvalue to the Y, Response role.
4. Assign the other columns (crim through lstat) to the X, Factor role.
5. Click OK.
6. Enter 0.2 for the Holdback Proportion.
7. Enter 1234 for the Random Seed.
**Note:** In general, results vary due to the random nature of choosing a validation set. Entering the seed above enables you to reproduce the results shown in this example.

8. Enter 3 for the number of TanH nodes in the first layer.
9. Check the **Transform Covariates** option.
10. Click **Go**.

**Figure 3.6 Neural Report**

Results are provided for both the training and validation sets. Use the results of the validation set as a representation of the model’s predictive power on future observations.

The R-Square statistic for the Validation set is 0.913, signifying that the model is predicting well on data not used to train the model. As an additional assessment of model fit, click the red triangle next to Model NTanH(3) and select **Plot Actual by Predicted**.

**Figure 3.7 Actual by Predicted Plot**

The points fall along the line, signifying that the predicted values are similar to the actual values.

To get a general understanding of how the X variables are impacting the predicted values, click the red triangle next to Model NTanH(3) and select **Profiler**.
Some of the variables have profiles with positive slopes, and some negative. For example, the variable rooms has a positive slope. This indicates that the more rooms a home has, the higher the predicted median value. The variable pt is the pupil teacher ratio by town. This variable has a negative slope, indicating that the higher the pupil to teacher ratio, the lower the median value.
The Partition platform recursively partitions data according to a relationship between the predictors and response values, creating a decision tree. The partition algorithm searches all possible splits of predictors to best predict the response. These splits (or \textit{partitions}) of the data are done recursively to form a tree of decision rules. The splits continue until the desired fit is reached. The partition algorithm chooses optimum splits from a large number of possible splits, making it a powerful modeling, and data discovery tool.

Overview of the Partition Platform

The Partition platform recursively partitions data according to a relationship between the predictors and response values, creating a decision tree. Variations of partitioning go by many names and brand names: decision trees, CART™, CHAID™, C4.5, C5, and others. The technique is often considered as a data mining technique for the following reasons:

- it is useful for exploring relationships without having a good prior model
- it handles large problems easily
- the results are interpretable

A classic application of partitioning is to create a diagnostic heuristic for a disease. Given symptoms and outcomes for a number of subjects, partitioning can be used to generate a hierarchy of questions to help diagnose new patients.

Predictors can be either continuous or categorical (nominal or ordinal). If a predictor is continuous, then the splits are created by a cutting value. The sample is divided into values below and above this cutting value. If a predictor is categorical, then the sample is divided into two groups of levels.

The response can also be either continuous or categorical (nominal or ordinal). If the response is continuous, then the platform fits the means of the response values and the split is chosen to minimize the sum of squared errors. If the response is categorical, then the fitted value is a probability for the levels of the response and the split is chosen to minimize the residual log-likelihood chi-square.

For more information about split criteria, see “Statistical Details for the Partition Platform” on page 85.

For more information about recursive partitioning, see Hawkins and Kass (1982) and Kass (1980).

Example of the Partition Platform

In this example, you use the Partition platform to construct a decision tree that predicts the one-year disease progression (low or high) of patients with diabetes.

1. Select Help > Sample Data Library and Diabetes.jmp.
2. Select Analyze > Predictive Modeling > Partition.
4. Select Age through Glucose and click X, Factor.
5. Enter 0.33 for the Validation Portion.
Note: In JMP Pro, a validation column can be used for validation. Select Validation and click Validation. Set the Validation Portion to 0.

6. Click OK.

7. On the platform report window, click Go to perform automatic splitting.

Note: Because you are using a random Validation Portion, your results differ from those in Figure 4.2.

Figure 4.2 Partition Report for Diabetes

Automatic splitting resulted in four splits. The final RSquare for the Validation set is 0.154. The decision tree shows the four splits and the counts of observations in each split.

8. Click the red triangle next to Partition for Y Binary and select Column Contributions.
The Column Contributions report shows that LTG and BMI are the only predictors in the decision tree model. Each column is used in two splits. Your results can differ. When the Validation Portion is used, the validation set is selected at random from the data table. If you redo your analysis, a new random validation set is selected and your results can differ from your first run.

9. Click the red triangle next to Partition for Y Binary and select **Save Columns > Profiler**.

The profiler enables you to change the values of BMI and LTG to obtain the predicted Y Binary outcome. No other factors had a split in the partition model. Their profiles are flat lines.

10. Click the red triangle next to Partition for Y Binary and select **Save Columns > Save Prediction Formula**.

In the Diabetes.jmp data table, columns called Prob(Y Binary==Low), Prob(Y Binary==High), and Most Likely Y Binary are added. To see how these response probabilities are calculated, in the Columns panel, next to each column, double-click the Formula icon .
Launch the Partition Platform

Launch the Partition platform by selecting **Analyze > Predictive Modeling > Partition.**

**Figure 4.5 Partition Launch Window**

For more information about the options in the Select Columns red triangle menu, see *Using JMP.*

**Y, Response**  The response variable or variables that you want to analyze.

**X, Factor**  The predictor variables.

**Weight**  A column whose numeric values assign a weight to each row in the analysis.

**Freq**  A column whose numeric values assign a frequency to each row in the analysis.

**Validation**  A numeric column that defines the validation sets. See “Validation in Partition” on page 75. If you click the Validation button with no columns selected in the Select Columns list, you can add a validation column to your data table. For more information about the Make Validation Column utility, see the “Make Validation Column” chapter on page 201.

**By**  A column or columns whose levels define separate analyses. For each level of the column, the corresponding rows are analyzed using the other variables that you specify. The results appear in separate reports. If more than one By variable is assigned, a separate report is produced for each possible combination of the levels of the By variables.
**Method** Enables you to select the partition method (Bootstrap Forest, Boosted Tree, K Nearest Neighbors, or Naive Bayes).

For more information about these methods, see Chapter 5, “Bootstrap Forest”, Chapter 6, “Boosted Tree”, Chapter 7, “K Nearest Neighbors”, and Chapter 8, “Naive Bayes”.

**Validation Portion** The portion of the data to be used as the validation set. See “Validation in Partition” on page 75.

**Informative Missing** If selected, enables missing value categorization for categorical predictors and informative treatment of missing values for continuous predictors. See “Informative Missing” on page 70.

**Ordinal Restricts Order** If selected, restricts consideration of splits to those that preserve the ordering.

---

**The Partition Report**

The initial Partition report shows a partition plot, control buttons, a summary panel, and a decision tree. The partition plot and decision tree are initialized without any splits. The reports details are different for categorical and continuous responses.

- “Control Buttons”
- “Report for Categorical Responses”
- “Report for Continuous Responses”

**Control Buttons**

Use the control buttons to interact with the decision tree.

**Split** Creates a partition of the data using the optimal split. To specify multiple splits, hold the Shift key as you click **Split**.

**Prune** Removes the worst split.

**Go** (Available when you are using validation.) Automatically adds splits to the decision tree until the validation statistic is optimized. See “Validation in Partition” on page 75. Without validation, you simply decide the number of splits to use in the partition model.

**Color Points** For categorical responses, colors observations according to response level. These colors are added to the data table.
Report for Categorical Responses

The sample data table Diabetes.jmp was used to create a report for the categorical response Y Binary.

Figure 4.6  Partition Report for a Categorical Response

Partition Plot

Each point in the Partition Plot represents an observation in the data table. If validation is used, the plot is only for the training data. The initial partition plot does not show splits.

Notice the following:

- The left vertical axis is the proportion of each response outcome.
- The right vertical axis shows the order in which the response levels are plotted.
- Horizontal lines divide each split by the response variable. The initial horizontal line shows the overall proportion of the first plotted response in the data set.
- Splits are shown below the X axis with a text description and a vertical line that splits the observations in the plot. The vertical lines extend into the plot and indicate the boundaries for each node. The most recent split appears directly below the horizontal axis and on top of existing splits. The plot is updated with each split or prune of the decision tree.

The Summary Report provides fit statistics for the training data and validation and test data (if used). The fit statistics in the Summary Panel update as you add splits or prune the decision tree.

**RSquare**  The current value of $R^2$.

**N**  The number of observations.

**Number of Splits**  The current number of splits in the decision tree.

Node Reports

Each node in the tree has a report and a red triangle menu with additional options. Terminal nodes also have a Candidates report.

</tbody>
</table>

**Count**  Number of training observations that are characterized by the node.

**$G^2$**  A fit statistic used for categorical responses (instead of sum of squares that is used for continuous responses). Lower values indicate a better fit. See “Statistical Details for the Partition Platform” on page 85.

**Candidates**  For each column, the Candidates report provides details about the optimal split for that column. The optimal split over all terms is marked with an asterisk.

**Term**  Shows the candidate columns.
Candidate $G^2$  Likelihood ratio chi-square for the best split. Splitting on the predictor with the largest $G^2$ maximizes the reduction in the model $G^2$.

LogWorth  The LogWorth statistic, defined as $-\log_{10}(p\text{-value})$. The optimal split is the one that maximizes the LogWorth. See “Statistical Details for the Partition Platform” on page 85.

Cut Point  The value of the predictor that determines the split. For a categorical term, the levels in the left-most split are listed.

The optimal split is noted by an asterisk. However, there are cases where the Candidate $G^2$ is higher for one variable, but the Logworth is higher for a different variable. In this case $>$ and $<$ are used to point in the best direction for each variable. The asterisk corresponds to the condition where they agree. See “Statistical Details for the Partition Platform” on page 85.

Report for Continuous Responses

The sample data table Diabetes.jmp was used to create a report for the continuous response $Y$.

**Figure 4.9** Partition Report for a Continuous Response

Partition Plot

The partition plot is initialized without any splits. Each point represents an observation in the data table. If validation is used, the plot is only for the training data.
Notice the following:

- The vertical axis represents the response value of the observations.
- Horizontal lines show the mean response value for each node of the decision tree. The initial horizontal line is at the overall mean of the response.
- Vertical axis divisions represent splits in the decision tree. A text description of the most recent split appears below the horizontal axis. Observations are reorganized into their respective nodes as splits are created or removed.

**Tip:** To see tooltips for narrow partitions, hover over the labels on the horizontal axis of the partition plot.

### Summary Report

</tr>
</tbody>
</table>

The Summary Report provides fit statistics for the training data and validation and test data (if used). The fit statistics in the Summary Panel update as you add splits or prune the decision tree.

**RSquare**  The current value of $R^2$.

**RASE**  The root average square error. See *Fitting Linear Models*.

**N**  The number of observations.

**Number of Splits**  The current number of splits in the decision tree.

**AICc**  The corrected Akaike’s Information Criterion. See *Fitting Linear Models*. 
Node Reports

Each node in the tree has a report and a red triangle menu with additional options. Terminal nodes also have a Candidates report.

Figure 4.11 Terminal Node Report for a Continuous Response

Count  The number of observations (rows) in the branch.

Mean  The average response for all observations in that branch.

Std Dev  The standard deviation of the response for all observations in that branch.

Candidates  For each column, the Candidates report provides details about the optimal split for that column. The optimal split over all columns is marked with an asterisk.

Term  Shows the candidate columns.

Candidate SS  Sum of squares for the best split.

LogWorth  The LogWorth statistic, defined as \(-\log_{10}(p\text{-value})\). The optimal split is the one that maximizes the LogWorth. See “Statistical Details for the Partition Platform” on page 85.

Cut Point  The value of the predictor that determines the split. For a categorical term, the levels in the left-most split are listed.

The optimum split is noted by an asterisk. However, there are cases where the Candidate SS is higher for one variable, but the LogWorth is higher for a different variable. In this case \(>\) and \(<\) are used to point in the best direction for each variable. The asterisk corresponds to the condition where they agree. See “Statistical Details for the Partition Platform” on page 85.
Partition Platform Options

The Partition red triangle menu options give you the ability to customize reports according to your needs. The available options are determined by the type of data that you use for your analysis.

Display Options Contains options that show or hide report elements.

- **Show Points** Shows the points. For categorical responses, this option shows the points or colored panels.
- **Show Tree** Shows the large tree of partitions.
- **Show Graph** Shows the partition graph.
- **Show Split Bar** (Available only for categorical responses.) Shows the colored bars that indicate the split proportions in each leaf.
- **Show Split Stats** Shows the split statistics. For more information about the categorical split statistic $G^2$, see “Statistical Details for the Partition Platform” on page 85.
- **Show Split Prob** (Available only for categorical responses.) Shows the Rate and Prob statistics in the node reports.
  
  JMP automatically shows the Rate and Prob statistics when you select **Show Split Count**. For more information about Rate and Prob, see “Statistical Details for the Partition Platform” on page 85.

- **Show Split Count** (Available only for categorical responses.) Shows frequency counts in the node reports. When you select this option, JMP automatically selects **Show Split Prob**. And when you deselect **Show Split Prob**, the counts do not appear.

- **Show Split Candidates** Shows the Candidates report.
- **Sort Split Candidates** Sorts the Candidates reports by the statistic or the log(worth), whichever is appropriate.

- **Split Best** Splits the tree at the optimal split point. This is equivalent to clicking the **Split** button.

- **Prune Worst** Removes the terminal split that has the least discrimination ability. This is equivalent to clicking the **Prune** button.

- **Minimum Size Split** Define the minimum size split allowed by entering a number or a fractional portion of the total sample size. To specify a number, enter a value greater than or equal to 1. To specify a fraction of the sample size, enter a value less than 1. The default value is set to the maximum of 5, or the floor of the number of rows divided by 10,000.
Lock Columns  Interactively lock columns so that they are not considered for splitting. You can turn the display off or back on without affecting the individual locks.

Plot Actual by Predicted  (Available only for continuous responses.) Shows a plot of actual values by predicted values. See “Actual by Predicted Plot” on page 71.

Small Tree View  Shows a small version of the partition tree to the right of the partition plot.

Tree 3D  Shows a 3-D plot of the tree structure. To access this option, press Shift and click the red triangle menu.

Leaf Report  Shows the mean and count or rates for the bottom-level leaves of the report.

Column Contributions  Shows a report indicating each input column’s contribution to the fit. The report also shows how many times it defined a split and the total $G^2$ or Sum of Squares attributed to that column.

Split History  Shows a plot of RSquare versus the number of splits. If you use excluded row validation, holdback validation, or a validation column, separate curves are drawn for training and validation RSquare values. The RSquare curve is blue for the training set and red for the validation set. If you select K Fold Crossvalidation, the RSquare curve for all of the data is blue, and the curve for the cross validation RSquare is green.

ROC Curve  (Available only for categorical responses.) Receiver Operating Characteristic (ROC) curves display the efficiency of a model’s fitted probabilities to sort the response levels. See “ROC Curve” on page 72.

Lift Curve  (Available only for categorical responses.) Lift curves display the predictive ability of a partition model. See “Lift Curve” on page 73.

Show Fit Details  (Appears only for categorical responses.) The Fit Details report shows several measures of fit and provides a Confusion Matrix report. See “Show Fit Details” on page 66.

Save Columns  Contains options for saving model and tree results, and creating SAS code.

  Save Residuals  Saves the residual values from the model to the data table.

  Save Predicteds  Saves the predicted values from the model to the data table.

  Save Leaf Numbers  Saves the leaf numbers of the tree to a column in the data table.
Save Leaf Labels  Saves leaf labels of the tree to the data table. The labels document each branch that the row would trace along the tree. Each branch is separated by “&”. An example label might be: “size(Small,Medium)&size(Small)”. However, JMP does not include redundant information in the form of category labels that are repeated. A category label for a leaf might refer to an inclusive list of categories in a higher tree node. A caret (“^”) appears where the tree node with redundant labels occurs. Therefore, “size(Small,Medium)&size(Small)” is presented as ^&size(Small).

Save Prediction Formula  Saves prediction formulas to a column or multiple columns in the data table. The formulas consist of nested conditional clauses that describe the tree structure. If the response is continuous, one column that contains a Predicting property is added. If the response is categorical, columns that contain a Response Probability property are added for each level of the response. In addition, a Most Likely column that contains the response level with the highest probability of occurrence for each observation is added.

Save Tolerant Prediction Formula  Saves a formula that predicts even when there are missing values and when Informative Missing has not been checked. The prediction formula tolerates missing values by randomly allocating response values for missing predictors to a split. If the response is continuous, the column contains a Predicting property. If the response is categorical, the column contains a Response Probability property. If you have checked Informative Missing, you can save the Tolerant Prediction Formula by holding the Shift key as you click the report’s red triangle.

Save Leaf Number Formula  Saves a column containing a formula in the data table that computes the leaf number.

Save Leaf Label Formula  Saves a column containing a formula in the data table that computes the leaf label.

Make SAS DATA Step  Creates SAS code for scoring a new data set.

Publish Prediction Formula  Creates a prediction formula and saves it as a formula column script in the Formula Depot platform. If a Formula Depot report is not open, this option creates a Formula Depot report. See the “Formula Depot” chapter on page 213.

Publish Tolerant Prediction Formula  Creates a tolerant prediction formula and saves it as a formula column script in the Formula Depot platform. If a Formula Depot report is not open, this option creates a Formula Depot report. See the “Formula Depot” chapter on page 213. If you have checked Informative Missing, you can use this option by holding the Shift key as you click the report’s red triangle.

Specify Profit Matrix  (Available only for categorical responses.) Enables you to specify profits or costs associated with correct or incorrect classification decisions. For a nominal
response, you can specify the profit matrix entries using a probability threshold. See “Show Fit Details” on page 66.

**Profiler**  Shows an interactive profiler report. Changes in the factor values are reflected in the estimated classification probabilities. See **Profiler**s.

**Color Points**  (Available only for categorical responses.) Colors points based on their response level. This is equivalent to clicking the Color Points button. See “Report for Categorical Responses” on page 58.

See *Using JMP* for more information about the following options:

**Local Data Filter**  Shows or hides the local data filter that enables you to filter the data used in a specific report.

**Redo**  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

**Save Script**  Contains options that enable you to save a script that reproduces the report to several destinations.

**Save By-Group Script**  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.

**Show Fit Details**

**Figure 4.12**  Fit Details for Categorical Response (Y Binary from Diabetes.jmp)
Entropy RSquare  A measure of fit that compares the log-likelihoods from the fitted model and the constant probability model. Entropy RSquare ranges from 0 to 1, where values closer to 1 indicate a better fit. See “Entropy RSquare” on page 541 in the “Statistical Details” chapter.

Generalized RSquare  A measure that can be applied to general regression models. It is based on the likelihood function L and is scaled to have a maximum value of 1. The Generalized RSquare measure simplifies to the traditional RSquare for continuous normal responses in the standard least squares setting. Generalized RSquare is also known as the Nagelkerke or Craig and Uhler $R^2$, which is a normalized version of Cox and Snell’s pseudo $R^2$. See Nagelkerke (1991). Values closer to 1 indicate a better fit.

Mean -$\log p$  The average of -$\log(p)$, where $p$ is the fitted probability associated with the event that occurred. Smaller values indicate a better fit.

RASE  The root average square error, where the differences are between the response and $p$ (the fitted probability for the event that actually occurred). Smaller values indicate a better fit.

Mean Abs Dev  The average of the absolute values of the differences between the response and $p$ (the fitted probability for the event that actually occurred). Smaller values indicate a better fit.

Misclassification Rate  The rate for which the response category with the highest fitted probability is not the observed category. Smaller values indicate a better fit.

The Confusion Matrix report shows matrices for the training set and for the validation and test sets (if defined). The Confusion Matrix Report contains confusion matrices and confusion rates matrices. A confusion matrix is a two-way classification of actual and predicted responses. A confusion rates matrix is equal to the confusion matrix, with the numbers divided by the row totals.

If the response has a Profit Matrix column property, or if you specify costs using the Specify Profit Matrix option, then a Decision Matrix report appears. See “Decision Matrix Report” on page 69.

Specify Profit Matrix

A profit matrix can be used with categorical responses. A profit matrix is used to assign costs to undesirable outcomes and profits to desirable outcomes.
**Figure 4.13 Specify Profit Matrix Window**

You can assign profit and cost values to each combination of actual and predicted response categories. To specify the costs of classifying into an alternative category, enter values in the Undecided column. To save your assignments to the response column as a property, check **Save to column as property**. Leaving this option unchecked applies the Profit Matrix only to the current Partition report.

**Probability Threshold Specification for Profit Matrix**

When the response is binary, instead of entering weights into the profit matrix, you can specify a probability threshold in the Profit Matrix window. For more information about how values are calculated for the profit matrix, see *Using JMP*.

**Target**  The level whose probability is modeled.

**Probability Threshold**  A threshold for the probability of the target level. If the probability that an observation falls into the target level exceeds the probability threshold, the observation is classified into that level.

When you define costs using the Specify Profit Matrix option and then select Show Fit Details, a Decision Matrix report appears. See “Decision Matrix Report” on page 69.

When you specify a profit matrix and save the model prediction formula, the formula columns saved to the data table include the following:

- **Profit for <level>**: For each level of the response, a column gives the expected profit for classifying each observation into that level.
Predictive and Specialized Modeling Partition Platform Options

– Most Profitable Prediction for <column name>: For each observation, gives the level of the response with the highest expected profit.

– Expected Profit for <column name>: For each observation, gives the expected profit for the classification defined by the Most Profitable Prediction column.

– Actual Profit for <column name>: For each observation, gives the actual profit for classifying that observation into the level specified by the Most Profitable Prediction column.

Decision Matrix Report

Figure 4.14 Fit Details Report with Decision Matrix Report

Note: This report is available only if the response has a Profit Matrix column property or if you specify costs using the Specify Profit Matrix option. The report is part of the Fit Details report.

When a profit matrix is defined, the partition algorithm uses the values in the matrix to calculate the profit for each decision. When you select Show Fit Details, a Decision Matrix report appears.
In the Decision Matrix report, the decision counts reflect the most profitable prediction decisions based on the weighting in the profit matrix. The report gives Decision Count and Decision Rate matrices for the training set and for validation and test sets (if defined). For reference, the profit matrix is also shown.

**Note:** If you change the weights in your Profit Matrix using the Specify Profit Matrix option, the Decision Matrix report automatically updates to reflect your changes.

**Decision Count Matrix**  Shows a two-way classification with actual responses in rows and classification counts in columns.

**Specified Profit Matrix**  Gives the weights that define the Profit Matrix.

**Decision Rate Matrix**  Shows rate values corresponding to the proportion of a given row’s observations that are classified into each category. If all observations are correctly classified, the rates on the diagonal are all equal to one.

**Tip:** You can obtain a decision rate matrices for a response using the default profit matrix with costs of 1 and -1. Select **Specify Profit Matrix** from the red triangle menu, make no changes to the default values, and click **OK**.

The matrices are arranged in two rows:

- The Decision Count matrices are in the first row.
- The Specified Profit Matrix is to the right in the first row.
- The Decision Rate matrices are in the second row.

### Informative Missing

The Informative Missing option enables informative treatment of missing values on the predictors. The model that is fit is deterministic. The Informative Missing option is found on the launch window and is selected by default. When the Informative Missing option is selected, categorical and continuous predictors are handled differently:

- Rows containing missing values for a categorical predictor are entered into the analysis as a separate level of the variable.
- Rows containing missing values for a continuous predictor are assigned to a split as follows: The values of the continuous predictor are sorted. Missing rows are first considered to be on the low end of the sorted values. All splits are constructed. The missing rows are then considered to be on the high end of the sorted values. Again, all splits are constructed. The optimal split is determined using the LogWorth criterion. For further splits on the given predictor, the algorithm commits the missing rows to high or low values, as determined by the first split induced by that predictor.
If the Informative Missing option is not selected, the missing values are handled as follows:

- When a predictor with missing values is used as a splitting variable, each row with a missing value on that predictor is randomly assigned to one of the two sides of the split.
- The first time a predictor with missing values is used as a splitting variable an *Imputes* column is added to the Summary Report showing the number of imputations. As additional imputations are made, the Imputes column updates (Figure 4.15), where five imputations were performed.

**Note:** The number of Imputes can be greater than the number of rows that contain missing values. The imputation occurs at each split. A row with missing values can be randomly assigned multiple times. Each time a row is randomly assigned it increments the imputation count.

**Actual by Predicted Plot**

For continuous responses, the Actual by Predicted plot is the typical plot of the actual response versus the predicted response. When you fit a Decision Tree, all observations in a leaf have the same predicted value. If there are \( n \) leaves, then the Actual by Predicted plot shows at most \( n \) distinct predicted values. The actual values form a scatter of points around each leaf mean on \( n \) vertical lines.

The diagonal line is the \( Y = X \) line. For a perfect fit, all the points would be on this diagonal. When validation is used, plots are shown for both the training and the validation sets (Figure 4.16).

**Figure 4.16**  Actual by Predicted Plots for a Continuous Response
ROC Curve

The ROC Curve option is available only for categorical responses. Receiver Operating Characteristic (ROC) curves display the efficiency of a model’s fitted probabilities in sorting the response levels. An introduction to ROC curves is found in Basic Analysis.

The predicted response for each observation in a partition model is a value between 0 and 1. To use the predicted response to classify observations as positive or negative, a cut point is used. For example, if the cut point is 0.5, an observation with a predicted response at or above 0.5 would be classified as positive, and an observation below 0.5 as negative. There are trade-offs in classification as the cut point is varied.

To generate a ROC curve, each predicted response level is considered as a possible cut point and the following values are computed for each possible cut point:

- The sensitivity is the proportion of true positives or the percent of positive observations with a predicted response greater than the cut point.
- The specificity is the proportion of true negatives or the proportion of negative observations with a predicted response less than the cut point.

The ROC curve plots sensitivity against 1 - specificity. A partition model with \( n \) splits has \( n+1 \) predicted values. The ROC curve for the partition model has \( n+1 \) line segments.

If your response has more than two levels, the Partition report contains a separate ROC curve for each response level versus the other levels. Each curve is the representation of a level as the positive response level. If there are only two levels, one curve is the reflection of the other.

**Figure 4.17  ROC Curves for a Three Level Response**
If the model perfectly rank-orders the response values, then the sorted data contains all of the positive values first, followed by all of the other values. In this situation, the curve moves all the way to the top before it moves at all to the right. If the model does not predict well, the curve follows the diagonal line from the bottom left to top right of the plot.

In practice, the ROC curve lies above the diagonal. The area under the curve is the indicator of the goodness of fit for the model. A value of 1 indicates a perfect fit and a value near 0.5 indicates that the model cannot discriminate among groups.

When your response has more than two levels, the ROC curve plot enables you to see which response categories have the largest area under the curve.

**Lift Curve**

The Lift Curve option provides another plot to display the predictive ability of a partition model. The lift curve plots the lift versus the portion of the observations. There is a point for each unique predicted probability value. Each predicted probability of a response level defines a portion of the observations that have a predicted probability greater than or equal to the unique predicted probability value. For a particular level of the response, the lift value is the ratio of the proportion of observed responses in that portion to the overall proportion of observed responses.

**Note:** For smaller models, it is possible that a large portion of the points have the same predicted probability value. If this probability is the highest predicted probability for the response level, the lift curve does not start at Portion = 0. For example, this is shown in the Low lift curve in Figure 4.18.

Figure 4.19 provides a table of values to demonstrate the calculation of Lift and Portion used for the High lift curve shown in Figure 4.18. A partition model with five splits was built to predict the response, Y Binary. Y Binary has two levels: Low and High. The lift curve is based on 309 observations. There are 83 observed High responses for an overall rate of 0.27.

- **Prob High**: The five unique predicted probability values from the partition model for the High response level.
- **N > Prob High**: The number of observations that have a predicted probability value equal to or greater than the value in Prob High.
- **Portion**: N > Prob High divided by 309, the total number of observations.
- **N High in Portion**: The number of observations in each portion that have an observed High response.
- **Portion High**: N High in Portion divided by N > Prob High.
- **Lift**: Portion High divided by 0.27, the overall rate of the observed High response.

Lift measures how many High responses fall in each portion as compared to the expected number of High responses for that portion. For the first 6% of the data set the lift is 3.72. Using the model to select the 6% of the observations with the highest predicted values results in 3.72 more High responses than if that 6% were selected at random.

**Node Options**

This section describes the options on the red triangle menu for each node.

**Split Best** Finds and executes the best split at or below this node.

**Split Here** Splits at the selected node on the best column to split by.

**Split Specific** Lets you specify where a split takes place. This is useful in showing what the criterion is as a function of the cut point, as well as in determining custom cut points. When specifying a splitting column, you can choose the following options for how the split is performed:

- **Optimal Value**: Splits at the optimal value of the selected variable.
- **Specified Value**: Enables you to specify the level where the split takes place.
**Output Split Table**  Produces a data table showing all possible splits and their associated split value.

**Prune Below**  Eliminates the splits below the selected node.

**Prune Worst**  Finds and removes the worst split below the selected node.

**Select Rows**  Selects the data table rows corresponding to this leaf. You can extend the selection by holding down the Shift key and choosing this command from another node.

**Show Details**  Produces a data table that shows the split criterion for a selected variable. The data table, composed of split intervals and their associated criterion values, has an attached script that produces a graph for the criterion.

**Lock**  Prevents a node or its subnodes from being chosen for a split. When checked, a lock icon appears in the node title.

---

**Validation in Partition**

The use of validation with partition models is important given that partition models are easily overfit. When this happens, the model predicts the data used to build the model very well, but predicts future observations poorly. Validation is the process of using part of a data set to estimate model parameters, and using the other part to assess the predictive ability of the model. For more information about validation, see “Validation in JMP Modeling” on page 541 in the “Statistical Details” appendix.

In Partition, when a validation method is used, the **Go** button appears. The **Go** button provides for repeated splitting without having to repeatedly click the **Split** button. When you click the **Go** button, splitting occurs until the validation RSquare is better than what the next 10 splits would obtain. This rule can result in complex trees that are not very interpretable, but have good predictive power.

Using the **Go** button turns on the **Split History** command. If using the **Go** button results in a tree with more than 40 nodes, the **Show Tree** command is turned off.

Select one of the following validation methods:

**Excluded Rows**  Uses row states to subset the data. Rows that are unexcluded are used as the training set, and excluded rows are used as the validation set.

For more information about using row states and how to exclude rows, see *Using JMP*.

**Holdback**  Randomly divides the original data into the training and validation data sets. The Validation Portion on the platform launch window is used to specify the proportion of the original data to use as the validation data set (holdback). See “Launch the Partition Platform” on page 56 for more information about the Validation Portion.
**Validation Column**  Uses a numeric column that defines the validation sets. This column should contain at most three distinct values:

- If the validation column has two levels, the smaller value defines the training set and the larger value defines the validation set.
- If the validation column has three levels, the values, in order of increasing size, define the training, validation, and test sets.
- If the validation column has more than three levels, the rows that contain the smallest three values define the validation sets. All other rows are excluded from the analysis.

If you click the Validation button with no columns selected in the Select Columns list, you can add a validation column to your data table. For more information about the Make Validation Column utility, see the “Make Validation Column” chapter on page 201.

**Tip:** To use K Fold or Nested K Fold crossvalidation, fit a partition model through the Model Screening platform. See the “Model Screening” chapter on page 173.

**Crossvalidation Report**

The Crossvalidation report shows the following:

**k-fold**   The number of folds.

**-2LogLike or SSE**   Gives twice the negative log-likelihood (-2LogLikelihood) values when the response is categorical. Gives sum of squared errors (SSE) when the response is continuous. The first row gives results averaged over the folds. The second row gives results for the single model fit to all observations. For more information about the log-likelihood, see *Fitting Linear Models*.

**RSquare**   The first row gives the RSquare value averaged over the folds. The second row gives the RSquare value for the single model fit to all observations.

**Additional Examples of Partitioning**

- “Example of a Continuous Response”
- “Example of Informative Missing”
- “Example of Profit Matrix and Decision Matrix Report”
Example of a Continuous Response

In this example, you use the Partition platform to construct a decision tree that predicts the one-year disease progression measured on a quantitative scale for patients with diabetes.

1. Select Help > Sample Data Library and Diabetes.jmp.
2. Select Analyze > Predictive Modeling > Partition.
4. Select Age through Glucose and click X, Factor.
5. Select a validation procedure based on your JMP installation:
   - For JMP Pro, select Validation and click Validation.
   - For JMP, enter 0.3 as the Validation Portion.

   **Note:** Results using the validation proportion can differ from those shown here due to the random selection of validation rows.

**Figure 4.20** Completed Launch Window with Validation Portion = 0.3

6. Click OK.
7. On the platform report window, click Split once to perform a split.
The original 309 values in the training data set are now split into two parts:
- The left leaf, corresponding to LTG < 4.6444, has 165 observations.
- The right leaf, corresponding to LTG >= 4.6444 has 144 observations.

For both the right and left leaf the next split would be on BMI. The Candidate SS for BMI on the right leaf is higher than the Candidate SS for BMI on the left leaf. Thus, the next split is on the right leaf.

8. Click **Go** to use automatic splitting.
The solution found has four splits. The Split History plot shows that there is no further improvement in the validation data set after four splits. The RSquare value of 0.39 on the validation data does not support this model as a strong predictor of disease progression. The scatter across partitions in the partition plot further indicate that this model does not separate the Y levels well.

**Example of Informative Missing**

In this example, you construct a decision tree model to predict if a customer is a credit risk. Since your data set contains missing values, you also explore the effectiveness of the Informative Missing option.
Launch the Partition Platform

1. Select Help > Sample Data Library and open Equity.jmp.
2. Select Analyze > Predictive Modeling > Partition.
4. Select LOAN through DEBTINC and click X, Factor.
5. Click OK.

Create the Decision Tree and ROC Curve with Informative Missing

1. Press Shift and click Split.
2. Enter 5 for the number of splits and click OK.
3. Click the red triangle next to Partition for BAD and select ROC Curve.
4. Click the red triangle next to Partition for BAD and select Save Columns > Save Prediction Formula.
   
   The columns Prob(BAD==Good Risk) and Prob(BAD==Bad Risk) contain the formulas that Informative Missing utility uses to classify the credit risk of future loan applicants. You are interested in how this model performs in comparison to a model that does not use informative missing.

Create the Decision Tree and ROC Curve without Informative Missing

1. Click the red triangle next to Partition for BAD and select Redo > Relaunch Analysis
2. De-select Informative Missing.
3. Click OK and repeat the steps in Create the Decision Tree and ROC Curve with Informative Missing.
   
   The columns Prob(BAD==Good Risk) 2 and Prob(BAD==Bad Risk) 2 contain the formulas that do not use the informative missing utility.

Compare the ROC Curves

Visually compare the ROC curves from the two models. The model at left is with Informative Missing, and the model at right is without Informative Missing.
Figure 4.23 ROC Curves for Models with (Left) and without (Right) Informative Missing

The area under the curve (AUC) for the model with informative missing (0.8695) is higher than the AUC for the model without informative missing (0.7283). Because there are only two levels for the response, the ROC curves for each model are reflections of one another and the AUCs are equal.

Note: Your AUC can differ from that shown for the model without informative missing. When informative missing is not used, the assignment of missing rows to sides of a split is random. Rerunning the analysis can result in slight differences in results.

Use the Model Comparison Platform

Next, compare the models using the Model Comparison platform to compare the two sets of formulas that you created in step 4 and step 3.

1. Select Analyze > Predictive Modeling > Model Comparison.
2. Select Prob(BAD==Good Risk), Prob(BAD==Bad Risk), Prob(BAD==Good Risk) 2, and Prob(BAD==Bad Risk) 2 and click Y, Predictors.

   The first pair of formula columns contains the formulas from the model with informative missing. The second pair of formula columns contains the formulas from the model without informative missing.

3. Click OK.

Figure 4.24 Measures of Fit from Model Comparison

<table>
<thead>
<tr>
<th>Measures of Fit for BAD</th>
<th>2. A. &amp; .8</th>
<th>Entropy RSquare</th>
<th>Generalized RSquare</th>
<th>Mean Log p</th>
<th>RMSE</th>
<th>Mean Abs Dev</th>
<th>Misclassification Rate</th>
<th>N</th>
</tr>
</thead>
<tbody>
<tr>
<td>Partition</td>
<td>0.3813</td>
<td>0.5015</td>
<td>0.3092</td>
<td>0.3013</td>
<td>0.1817</td>
<td>0.1158</td>
<td>0.1768</td>
<td>5960</td>
</tr>
<tr>
<td>Partition</td>
<td>0.1232</td>
<td>0.1834</td>
<td>0.4381</td>
<td>0.3687</td>
<td>0.2737</td>
<td>0.1768</td>
<td>0.1768</td>
<td>5960</td>
</tr>
</tbody>
</table>
The Measures of Fit report shows that the first model, which was fit with informative missing, performs better than the second model, which was not fit with informative missing. The first model has higher RSquare values as well as a lower RMSE value and a lower Misclassification Rate. These findings align the ROC curves comparison.

**Note:** Again, your results can differ due to the random differences when Informative Missing is not used.

### Example of Profit Matrix and Decision Matrix Report

For this example, consider a study of patients who have liver cancer. Based on various measurements and markers, you want to classify patients according to their disease severity (high or low). There are two errors that one can make in classification of patients: classifying a subject who has high severity into the low group, or classifying a patient with low severity into the high group. Clinically, the misclassification of a high patient as low is a costly error, as that patient might not receive the aggressive treatment needed. Classifying a patient with low severity into the high severity group is a less costly error. That patient might receive the more aggressive treatment than needed, but this is not a major concern.

In this example, you define a profit matrix in the context of a liver cancer study and obtain a Decision Matrix report. The Decision Matrix report helps you assess your classification rates relative to the costs in your profit matrix.

1. Select **Help > Sample Data Library** and open Liver Cancer.jmp.
2. Select **Analyze > Predictive Modeling > Partition**.
3. Select Severity and click **Y, Response**.
4. Select BMI through Jaundice and click **X, Factor**.
5. Select a validation procedure based on your JMP installation:
   - For JMP Pro, select Validation and click **Validation**.
   - For JMP, enter 0.3 as the **Validation Proportion**.

**Note:** Results using the validation proportion can differ from those shown here, due to the random selection of validation rows.
Figure 4.25  Completed Launch Window with Validation Portion = 0.3

6. Click **OK**.
7. Press Shift and click **Split**.
8. Enter 10 for the number of splits and click **OK**.
   Check that the Number of Splits is 10 in the panel beneath the plot.
9. Click the red triangle next to Partition for Severity and select **Specify Profit Matrix**.
10. Change the entries to the following values:
    - Enter 1 in the High, High box.
    - Enter -5 in the High, Low box.
    - Enter -3 in the Low, High box.
    - Enter 1 in the Low, Low box.

Figure 4.26  Completed Profit Matrix

**Tip:** You can save this profit matrix as a column property for use in later analyses. Select the check box “Save to column as property” at the bottom of the profit matrix window.

Note the following:
- Each value of 1 reflects your profit when you make a correct decision.
- The -3 value indicates that if you classify a Low severity patient as High severity, your loss is 3 times as much as the profit of a correct decision.
– The -5 value indicates that if you classify a High severity patient as Low severity, your loss is 5 times as much as the profit of a correct decision.

11. Click **OK**.

12. Click the red triangle next to Partition for Severity and select **Show Fit Details**.

**Figure 4.27** Confusion Matrix and Decision Matrix Reports

The Confusion Matrix and Decision Matrix reports follow the list of Measures in the Fit Details report. Notice that the Confusion Matrix report and the confusion matrices in the Decision Matrix report show different counts. This is because the weighting in the profit matrix results in different decisions than do the predicted probabilities without weighting.

The Confusion Matrix for the validation set shows classifications based on predicted probabilities alone. Based on these, 11 High severity patients would be classified as Low severity and 5 Low severity patients would be classified as High severity.

The Decision Matrix report incorporates the profit matrix weights. Using those weights, only 6 High severity patients are classified as Low severity. However, this comes at the expense of misclassifying 6 Low severity patients into the High severity group (1 additional patient).
13. Click the red triangle next to Partition for Severity and select **Save Columns > Save Prediction Formula**.

Eight columns are added to the data table.

**Tip:** To quickly return to the data table, click the View Associated Data icon in the bottom right corner of the report window (Windows) or the Show Data Table icon on the tool bar menu (macOS).

- The first three columns involve only the predicted probabilities. The confusion matrix counts are based on the Most Likely Severity column, which classifies a patient into the level with the highest predicted probability. These probabilities are given in the Prob(Severity == High) and Prob(Severity == Low) columns.
- The last five columns involve the profit matrix weighting. The column called Most Profitable Prediction for Severity contains the decision based on the profit matrix. The decision for a patient is the level that results in the largest profit. The profits are given in the Profit for High and Profit for Low columns.

### Statistical Details for the Partition Platform

- “Responses and Factors”
- “Splitting Criterion”
- “Predicted Probabilities in Decision Tree and Bootstrap Forest”

### Responses and Factors

The response can be either continuous or categorical (nominal or ordinal):

- If the response is categorical, then it is fitting the probabilities estimated for the response levels, minimizing the residual log-likelihood chi-square [2*entropy].
- If the response is continuous, then the platform fits means, minimizing the sum of squared errors.

The factors can be either continuous or categorical (nominal or ordinal):

- If the factor is continuous, then the partition is done according to a splitting “cut” value for the factor.
- If the factor is categorical, then it divides the $X$ categories into two groups of levels and considers all possible groupings into two levels.
Splittling Criterion

Node splitting is based on the LogWorth statistic, which is reported in Candidate reports for nodes. LogWorth is calculated as follows:

\[-\log_{10}(p\text{-value})\]

where the adjusted \( p \)-value is calculated in a complex manner that takes into account the number of different ways splits can occur. This calculation is very fair compared to the unadjusted \( p \)-value, which favors \( X \)s with many levels, and the Bonferroni \( p \)-value, which favors \( X \)s with small numbers of levels. Details about the method are discussed in Sall (2002).

For continuous responses, the Sum of Squares (SS) is reported in node reports. This is the change in the error sum-of-squares due to the split.

A candidate SS that has been chosen is:

\[SS_{test} = SS_{parent} - (SS_{right} + SS_{left})\]

where SS in a node is just \( s^2(n - 1) \).

Also reported for continuous responses is the Difference statistic. This is the difference between the predicted values for the two child nodes of a parent node.

For categorical responses, the \( G^2 \) (likelihood ratio chi-square) appears in the report. This is actually twice the \([\text{natural log}] \) entropy or twice the change in the entropy. Entropy is \( \sum -\log(p) \) for each observation, where \( p \) is the probability attributed to the response that occurred.

A candidate \( G^2 \) that has been chosen is:

\[G^2_{test} = G^2_{parent} - (G^2_{left} + G^2_{right})\]

Partition actually has two rates; one used for training that is the usual ratio of count to total, and another that is slightly biased away from zero. By never having attributed probabilities of zero, this allows logs of probabilities to be calculated on validation or excluded sets of data, used in Entropy R-Square.

Predicted Probabilities in Decision Tree and Bootstrap Forest

The predicted probabilities for the Decision Tree and Bootstrap Forest methods are calculated as described below by the Prob statistic.

For categorical responses in Decision Tree, the Show Split Prob command shows the following statistics:

**Rate** The proportion of observations at the node for each response level.

**Prob** The predicted probability for that node of the tree. The method for calculating Prob for the \( i^{th} \) response level at a given node is defined as follows:
\[
\text{Prob}_i = \frac{n_i + \text{prior}_i}{\sum (n_i + \text{prior}_i)}
\]

where the summation is across all response levels; \(n_i\) is the number of observations at the node for the \(i\)th response level; and \(\text{prior}_i\) is the prior probability for the \(i\)th response level, calculated as follows:

\[
\text{prior}_i = \lambda p_i + (1-\lambda)P_i
\]

where \(p_i\) is the prior\(_i\) from the parent node, \(P_i\) is the Prob\(_i\) from the parent node, and \(\lambda\) is a weighting factor currently set at 0.9.

The method for calculating Prob assures that the predicted probabilities are always nonzero.
The Bootstrap Forest platform fits an ensemble model by averaging many decision trees each of which is fit to a bootstrap sample of the training data. Each split in each tree considers a random subset of the predictors. In this way, many weak models are combined to produce a more powerful model. The final prediction for an observation is the average of the predicted values for that observation over all the decision trees.

Overview of the Bootstrap Forest Platform

The Bootstrap Forest platform predicts a response value by averaging the predicted response values across many decision trees. Each tree is grown on a bootstrap sample of the training data. A bootstrap sample is a random sample of observations, drawn with replacement. In addition, the predictors are sampled at each split in the decision tree. The decision tree is fit using the recursive partitioning methodology described in the “Partition Models” chapter on page 51.

This is the fitting process for the training set:

1. For each tree, select a bootstrap sample of observations.
2. Fit the individual decision tree, using recursive partitioning.
   - Select a random set of predictors for each split.
   - Continue splitting until a stopping rule that is specified in the Bootstrap Forest Specification window is met.
3. Repeat step 1 and step 2 until the number of trees specified in the Bootstrap Forest Specification window is reached or until Early Stopping occurs.

For an individual tree, the bootstrap sample of observations that is used to fit the tree is drawn with replacement. You can specify the proportion of observations to be sampled. If you specify that 100% of the observations are to be sampled, because they are drawn with replacement, the expected proportion of unused observations is 1/e, or approximately 36.8%. For each individual tree, these unused observations are called the out-of-bag observations. The observations used in fitting the tree are called in-bag observations. For a continuous response, the Bootstrap Forest platform provides measures for the error rate for out-of-bag observations, called out-of-bag error.

For a continuous response, the predicted value for an observation is the average of its predicted values over the collection of individual trees. For a categorical response, the predicted probability for an observation is the average of its predicted probabilities over the collection of individual trees. The observation is classified into the level for which its predicted probability is the highest.

For more information about bootstrap forests, see Hastie et al. (2009).
Example of Bootstrap Forest with a Categorical Response

In this example, you construct a bootstrap forest model to predict whether a customer is a bad credit risk. But you are aware that your data set contains missing values, so you also explore the degree to which values are missing.

Bootstrap Forest Model

1. Select Help > Sample Data Library and open Equity.jmp.
2. Select Analyze > Predictive Modeling > Bootstrap Forest.
4. Select LOAN through DEBTINC and click X, Factor.
5. Select Validation and click Validation.
6. Click OK.
7. Enter 4 next to Number of Terms per Split.
8. Enter 30 next to Maximum Splits per Tree.
9. Select Multiple Fits over Number of Terms and enter 10 next to Max Number of Terms.
10. (Optional) Select Suppress Multithreading and enter 123 next to Random Seed.

Because the bootstrap forest method involves random sampling, these actions ensure that your results are exactly the same as the results shown below.
11. Click OK.
Because the Multiple Fits over Number of Terms option was specified, models were created using 4, 5, 6, 8, and 10 as the number of predictors in each split. The Model Validation-Set Summaries report shows that the model whose Validation set has the highest Entropy RSquare is the five-term model. This is also the model with the smallest misclassification rate. This model is determined to be the best model, and the results in the Overall report are for this model.

The Overall report shows that the misclassification rates for the Validation and Test sets are about 11.3% and 9.9%, respectively. The confusion matrices suggest that the largest source of misclassification is the classification of bad risk customers as good risks.

The results for the Test set give you an indication of how well your model extends to independent observations. The Validation set was used in selecting the Bootstrap Forest model. For this reason, the results for the Validation set give a biased indication of how the model generalizes to independent data.

You are interested in determining which predictors contributed the most to your model.

12. Click the red triangle next to Bootstrap Forest for BAD and select Column Contributions.
The Column Contributions report suggests that the strongest predictor of a customer’s credit risk is **DEBTINC**, which is the debt to income ratio. The next highest contributors to the model are **DELINQ**, the number of delinquent credit lines, and **VALUE**, the assessed value of the customer.

### Missing Values

Next, you explore the extent to which predictor values are missing.

1. Select **Analyze > Screening > Explore Missing Values**.
2. Select **Bad through DEBTINC** and click **Y, Columns**.
3. Click **OK** in the Alert that appears.
   
   The columns **REASON** and **JOB** are not added to the **Y, Columns** list because they have a Character data type. You can see how many values are missing for these two columns using Distribution (not illustrated in this example).
4. Click **OK**.
The DEBTINC column contains 1267 missing values, which amounts to about 21% of the observations. Most other columns involved in the Bootstrap Forest analysis also contain missing values. The Informative Missing option in the launch window ensures that the missing values are treated in a way that acknowledges any information that they carry. See “Informative Missing” on page 70 in the “Partition Models” chapter.

Example of Bootstrap Forest with a Continuous Response

In this example, you construct a bootstrap forest model to predict the percent body fat for male subjects.

1. Select Help > Sample Data Library and open Body Fat.jmp.
2. Select Analyze > Predictive Modeling > Bootstrap Forest.
3. Select Percent body fat and click Y, Response.
4. Select Age (years) through Wrist circumference (cm) and click X, Factor.
5. Select Validation and click Validation.
6. Click OK.
7. (Optional) Select Suppress Multithreading and enter 123 next to Random Seed.

Because the bootstrap forest method involves random sampling, these actions ensure that your results are exactly the same as the results shown below.
8. Click OK.

**Figure 5.5** Overall Statistics

The Overall Statistics report shows that the Validation RSquare is 0.675. You are interested in obtaining a model-independent indication of the most important predictors.

9. Click the red triangle next to Bootstrap Forest for Percent body fat and select *Column Contributions*.

**Figure 5.6** Column Contributions

The Column Contributions report suggests that Abdomen circumference (cm), Chest circumference (cm), and Age (years) are the strongest predictors for Percent body fat.
Launch the Bootstrap Forest Platform

Launch the Bootstrap Forest platform by selecting Analyze > Predictive Modeling > Bootstrap Forest.

Launch Window

Figure 5.7 Bootstrap Forest Launch Window

For more information about the options in the Select Columns red triangle menu, see Using JMP.

The Bootstrap Forest platform launch provides the following options:

**Y, Response**  The response variable or variables that you want to analyze.

**X, Factor**  The predictor variables.

**Weight**  A column whose numeric values assign a weight to each row in the analysis.

**Freq**  A column whose numeric values assign a frequency to each row in the analysis.

**Validation**  A numeric column that defines the validation sets. This column should contain at most three distinct values:

- If the validation column has two levels, the smaller value defines the training set and the larger value defines the validation set.
If the validation column has three levels, the values, in order of increasing size, define the training, validation, and test sets.

If the validation column has more than three levels, the rows that contain the smallest three values define the validation sets. All other rows are excluded from the analysis.

The Bootstrap Forest platform uses the validation column to train and tune the model or to train, tune, and evaluate the model. For more information about validation, see “Validation in JMP Modeling” on page 541 in the “Statistical Details” appendix.

If you click the Validation button with no columns selected in the Select Columns list, you can add a validation column to your data table. For more information about the Make Validation Column utility, see the “Make Validation Column” chapter on page 201.

**By** A column or columns whose levels define separate analyses. For each level of the specified column, the corresponding rows are analyzed using the other variables that you have specified. The results are presented in separate reports. If more than one By variable is assigned, a separate report is produced for each possible combination of the levels of the By variables.

**Method** Enables you to select the partition method (Decision Tree, Bootstrap Forest, Boosted Tree, K Nearest Neighbors, or Naive Bayes). These alternative methods, except for Decision Tree, are available in JMP Pro.

For more information about these methods, see Chapter 4, “Partition Models”, Chapter 6, “Boosted Tree”, Chapter 7, “K Nearest Neighbors”, and Chapter 8, “Naive Bayes”.

**Validation Portion** The portion of the data to be used as the validation set.

**Informative Missing** If selected, enables missing value categorization for categorical predictors and informative treatment of missing values for continuous predictors. See “Informative Missing” on page 70 in the “Partition Models” chapter.

**Ordinal Restricts Order** If selected, restricts consideration of splits to those that preserve the ordering.
Chapter 5
Predictive and Specialized Modeling

Bootstrap Forest

Launch the Bootstrap Forest Platform

Specification Window

After you select OK in the launch window, the Bootstrap Forest Specification window appears.

Figure 5.8 Bootstrap Forest Specification Window

Specification Panel

Number of Rows  The number of rows in the data table.

Number of Terms  The number of columns that are specified as predictors.

Forest Panel

Number of Trees in the Forest  The number of trees to grow and then average.

Number of Terms Sampled per Split  The number of predictors to consider as splitting candidates at each split. For each split, a new random sample of predictors is taken as the candidate set.

Bootstrap Sample Rate  The proportion of observations to sample (with replacement) for growing each tree. A new random sample is generated for each tree.

Minimum Splits Per Tree  The minimum number of splits for each tree.

Maximum Splits Per Tree  The maximum number of splits for each tree.

Minimum Size Split  The minimum number of observations needed on a candidate split.

Early Stopping  (Available only if validation is used.) If selected, the process stops growing additional trees if the additional trees do not improve the validation statistic. The validation statistic is the validation set’s Entropy RSquare value for a categorical response.
and its RSquare value for a continuous response. If not selected, the process continues until the specified number of trees is reached.

**Multiple Fits Panel**

**Multiple Fits over Number of Terms** If selected, creates a bootstrap forest for several values of number of terms sampled per split. The model for which results are displayed is the model whose Validation Set’s Entropy RSquare value (for a categorical response) or RSquare (for a continuous response) is the largest.

The lower bound is the Number of Terms Sampled per Split specification. The upper bound is specified by the following option:

**Max Number of Terms** The maximum number of terms to consider for a split.

**Use Tuning Table Design** Opens a window where you can select a data table containing values for the Forest panel tuning parameters, called a tuning design table. A tuning design table has a column for each option that you want to specify and has one or multiple rows that each represent a single Bootstrap Forest model design. If an option is not specified in the tuning design table, the default value is used.

For each row in the table, JMP creates a Bootstrap Forest model using the tuning parameters specified. If more than one model is specified in the tuning design table, the Model Validation-Set Summaries report lists the RSquare value for each model. The Bootstrap Forest report shows the fit statistics for the model with the largest RSquare value.

You can create a tuning design table using the Design of Experiments facilities. A bootstrap forest tuning design table can contain the following case-insensitive columns in any order:

- Number Trees
- Number Terms
- Portion Bootstrap
- Minimum Splits per Tree
- Maximum Splits per Tree
- Minimum Size Split

**Reproducibility Panel**

**Suppress Multithreading** If selected, all calculations are performed on a single thread.

**Random Seed** Specify a nonzero numeric random seed to reproduce the results for future launches of the platform. By default, the Random Seed is set to zero, which does not
produce reproducible results. When you save the analysis to a script, the random seed that you enter is saved to the script.

The Bootstrap Forest Report

After you click **OK** in the Bootstrap Forest Specification window, a window appears that informs you of approximately how long it will take JMP to fit the model. If the approximated time is too long, you have the option to view the current model by selecting **Accept Current Model**. The Bootstrap Forest report appears after the complete model is fit or after the current model is accepted.

**Figure 5.9** Accept Current Model Dialog

**Figure 5.10** Bootstrap Forest Report for a Categorical Response
The following reports are provided, depending on whether the response is categorical or continuous:

- “Model Validation-Set Summaries” on page 102
- “Specifications” on page 102
- “Overall Statistics” on page 102
- “Cumulative Validation” on page 104
- “Per-Tree Summaries” on page 105

**Model Validation-Set Summaries**

(Available when you select the Multiple Fits over Number of Terms option in Bootstrap Forest Specification window.) Provides fit statistics for all the models fit. See Figure 5.10 and “Multiple Fits Panel” on page 100.

**Specifications**

Shows the settings used in fitting the model.

**Overall Statistics**

Provides fit statistics for the training set, and for the validation and test sets if they are specified. The specific form of the report depends on the modeling type of the response.
Suppose that multiple models are fit using the Multiple Fits over Multiple Terms option in the Bootstrap Forest Specification window. Then the model for which results are displayed in the Overall Statistics and Cumulative Validation reports is the model for which the validation set’s Entropy RSquare value (for a categorical response) or RSquare (for a continuous response) is the largest.

**Categorical Response**

**Measures Report**

Gives the following statistics for the training set, and for the validation and test sets if they are specified.

**Note:** For Entropy RSquare and Generalized RSquare, values closer to 1 indicate a better fit. For Mean -Log p, RASE, Mean Abs Dev, and Misclassification Rate, smaller values indicate a better fit.

**Entropy RSquare** A measure of fit that compares the log-likelihoods from the fitted model and the constant probability model. It ranges from 0 to 1. See “Entropy RSquare” on page 541 in the “Statistical Details” chapter.

**Generalized RSquare** A measure that can be applied to general regression models. It is based on the likelihood function $L$ and is scaled to have a maximum value of 1. The value is 1 for a perfect model, and 0 for a model no better than a constant model. The Generalized RSquare measure simplifies to the traditional RSquare for continuous normal responses in the standard least squares setting. Generalized RSquare is also known as the Nagelkerke or Craig and Uhler R2, which is a normalized version of Cox and Snell’s pseudo R2.

**Mean -Log P** The average of negative log($p$), where $p$ is the fitted probability associated with the event that occurred.

**RASE** The root average squared prediction error. The differences are between 1 and $p$, the fitted probability for the response level that actually occurred.

**Mean Abs Dev** The average of the absolute values of the differences between the response and the predicted response. The differences are between 1 and $p$, the fitted probability for the response level that actually occurred.

**Misclassification Rate** The rate for which the response category with the highest fitted probability is not the observed category.

**N** The number of observations.
Confusion Matrix Report

(Available only for categorical responses.) Shows classification statistics for the training set, and for the validation and test sets if they are specified. The Confusion Matrix Report contains confusion matrices and confusion rates matrices. A confusion matrix is a two-way classification of actual and predicted responses. A confusion rates matrix is equal to the confusion matrix, with the numbers divided by the row totals.

Decision Matrix

(Available only for categorical responses and if the response has a Profit Matrix column property or if you specify costs using the Specify Profit Matrix option.) Gives Decision Count and Decision Rate matrices for the training set, and for the validation and test sets if they are specified. See “Additional Examples of Partitioning” on page 76 in the “Partition Models” chapter.

Continuous Response

Individual Trees Report

Gives RASE values, which are averaged over all trees, for In Bag and Out of Bag observations. Training set observations that are used to construct a tree are called in-bag observations. Training observations that are not used to construct a tree are called out-of-bag (OOB) observations.

For each tree, the Out of Bag RASE is computed as the square root of the sum of squared errors divided by the number of OOB observations. The squared Out of Bag RASE for each tree is given in the Per-Tree Summaries report as OOB SSE/N.

RSquare and RASE Report

Gives Rsquare, root average squared prediction error, and the number of observations for the training set, and for the validation and test sets, if they are defined.

Cumulative Validation

(Available only if validation is used.) Shows a plot of the fit statistics for the Validation set versus the number of trees.

For a continuous response, the single fit statistic is R-Square. For a categorical response, the fit statistics are listed below and are described in “Measures Report” on page 103.

- RSquare (Entropy RSquare)
- Avg - Log p (Mean - Log p)
• Root Average Squared Prediction Error (RASE)
• Avg Abs Error (Mean Abs Dev)
• MR (Misclassification Rate)

The Cumulative Details report below the Cumulative Validation plot gives the values used in the plot.

**Per-Tree Summaries**

The Per-Tree Summaries report involves the concepts of in-bag and out-of-bag observations. For an individual tree, the bootstrap sample of observations used in fitting the tree is drawn with replacement. Even if you specify that 100% of the observations are to be sampled, because they are drawn with replacement, the expected proportion of unused observations is \(1/e\). For each individual tree, the unused observations are called the *out-of-bag* observations. The observations used in fitting the tree are called *in-bag* observations.

The Per-Tree Summaries report shows the following summary statistics for each tree:

**Splits** The number of splits in the decision tree.

**Rank** The rank of the tree’s OOB Loss in ascending order. The tree with the smallest OOB loss has Rank 1.

**OOB Loss** A measure of the total predictive inaccuracy of the tree when applied to the Out Of Bag rows. Lower values indicate a higher predictive accuracy.

**OOB Loss/N** The OOB Loss divided by the number of OOB rows, OOB N.

**RSquare** (Available only for continuous responses.) The RSquare value for the tree.

**IB SSE** (Available only for continuous responses.) Sum of squared errors for the In Bag rows.

**IB SSE/N** (Available only for continuous responses.) Sum of squared errors for the In Bag rows divided by the number of In Bag observations. The number of In Bag observations is equal to the number of observations in the training set multiplied by the bootstrap sampling rate that you specify in the Bootstrap Forest Specification window.

**OOB N** (Available only for continuous responses.) The number of Out Of Bag rows.

**OOB SSE** (Available only for continuous responses.) Sum of squared errors when the tree is applied to the Out Of Bag rows.

**OOB SSE/N** (Available only for continuous responses.) The OOB SSE divided by the number of OOB rows, OOB N.
Bootstrap Forest Platform Options

The Bootstrap Forest red triangle menu contains the following options:

**Plot Actual by Predicted**  (Available only for continuous responses.) Provides a plot of actual versus predicted values.

**Column Contributions**  Displays a report that shows each input column’s contribution to the fit. The report also shows:
- The total number of instances over all of the trees when the specified column is used to split the data.
- The total $G^2$ (for a categorical response) or SS, sum of squares (for a continuous response), attributed to the column.
- A bar chart of $G^2$ or SS.
- The proportion of $G^2$ or SS attributed to the column.

**Show Trees**  Provides various options for displaying trees in the Tree Views report. The report gives a picture of the tree that is fit at each layer of the boosting process. For a description of the Prob column shown by the Show names categories estimates option, see “Predicted Probabilities in Decision Tree and Bootstrap Forest” on page 86 in the “Partition Models” chapter.

**ROC Curve**  (Available only for categorical responses.) See “ROC Curve” on page 72 in the “Partition Models” chapter.

**Lift Curve**  (Available only for categorical responses.) See “Lift Curve” on page 73 in the “Partition Models” chapter.

**Save Columns**  Contains options for saving model and tree results, and creating SAS code.

- **Save Predicteds**  Saves the predicted values from the model to the data table.

- **Save Prediction Formula**  Saves the prediction formula to a column in the data table. The formula consists of nested conditional clauses that describe the tree structure. If the response is continuous, the column contains a Predicting property. If the response is categorical, the column contains a Response Probability property.
Save Tolerant Prediction Formula  (The Save Prediction Formula option should be used instead of this option. Use this option only when Save Prediction Formula is not available.) Saves a formula that predicts even when there are missing values and when Informative Missing has not been selected. The prediction formula tolerates missing values by randomly allocating response values for missing predictors to a split. If the response is continuous, the column contains a Predicting property. If the response is categorical, the column contains a Response Probability property. If you have selected Informative Missing, you can save the Tolerant Prediction Formula by holding the Shift key as you click the report’s red triangle.

Save Residuals  (Available only for continuous responses.) Saves the residuals to the data table.

Save Cumulative Details  (Available only if validation is used.) Creates a data table containing the fit statistics for each tree.

Publish Prediction Formula  Creates a prediction formula and saves it as a formula column script in the Formula Depot platform. If a Formula Depot report is not open, this option creates a Formula Depot report. See the “Formula Depot” chapter on page 213.

Publish Tolerant Prediction Formula  (The Publish Prediction Formula option should be used instead of this option. Use this option only when Publish Prediction Formula is not available.) Creates a tolerant prediction formula and saves it as a formula column script in the Formula Depot platform. If a Formula Depot report is not open, this option creates a Formula Depot report. See the “Formula Depot” chapter on page 213. If you have selected Informative Missing, you can use this option by holding the Shift key as you click the report’s red triangle.

Make SAS DATA Step  Creates SAS code for scoring a new data set.

Specify Profit Matrix  (Available only for categorical responses.) Enables you to specify profit or costs associated with correct or incorrect classification decisions. See “Show Fit Details” on page 66 in the “Partition Models” chapter.

Profiler  Shows a Prediction Profiler. See Profilers.

See Using JMP for more information about the following options:

Local Data Filter  Shows or hides the local data filter that enables you to filter the data used in a specific report.

Redo  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.
Save Script  Contains options that enable you to save a script that reproduces the report to several destinations.

Save By-Group Script  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.
The Boosted Tree platform is available only in JMP Pro.

Boosting is the process of building a large, additive decision tree by fitting a sequence of smaller decision trees, called layers. The tree at each layer consists of a small number of splits. The tree is fit based on the residuals of the previous layers, which allows each layer to correct the fit for bad fitting data from the previous layers. The final prediction for an observation is the sum of the predictions for that observation over all of the layers.

Overview of the Boosted Tree Platform

The Boosted Tree platform produces an additive decision tree model that is based on many smaller decision trees that are constructed in *layers*. The tree in each layer consists of a small number of splits, typically five or fewer. Each layer is fit using the recursive fitting methodology described in the “Partition Models” chapter on page 51. The only difference is that fitting stops at a specified number of splits. For a given tree, the predicted value for an observation in a leaf is the mean of all observations in that leaf.

This is the fitting process:

1. Fit an initial layer.
2. Compute residuals. These are obtained by subtracting the predicted mean for observations within a leaf from their actual value.
3. Fit a layer to the residuals.
4. Construct the additive tree. For a given observation, sum its predicted values over the layers.
5. Repeat step 2 to step 4 until the specified number of layers is reached, or, if validation is used, until fitting an additional layer no longer improves the validation statistic.

The final prediction is the sum of the predictions for an observation over all the layers.

By fitting successive layers on residuals from previous layers, each layer can improve the fit.

For categorical responses, only those with two response levels are supported. For a categorical response, the residuals fit at each layer are offsets of linear logits. The final prediction is a logistic transformation of the sum of the linear logits over all the layers.

For more information about boosted trees, see Hastie et al. (2009).

Example of Boosted Tree with a Categorical Response

In this example, you construct a boosted tree model to predict which printing jobs are affected by a defect called *banding*.

1. Select Help > Sample Data and open Bands Data.jmp.
2. Select Analyze > Predictive Modeling > Boosted Tree.
4. Select the Predictors column group and click X, Factor.
5. Enter 0.2 for Validation Portion.
6. Click **OK**.

   The Boosted Tree Specification window appears.

7. (Optional) In the Reproducibility panel, select **Suppress Multithreading** and enter 123 for Random Seed.

   Because the boosted tree fit involves a random component, these actions ensure that you obtain the exact results shown below.

8. Click **OK**.

---

**Figure 6.2** Overall Statistics for Nominal Response

<table>
<thead>
<tr>
<th>Measure</th>
<th>Training</th>
<th>Validation</th>
<th>Definition</th>
</tr>

<td>n</td>
</tr>
</tbody>
</table>

Because the response, **Banding?**, is categorical, the Boosted Tree analysis provides a Misclassification Rate under Measure and a Confusion Matrix report. The Misclassification Rate for the validation set is 0.1852, or about 19%.

9. Click the red triangle next to Boosted Tree for **Banding?** and select **Show Trees > Show names categories estimates**.

   A Tree Views report appears, with outlines for the layers. You can examine the layers to see the trees that are fit and the predicted values.
Chapter 6
Predictive and Specialized Modeling

Boosted Tree

Example of Boosted Tree with a Continuous Response

Figure 6.3 Layer 1 of the Boosted Tree

10. Click the red triangle next to Boosted Tree for Banding? and select Save Columns > Save Prediction Formula.

Columns called Prob(Banding?==noband), Prob(Banding?==band), and Most Likely Banding? are added to the data table. Examine the Prob(Banding?==noband) column to see how model predictions are calculated from the layers.

Example of Boosted Tree with a Continuous Response

In this example, you construct a boosted tree model to predict the percent body fat given a combination of nominal and continuous factors.

1. Select Help > Sample Data and open the Body Fat.jmp sample data table.
2. Select Analyze > Predictive Modeling > Boosted Tree.
3. Select Percent body fat and click Y, Response.
4. Select Age (years) through Wrist circumference (cm) and click X, Factor.
5. Select Validation and click Validation.
6. Click OK.
7. Click OK.
Figure 6.4 Overall Statistics for Continuous Response

<tr>
<td>Training</td>
</tr>
<tr>
<td>Validation</td>
</tr>
</tbody>
</table>

The Overall Statistics report provides the R-square and RASE for the boosted tree model. The R-square for the validation set is 0.611. The RASE for the validation set is about 5.43.

You are interested in obtaining a model-independent indication of the important predictors for Percent body fat.

8. Click the red triangle next to Boosted Tree for Percent body fat and select **Profiler**.

9. Click the red triangle next to Prediction Profiler and select **Assess Variable Importance > Independent Uniform Inputs**.

**Note:** Because Assess Variable Importance uses randomization, your results might not exactly match those in Figure 6.5.

</tbody>
</table>

The Summary Report shows that Abdomen circumference (cm) is the most important predictor of Percent body fat.
Launch the Boosted Tree Platform

Launch the Boosted Tree platform by selecting Analyze > Predictive Modeling > Boosted Tree.

Figure 6.6 Boosted Tree Launch Window Using Body Fat.jmp

For more information about the options in the Select Columns red triangle menu, see Using JMP.

The Boosted Tree platform launch window has the following options:

**Y, Response**  The response variable or variables that you want to analyze.

**X, Factor**  The predictor variables.

**Weight**  A column whose numeric values assign a weight to each row in the analysis.

**Freq**  A column whose numeric values assign a frequency to each row in the analysis.

**Validation**  A numeric column that defines the validation sets. This column should contain at most three distinct values:

- If the validation column has two levels, the smaller value defines the training set and the larger value defines the validation set.
– If the validation column has three levels, the values, in order of increasing size, define the training, validation, and test sets.

– If the validation column has more than three levels, the rows that contain the smallest three values define the validation sets. All other rows are excluded from the analysis.

The Boosted Tree platform uses the validation column to train and tune the model or to train, tune, and evaluate the model. For more information about validation, see “Validation in JMP Modeling” on page 541 in the “Statistical Details” appendix.

If you click the Validation button with no columns selected in the Select Columns list, you can add a validation column to your data table. For more information about the Make Validation Column utility, see the “Make Validation Column” chapter on page 201.

**By**  A column or columns whose levels define separate analyses. For each level of the specified column, the corresponding rows are analyzed using the other variables that you have specified. The results are presented in separate reports. If more than one By variable is assigned, a separate report is produced for each possible combination of the levels of the By variables.

**Method**  Enables you to select the partition method (Decision Tree, Bootstrap Forest, Boosted Tree, K Nearest Neighbors, or Naive Bayes). These alternative methods, except for Decision Tree, are available in JMP Pro.

For more information about these methods, see Chapter 4, “Partition Models”, Chapter 5, “Bootstrap Forest”, Chapter 7, “K Nearest Neighbors”, and Chapter 8, “Naive Bayes”.

**Validation Portion**  The portion of the data to be used as the validation set.

**Informative Missing**  If selected, enables missing value categorization for categorical predictors and informative treatment of missing values for continuous predictors. See “Informative Missing” on page 70 in the “Partition Models” chapter.

**Ordinal Restricts Order**  If selected, restricts consideration of splits to those that preserve the ordering.
Specification Window

After you select OK in the launch window, the Gradient-Boosted Trees Specification window appears.

**Figure 6.7 Boosted Tree Specification Window**

![Boosted Tree Specification Window](image)

**Boosting Panel**

**Number of Layers** The maximum number of layers to include in the final tree.

**Splits per Tree** The number of splits for each layer.

**Learning Rate** A number such that $0 < r \leq 1$. Learning rates close to 1 result in faster convergence on a final tree, but also have a higher tendency to overfit data. Use learning rates closer to 1 when a small Number of Layers is specified. The learning rate is a small fraction typically between 0.01 and 0.1 that slows the convergence of the model. This preserves opportunities for later layers to use different splits than the earlier layers.

**Overfit Penalty** (Available only for categorical responses.) A biasing parameter that helps protect against fitting probabilities equal to zero. See “Overfit Penalty” on page 125.

**Minimum Size Split** The minimum number of observations needed on a candidate split.

**Multiple Fits Panel**

**Multiple Fits over Splits and Learning Rate** If selected, creates a boosted tree for every combination of Splits per Tree (in integer increments) and Learning Rate (in 0.1 increments).

The lower bounds for the combinations are specified by the Splits per Tree and Learning Rate options. The upper bounds for the combinations are specified by the following options:
Max Splits per Tree  Upper bound for Splits per Tree.

Max Learning Rate  Lower bound for Learning Rate.

Use Tuning Design Table  Opens a window where you can select a data table containing values for some tuning parameters, called a tuning design table. A tuning design table has a column for each option that you want to specify and has one or multiple rows that each represent a single Boosted Tree model design. If an option is not specified in the tuning design table, the default value is used.

For each row in the table, JMP creates a Boosted Tree model using the tuning parameters specified. If more than one model is specified in the tuning design table, the Model Validation-Set Summaries report lists the R-Square value for each model. The Boosted Tree report shows the fit statistics for the model with the largest R-Square value.

You can create a tuning design table using the Design of Experiments facilities. A boosted tree tuning design table can contain the following case-insensitive columns in any order:

- Number of Layers
- Splits per Tree
- Learning Rate
- Minimum Size Split
- Row Sampling Rate
- Column Sampling Rate

Stochastic Boosting Panel

Row Sampling Rate  Proportion of training rows to sample for each layer.

Note: When the response is categorical, the training rows are sampled using stratified random sampling.

Column Sampling Rate  Proportion of predictor columns to sample for each layer.

Reproducibility Panel

Suppress Multithreading  If selected, all calculations are performed on a single thread.

Random Seed  Specify a nonzero numeric random seed to reproduce the results for future launches of the platform. By default, the Random Seed is set to zero, which does not produce reproducible results. When you save the analysis to a script, the random seed that you enter is saved to the script.
Early Stopping

If selected, the boosting process stops fitting additional layers when the additional layers do not improve the validation statistic. If not selected, the boosting process continues until the specified number of layers is reached. This option appears only if validation is used.

The Boosted Tree Report

After you click OK in the Gradient-Boosted Trees Specification window, the Boosted Tree report opens.

Figure 6.8  Boosted Tree Report for a Continuous Response
Figure 6.9 Boosted Tree Report for a Categorical Response

The following reports are provided, depending on whether the response is categorical or continuous:

- “Model Validation - Set Summaries” on page 120
- “Specifications” on page 121
- “Overall Statistics” on page 121
- “Cumulative Validation” on page 122

**Model Validation - Set Summaries**

Shows fit statistics for all the models fit if you selected the Multiple Fits over Splits and Learning Rate option in the Specification window. See Figure 6.8 and “Multiple Fits Panel” on page 117.
Specifications

Shows the settings used in fitting the model.

Overall Statistics

Shows fit statistics for the training set, and for the validation and test sets if they are specified.

Suppose that you fit multiple models using the Multiple Fits over Splits and Learning Rate option in the Boosted Tree Specification window. Then the model for which results are displayed in the Overall Statistics and Cumulative Validation reports is the model for which the validation set’s Entropy R-square value (for a categorical response) or R-square (for a continuous response) is the largest.

Measures Report

(Available only for categorical responses.) Gives the following statistics for the training set, and for the validation and test sets if they are specified.

**Note:** For Entropy R-Square and Generalized R-Square, values closer to 1 indicate a better fit. For Mean -Log p, RASE, Mean Abs Dev, and Misclassification Rate, smaller values indicate a better fit.

**Entropy RSquare**  A measure of fit that compares the log-likelihoods from the fitted model and the constant probability model. It ranges from 0 to 1. See “Entropy RSquare” on page 541 in the “Statistical Details” chapter.

**Generalized RSquare**  A measure that can be applied to general regression models. It is based on the likelihood function $L$ and is scaled to have a maximum value of 1. The value is 1 for a perfect model, and 0 for a model no better than a constant model. The Generalized R-Square measure simplifies to the traditional R-Square for continuous normal responses in the standard least squares setting. Generalized R-Square is also known as the Nagelkerke or Craig and Uhler $R^2$, which is a normalized version of Cox and Snell’s pseudo $R^2$.

**Mean -Log P**  The average of negative log($p$), where $p$ is the fitted probability associated with the event that occurred.

**RASE**  The root average squared prediction error. The differences are between 1 and $p$, the fitted probability for the response level that actually occurred.
Mean Abs Dev  The average of the absolute values of the differences between the response and the predicted response. The differences are between 1 and \( p \), the fitted probability for the response level that actually occurred.

Misclassification Rate  The rate for which the response category with the highest fitted probability is not the observed category.

N  The number of observations.

Confusion Matrix Report

(Available only for categorical responses.) Shows classification statistics for the training set, and for the validation and test sets if they are specified. The Confusion Matrix Report contains confusion matrices and confusion rates matrices. A confusion matrix is a two-way classification of actual and predicted responses. A confusion rates matrix is equal to the confusion matrix, with the numbers divided by the row totals.

Decision Matrix

(Available only for categorical responses and if the response has a Profit Matrix column property or if you specify costs using the Specify Profit Matrix option.) Gives Decision Count and Decision Rate matrices for the training set, and for the validation and test sets if they are specified. See “Additional Examples of Partitioning” on page 76 in the “Partition Models” chapter.

Cumulative Validation

(Available only if validation is used.) Shows a plot of the fit statistics for the Validation set versus the number of layers.

For a continuous response, the single fit statistic is R-Square. For a categorical response, the fit statistics are listed below and are described in “Measures Report” on page 121.

- R-Square (Entropy R-Square)
- Avg - Log p (Mean - Log p)
- Root Average Squared Prediction Error (RASE)
- Avg Abs Error (Mean Abs Dev)
- MR (Misclassification Rate)

The Cumulative Details report below the Cumulative Validation plot gives the values used in the plot.
Boosted Tree Platform Options

The Boosted Tree red triangle menu contains the following options:

**Show Trees**  Provides options for displaying trees in the Tree Views report. The report gives a picture of the tree that is fit at each layer of the boosting process.

**Plot Actual by Predicted**  (Available only for continuous responses.) Provides a plot of actual versus predicted values.

**Column Contributions**  Displays a report showing each input column’s contribution to the fit. The report also shows:
- The total number of instances over all of the trees when the specified column is used to split the data.
- The total $G^2$ (for a categorical response) or SS, sum of squares (for a continuous response) attributed to the column.
- A bar chart of $G^2$ or SS.
- The proportion of $G^2$ or SS attributed to the column.

**ROC Curve**  (Available only for categorical responses.) See “ROC Curve” on page 72 in the “Partition Models” chapter.

**Lift Curve**  (Available only for categorical responses.) See “Lift Curve” on page 73 in the “Partition Models” chapter.

**Save Columns**  Contains options for saving model and tree results, and creating SAS code.

**Save Predicteds**  Saves the predicted values from the model to the data table.

**Save Prediction Formula**  Saves the prediction formula to a column in the data table. The formula consists of nested conditional clauses that describe the tree structure. If the response is continuous, the column contains a Predicting column property. If the response is categorical, the column contains a Response Probability column property.

**Save Tolerant Prediction Formula**  (The Save Prediction Formula option should be used instead of this option. Use this option only when Save Prediction Formula is not available.) Saves a formula that predicts even when there are missing values and when Informative Missing has not been selected. The prediction formula tolerates missing values by randomly allocating response values for missing predictors to a split. If the response is continuous, the column contains a Predicting column property. If the response is categorical, the column contains a Response Probability column property. If you have selected Informative Missing, you can save the Tolerant Prediction Formula by holding the Shift key as you click the report’s red triangle.
**Save Residuals**  (Available only for continuous responses.) Saves the residuals to the data table.

**Save Offset Estimates**  (Available only for categorical responses.) Saves the sums of the linear components. These are the logits of the fitted probabilities.

**Save Tree Details**  Creates a data table containing split details and estimates for each layer.

**Save Cumulative Details**  (Available only if validation is used.) Creates a data table containing the fit statistics for each layer.

**Publish Prediction Formula**  Creates a prediction formula and saves it as a formula column script in the Formula Depot platform. If a Formula Depot report is not open, this option creates a Formula Depot report. See the “Formula Depot” chapter on page 213.

**Publish Tolerant Prediction Formula**  (The Publish Prediction Formula option should be used instead of this option. Use this option only when Publish Prediction Formula is not available.) Creates a tolerant prediction formula and saves it as a formula column script in the Formula Depot platform. If a Formula Depot report is not open, this option creates a Formula Depot report. See the “Formula Depot” chapter on page 213. If you have selected Informative Missing, you can use this option by holding the Shift key as you click the report’s red triangle.

**Make SAS DATA Step**  Creates SAS code for scoring a new data set.

**Specify Profit Matrix**  (Available only for categorical responses.) Enables you to specify profit or costs associated with correct or incorrect classification decisions. See “Show Fit Details” on page 66 in the “Partition Models” chapter.

**Profiler**  Shows a Prediction Profiler. See Profilers.

See *Using JMP* for more information about the following options:

**Local Data Filter**  Shows or hides the local data filter that enables you to filter the data used in a specific report.

**Redo**  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

**Save Script**  Contains options that enable you to save a script that reproduces the report to several destinations.

**Save By-Group Script**  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.
Statistical Details for the Boosted Tree Platform

This section describes details specific to the Boosted Tree Platform. For statistical details about recursive decision trees, see “Statistical Details for the Partition Platform” on page 85 in the “Partition Models” chapter.

Overfit Penalty

When the response is categorical, a parametric penalty is imposed. For each layer, the estimates minimize the negative log-likelihood plus the penalty value multiplied by the sum of squares of the estimates for each observation. This penalty encourages each new layer not to overfit the training data.
The K Nearest Neighbors platform is available only in JMP Pro.

The K Nearest Neighbors platform predicts a response value for a given observation using the responses of the observations in that observation’s local neighborhood. It can be used for classification of a categorical response as well as for prediction of a continuous response.

K Nearest Neighbors is a nonparametric method that is based on the distance to neighboring observations. Because of this fact, K Nearest Neighbors is able to classify observations using irregular predictor value boundaries. However, because the algorithm is sensitive to irrelevant predictors, the selection of predictors can impact your results.

K Nearest Neighbors has been used successfully in many applications, such as classifying satellite imagery and electrocardiogram (EKG) patterns.

Overview of the K Nearest Neighbors Platform

The K Nearest Neighbors platform predicts a response value based on the responses of the $k$ nearest neighbors. The $k$ nearest neighbors to a given observation are determined by identifying the $k$ smallest Euclidean distances between the predictor values for that observation and the predictor values for each of the other observations. The K Nearest Neighbors platform models both continuous and categorical responses.

A potential drawback of the $k$ nearest neighbors method is that for large scale problems, the prediction formula is often complex and hard to interpret, limiting its usefulness. In addition, K Nearest Neighbors does not calculate probabilities for categorical responses. For more information about the $k$ nearest neighbors method, see Hastie et al. (2009), Hand et al. (2001), and Shmueli et al. (2017).

Continuous Responses

For a continuous response, the predicted value is the average of the responses for the $k$ nearest neighbors. Each continuous predictor is scaled by its standard deviation. With this scaling, a single predictor with a large range does not excessively influence the distance calculation. Missing values for a continuous predictor are replaced by the mean of that predictor. See “Example of K Nearest Neighbors with Continuous Response” on page 132.

Categorical Responses

For a categorical response, the predicted value is the most frequent response level for the $k$ nearest neighbors. If two or more levels are tied as the most frequent levels, the predicted response is assigned by selecting one of these levels at random.

Note: Because ties for most frequent levels in the case of a categorical response are broken at random, results from independent runs of the platform might differ. To obtain reproducible results, use the Set Random Seed option in the launch window or include the Set Random Seed() function in a JSL script.

In the categorical prediction models, each categorical predictor is expressed in terms of indicator variables, with one indicator variable representing each level. A row with a missing value for a categorical predictor is represented by values of zero on all indicator variables for that predictor.
Example of K Nearest Neighbors with Categorical Response

You have historical financial data for 5,960 customers who applied for home equity loans. Each customer was classified as being a Good Risk or Bad Risk. There are missing values for many of the predictors. You want to construct a model to use in classifying the credit risk of future customers.

1. Select Help > Sample Data Library and open Equity.jmp.
4. Select LOAN through CLNO and click X, Factor.

   Because one of the potential predictors, DEBTINC, has many missing values, you do not include it in your model. Missing values for continuous predictors are replaced by the average of the predictor. This procedure sometimes works well for values that are missing at random. Although the high missing rate of the DEBTINC indicates that the missing might be informative, we do not investigate that in this example.

5. Select Validation and click Validation.
6. Click OK.
For each value of $K$, JMP constructs a model using only the training set observations. Each of these models is used to classify the validation set observations. The validation set results are used to select a best model. In this example, the model based on the single nearest neighbor ($K = 1$) has the smallest misclassification rate. The test set verifies that the single nearest neighbor model is the best performer for independent data.

7. Click the BAD red triangle and select **Publish Prediction Formula**.
8. Next to **Number of Neighbors, K**, leave the default value of 1.
9. Click **OK**.

The prediction equation is saved in the Formula Depot. You can compare the performance of alternative models published to the Formula Depot with that of the $K = 1$ nearest neighbor model using the Model Comparison option in the Formula Depot. See the “Formula Depot” chapter on page 213.
Example of K Nearest Neighbors with Continuous Response

In this example, you want to predict the percent body fat for males using 13 predictors. The Body Fat.jmp sample data table contains percent body fat estimates that are based on underwater weighing and on various body circumference measurements.

1. Select Help > Sample Data Library and open Body Fat.jmp.
3. Select Percent body fat and click Y, Response.
4. Select Age (years) through Wrist circumference (cm) and click X, Factor.
5. Select Validation and click Validation.
6. Click OK.
7. Click the Percent body fat red triangle and select Plot Actual by Predicted.
The $K = 8$ model had the lowest RASE for the validation set. Among $k$ nearest neighbor models, the model based on 8 nearest neighbors seems to perform the best. The Actual by Predicted plot for the training set shows that the points fall along the line, signifying that the predicted values are similar to the actual values. Most of the points on the plot for the validation set fall along the line, with a few observations on the upper end that are a bit farther away.
Launch the K Nearest Neighbors Platform

Launch the K Nearest Neighbors platform by selecting Analyze > Predictive Modeling > K Nearest Neighbors.

**Figure 7.4 K Nearest Neighbors Launch Window**

For more information about the options in the Select Columns red triangle menu, see *Using JMP*.

The K Nearest Neighbors launch window provides the following options:

**Y, Response**  The response variable or variables that you want to analyze.

**Note:** The K Nearest Neighbors platform can be used as a utility to determine the distances between neighboring observations, even without the presence of a response variable. If you do not specify a response variable, a blank report appears. However, the red triangle menu options Save Near Neighbor Rows and Save Near Neighbor Distances are available.

**X, Factor**  The predictor variables.

**Validation**  A numeric column that defines the validation sets. This column should contain at most three distinct values:

- If the validation column has two levels, the smaller value defines the training set and the larger value defines the validation set.
– If the validation column has three levels, the values, in order of increasing size, define the training, validation, and test sets.

– If the validation column has more than three levels, the rows that contain the smallest three values define the validation sets. All other rows are excluded from the analysis.

The K Nearest Neighbors platform uses the validation column to train and tune the model or to train, tune, and evaluate the model. For more information about validation, see “Validation in JMP Modeling” on page 541 in the “Statistical Details” appendix.

If you click the Validation button with no columns selected in the Select Columns list, you can add a validation column to your data table. For more information about the Make Validation Column utility, see the “Make Validation Column” chapter on page 201.

**By**  A column or columns whose levels define separate analyses. For each level of the specified column, the corresponding rows are analyzed using the other variables that you have specified. The results are presented in separate reports. If more than one By variable is assigned, a separate report is produced for each possible combination of the levels of the By variables.

**Validation Portion**  The portion of the data to be used as the validation set.

**Number of Neighbors, K**  Maximum number of nearest neighbors to analyze. Models are fit for one nearest neighbor up to the value that you specify for K.

*Note: The maximum number of neighbors, K, must be no larger than one less than the number of rows in the training data table. If you specify a K that is larger than the maximum allowable K, a warning appears."

**Category Bias**  Specifies a tuning parameter that ensures that the fitted probabilities for categorical responses are always positive. By default, the Category Bias is 0.5.

**Set Random Seed**  Sets the seed for the randomization process used in tie-breaking for nominal and ordinal responses. If you specify a Validation Portion, this option also sets the seed for the rows used for validation. Set Random Seed is useful if you want to reproduce an analysis. If you set a random seed and save the script, the seed is automatically saved in the script.

---

**The K Nearest Neighbors Report**

The K Nearest Neighbors report contains a separate report for each response variable. Each response variable report contains information about the fitted model for that response. This information includes a Model Selection report and summary information for each of the k models that were fit. The report shows tables for the training set and for the validation and test sets if you defined these using validation.
The Model Selection report displays a solution path plot across $K$ based on the Misclassification Rate for categorical responses or the RASE for continuous responses. By default, the slider is placed on the value of $K$ that corresponds to the best performing model. You can drag the slider to change the value of $K$ in the report.

The statistics reported depend on the modeling type of the response. Each row in the summary tables corresponds to a model defined by $k$ nearest neighbors, where $K$ ranges from one to the value that you specified as Number of Neighbors, $K$ in the launch window.

### Continuous Responses

By default, in addition to the Model Selection graph, the report for a continuous response contains the Summary Table report.

**Summary Table**

An asterisk marks the model for the value of $K$ that has the smallest RASE. The report for a continuous response contains the following columns:

- **$K$** Number of nearest neighbors used in the model. $K$ ranges from 1 to the Number of Neighbors, $K$ that you specified in the launch window.
- **Count** Number of observations.
- **RSquare** The RSquare value for the model.
- **RASE** Root mean average squared prediction error for the model. The model with the smallest RASE is marked with an asterisk. If there are tied RASE values, the model with the smallest $K$ is marked with the asterisk.
- **SSE** Sum of squared errors for the model.

### Categorical Responses

By default, in addition to the Model Selection graph, the report for a categorical response contains the Summary Table, Confusion Matrix, and Mosaic Plot reports.

**Summary Table**

An asterisk marks the model for the value of $K$ that has the smallest misclassification rate. The report for a categorical response contains the following columns:

- **$K$** Number of nearest neighbors used in the model. $K$ ranges from 1 to the Number of Neighbors, $K$ that you specified in the launch window.
- **Count** Number of observations.
**Misclassification Rate**  Proportion of observations misclassified by the model. This is calculated as Misclassifications divided by Count. The model with the smallest misclassification rate is marked with an asterisk. If there are tied misclassification rates, the model with the smallest \( K \) is marked with the asterisk.

**Misclassifications**  Number of observations that are incorrectly predicted by the model.

**Confusion Matrix**

By default, a Confusion Matrix Report is shown for the model with the smallest Misclassification Rate. If there are ties for the smallest misclassification rate, a report is shown for the model with the smallest \( K \). The Confusion Matrix Report contains confusion matrices and confusion rates matrices. A confusion matrix is a two-way classification of actual and predicted responses. A confusion rates matrix is equal to the confusion matrix, with the numbers divided by the row totals. If you use validation, confusion matrices and confusion rates matrices for the validation and test sets appear. Use the Confusion Matrix Report and the misclassification rates to evaluate your model.

**Tip:** If you change the position of the slider in the solution path plot, an additional Confusion Matrix Report is displayed for the chosen value of \( K \). Use the additional report to compare an alternative model to the default best model.

**Mosaic Plot**

By default, a mosaic plot is shown for the model with the smallest Misclassification Rate. If there are ties for the smallest misclassification rate, a mosaic plot is shown for the model with the smallest \( K \). A mosaic plot is a stacked bar chart where each segment is proportional to its group’s frequency count. For more information about mosaic plots, see *Basic Analysis*. If you use validation, mosaic plots for the validation and test sets are shown.

**Tip:** If you change the position of the slider in the solution path plot, the mosaic plot updates to display the results for the chosen value of \( K \).

---

### K Nearest Neighbors Platform Options

The K Nearest Neighbors red triangle menu contains the following options:

**Save Near Neighbor Rows**  Saves \( K \) columns to the data table. The columns are named RowNear \(<k>\). For a given row, the \( k^{th} \) column contains the row number of its \( k^{th} \) nearest neighbor.
**Caution:** The row numbers in the columns RowNear <k> do not update when you reorder the rows in your data table. If you reorder the rows, the values in those columns are incorrect.

**Save Near Neighbor Distances** Saves K columns to the data table. The columns are named Distance <k>. For a given row, the k<sup>th</sup> column contains the distance to that row’s k<sup>th</sup> nearest neighbor.

See *Using JMP* for more information about the following options:

**Local Data Filter** Shows or hides the local data filter that enables you to filter the data used in a specific report.

**Redo** Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

**Save Script** Contains options that enable you to save a script that reproduces the report to several destinations.

**Save By-Group Script** Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.

### Model Fit Options

**Mosaic Plot** (Available only for nominal or ordinal responses.) Shows or hides the mosaic plot. See “Mosaic Plot” on page 137.

**Plot Actual by Predicted** (Available only for continuous responses.) Plots the actual versus the predicted responses for the model with the smallest RASE. If there are ties for the smallest RASE, the plot is based on the model with the smallest K.

**Tip:** If you change the position of the slider on the solution path plot to a different K, the Actual by Predicted plot is updated to reflect the model for the chosen value of K.

**Plot Residual by Predicted** (Available only for continuous responses.) Plots the residuals versus the predicted responses for the model with the smallest RASE. If there are ties for the smallest RASE, the plot is based on the model with the smallest K.

**Tip:** If you change the position of the slider on the solution path plot to a different K, the Residual by Predicted plot is updated to reflect the model for the chosen value of K.
**Save Predicteds**  Saves $K$ predicted value columns to the data table. The columns are named Predicted <Response> $<k>$. The $k^{th}$ column contains predictions for the model based on the $k$ nearest neighbors, where Response is the name of the response column.

**Save Prediction Formula**  Saves a column that contains a prediction formula for a specific $k$ nearest neighbor model. Enter a value for $K$ when prompted. The prediction formula contains all the training data, so this option might not be practical for large data tables.

---

**Caution:** The values obtained from Save Prediction Formula and Save Predicteds do not necessarily match. The values obtained from the Save Prediction Formula option use all of the rows in the training set, including the row for the predicted value. The values from the Save Predicteds option do not use the row for the predicted value in the training set, only all other rows.

**Publish Prediction Formula**  Creates a prediction formula for the specified $k$ nearest neighbor model and saves it as a formula column script in the Formula Depot platform. If a Formula Depot report is not open, this option creates a Formula Depot report. See the “Formula Depot” chapter on page 213.
The Naive Bayes platform is available only in JMP Pro.

The Naive Bayes platform fits a model to predict the value of a categorical variable. Naive Bayes is a fast and computationally simple method. It is especially suitable for situations where there are a large number of predictors.

Overview of the Naive Bayes Platform

The Naive Bayes platform classifies observations into *classes* that are defined by the levels of a categorical response variable. The variables (or factors) that are used for classification are often called *features* in the data mining literature.

For each class, the naive Bayes algorithm computes the conditional probability of each feature value occurring. If a feature is continuous, its conditional marginal density is estimated. The naive Bayes technique assumes that, within a class, the features are independent. (This is the reason that the technique is referred to as “naive”.) Classification is based on the idea that an observation whose feature values have high conditional probabilities within a certain class has a high probability of belonging to that class. See Hastie et al. (2009).

Because the algorithm estimates only one-dimensional densities or distributions, the algorithm is extremely fast. This makes it suitable for large data sets, and in particular, data sets with large numbers of features. All nonmissing feature values for an observation are used in calculating the conditional probabilities.

Each observation is assigned a *naive score* for each class. An observation’s naive score for a given class is the proportion of training observations that belong to that class multiplied by the product of the observation’s conditional probabilities. The *naive probability* that an observation belongs to a class is its naive score for that class divided by the sum of its naive scores across all classes. The observation is assigned to the class for which it has the highest naive probability.

**Caution:** Because the conditional probabilities of class membership are assumed independent, the naive Bayes estimated probabilities are inefficient.

Naive Bayes requires a large number of training observations to ensure representation for all predictor values and classes. If an observation in the Validation set is being classified and it has a categorical predictor value that was missing in the Training set, then the platform uses the non-missing features to predict. If an observation is missing all predictor values, the predicted response is the most frequent response. The prediction formulas handle missing values by having them contribute nothing to the observation’s score.

For more information about the naive Bayes technique, see Hand et al. (2001), and Shmueli et al. (2010).
You want to construct a classification model to be used in predicting the disease progression for future patients as High or Low. You have baseline medical data for 442 diabetic patients. You also have a binary measure of diabetes disease progression obtained one year after each patient’s initial visit. This measure quantifies disease progression as being either Low or High.

1. Select **Help > Sample Data Library** and open Diabetes.jmp.
2. Select **Analyze > Predictive Modeling > Naive Bayes**.
3. Select **Y Binary** and click **Y, Response**.
4. Select **Age through Glucose** and click **X, Factor**.
5. Select **Validation** and click **Validation**.
6. Click **OK**.

**Figure 8.2** Naive Bayes Report

The Training Set has about a 21% misclassification rate and the Validation Set has about a 24% misclassification rate. The Confusion matrix suggests that, for both the Training and Validation sets, the larger source of misclassification comes from classifying patients with Low disease progression as having High disease progression. The Validation set results indicate how your model extends to independent observations.

You are interested in which individual predictors have the greatest impact on the naive Bayes classification.

7. Click the Naive Bayes red triangle and select **Profiler**.
Figure 8.3 Prediction Profiler for Disease Progression

![Prediction Profiler](image)

8. Click the Prediction Profiler red triangle and select **Assess Variable Importance > Independent Uniform Inputs**.

The Summary Report indicates that HDL, BMI, and LTG have the greatest impact on the estimated probabilities.

Figure 8.5 Marginal Model Plots Report

![Marginal Model Plots](image)

The second row of plots in the Marginal Model Plots report shows that higher values of HDL are associated with a lower probability of classifying a patient as High. Also, higher BMI and LTG values are associated with a higher probability of classifying a patient as High.
Launch the Naive Bayes Platform

Launch the Naive Bayes platform by selecting **Analyze > Predictive Modeling > Naive Bayes**.

**Figure 8.6** Naive Bayes Launch Window

For more information about the options in the Select Columns red triangle menu, see *Using JMP*.

The Naive Bayes launch window provides the following options:

- **Y, Response**  The categorical response column whose values are the classes of interest.

- **X, Factor**  Categorical or continuous predictor columns.

- **Weight**  A column whose numeric values assign a weight to each row in the analysis.

- **Freq**  A column whose numeric values assign a frequency to each row in the analysis.

- **Validation**  A numeric column that defines the validation sets. This column should contain at most three distinct values:
  
  - If the column has three unique values, then:
    rows with the smallest value are used for the Training set.
    rows with the middle value are used for the Validation set.
    rows with the largest value are used for the Test set.
  
  - If the column has two unique values, then only Training and Validation sets are used.
  
  - If the validation column has more than three levels, the rows that contain the smallest three values define the validation sets. All other rows are excluded from the analysis.
The Naive Bayes platform uses the validation column to train and evaluate the model. For more information about validation, see “Validation in JMP Modeling” on page 541 in the “Statistical Details” appendix.

If you click the Validation button with no columns selected in the Select Columns list, you can add a validation column to your data table. For more information about the Make Validation Column utility, see the “Make Validation Column” chapter on page 201.

**By** A column or columns whose levels define separate analyses. For each level of the specified column, the corresponding rows are analyzed using the other variables that you have specified. The results are presented in separate reports. If more than one By variable is assigned, a separate analysis is produced for each possible combination of the levels of the By variables.

**Validation Portion** The portion of the data to be used as the Validation set.

**Note:** If neither a Validation column or a Validation Portion is specified in the launch window and if there are excluded rows, these rows are treated as a Validation set. For more information about validation see “Validation in JMP Modeling” on page 541 in the “Statistical Details” chapter.
After you click **OK** in the launch window, the Naive Bayes report appears. By default, the Naive Bayes report contains reports for fit details, the response column, the Confusion Matrix Report, and the ROC and Lift curves.

**Figure 8.7  Naive Bayes Report**

### Fit Details Report

The Fit Details report shows various measures of fit for the model for the Training set, and for the Validation and Test sets if they are specified. The Measure column lists the different fit statistics and the Definition column shows the formulas for the corresponding fit statistics. See “Measures of Fit for Categorical Responses” on page 196 in the “Model Comparison” chapter. By default, the Fit Details report in the Naive Bayes report window is closed.

### Response Column Report

The response column report shows performance statistics for the naive Bayes classification in a summary table for the Training set, and the Validation and Test sets if they are specified. The summary tables contain the following columns:

- **Count**  The number of observations in the set corresponding to the table (Training, Validation, or Test set).

- **Misclassification Rate**  Proportion of observations in the corresponding set that are misclassified by the model. This is calculated as Misclassifications divided by Count.
Misclassifications  The number of observations in the corresponding set that are classified incorrectly.

Confusion Matrix Report

The Confusion Matrix Report shows a confusion matrix and a confusion rates matrix for the Training set, and for the Validation and Test sets if they are specified. A confusion matrix is a two-way classification of actual and predicted responses. A confusion rates matrix is equal to the confusion matrix, with the numbers divided by the row totals.

ROC Curves

The report displays the Receiver Operating Characteristic (ROC) curve for the Training set, and for the Validation and Test sets if they are specified. The ROC curve measures the ability of the fitted probabilities to classify response levels correctly. The further the curve from the diagonal, the better the fit. An introduction to ROC curves is found in Basic Analysis.

See “ROC Curve” on page 72 in the “Partition Models” chapter for more information about ROC curves.

Naive Bayes Platform Options

The Naive Bayes red triangle menu contains the following options:

ROC Curve  Shows or hides the ROC plot. The ROC plot is shown by default. See “ROC Curves” on page 149.

Lift Curve  Shows or hides the lift curve for the model. If you used validation, Lift curve is shown for each of the Training, Validation, and Test sets, if specified.

A lift curve shows how effectively response levels are classified as their fitted probabilities decrease. The fitted probabilities are plotted along the horizontal axis in descending order. The vertical coordinate for a fitted probability is the proportion of correct classifications for that probability or higher, divided by the overall correct classification rate. Use the lift curve to see whether you can correctly classify a large proportion of observations if you select only those with a fitted probability that exceeds a threshold value.

If the response has two levels, the Lift curve plot displays a lift curve for the first level of the response only. If the response has more than two levels, the Lift curve plot displays a sub-outline of the curves for each response level. See “Lift Curve” on page 73 in the “Partition Models” chapter for more information about lift curves.
**Save Predicteds**  Saves the predicted classifications to the data table in a column called *Naive Predicted <Y, Response>*.

**Save Prediction Formula**  Saves a column called *Naive Predicted Formula <Y, Response>* to the data table. This column contains the prediction formula for the classifications.

**Save Probability Formula**  Saves columns to the data table that contain formulas used for classifying each observation. Three groups of columns are saved:

- **Naive Score <Class>, Sum**  For each column that represents a class, this column gives a score formula that measures strength of membership in the given class. In the Naive Score Sum column, these scores are summed across classes. See “Saved Probability Formulas” on page 153.

- **Naive Prob <Class>**  For each class, this column gives a formula for the conditional probability that an observation is in that class. See “Saved Probability Formulas” on page 153.

- **Naive Predicted Formula <Y, Response>**  Gives the formula for the predicted class.

**Publish Probability Formula**  Creates probability formulas and saves them as formula column scripts in the Formula Depot platform. If a Formula Depot report is not open, this option opens the Formula Depot window. See the “Formula Depot” chapter on page 213.

**Profiler**  Shows or hides an interactive profiler report. Changes in the factor values are reflected in the estimated classification probabilities. See *Profilers*.

See *Using JMP* for more information about the following options:

**Local Data Filter**  Shows or hides the local data filter that enables you to filter the data used in a specific report.

**Redo**  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

**Save Script**  Contains options that enable you to save a script that reproduces the report to several destinations.

**Save By-Group Script**  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.
Additional Example of Naive Bayes

You have historical financial data for 5,960 customers who applied for home equity loans. Each customer was classified as being a Good Risk or Bad Risk. There is missing data on most of the predictors. You want to construct a model to use in classifying the credit risk of future customers.

1. Select Help > Sample Data Library and open Equity.jmp.
2. Select Analyze > Predictive Modeling > Naive Bayes.
   One of the potential predictors, DEBTINC, has many missing values that might be informative. However, naive Bayes is not prepared to handle large number of missing values well, so you do not include DEBTINC in your model.
4. Select LOAN through CLNO and click X, Factor.
5. Select Validation and click Validation.
6. Click OK.

Figure 8.8 Naive Bayes Report for BAD

The Training, Validation, and Test sets show misclassification rates between 18% and 19%. The confusion matrices for all of the sets suggest that the largest source of misclassification is the classification of Bad Risk customers as Good Risk customers.

You are interested in the probabilities that customers with certain financial background values are classified as High Risk.

7. Click the Naive Bayes red triangle and select Save Probability Formulas.
   Three sets of columns are added to the data table.
   - The three Naive Score columns contain naive score formulas for Good Risk, Bad Risk, and the sum of both.
   - The two Naive Prob columns contain probability formulas for Good Risk and Bad Risk.
– The Naive Predicted Formula Bad column contains a formula that assigns an observation to the class for which the observation has the highest naive probability. Use these formulas to score new customers. For more information about the formula columns, see “Saved Probability Formulas” on page 153.

### Statistical Details for the Naive Bayes Platform

- “Algorithm”
- “Saved Probability Formulas”

### Algorithm

The naive Bayes method classifies an observation into the class for which its probability of membership, given the values of its features, is highest. The method assumes that the features are conditionally independent within each class.

Denote the possible classifications by $C_1, \ldots, C_K$. Denote the features, or predictors, by $X_1, X_2, \ldots, X_p$.

The conditional probability that an observation with predictor values $x_1, x_2, \ldots, x_p$ belongs in the class $C_k$ is computed as follows:

$$
P(C_k|(x_1, \ldots, x_p)) = \frac{\left( P(C_k) \prod_{j=1}^{p} [P(x_j|C_k)] \right) / (R)}{\sum_{k=1}^{K} \left( P(C_k) \prod_{j=1}^{p} [P(x_j|C_k)] / R \right)},
$$

where $R$ is a regularization constant. In the formula above, the conditional probability that an observation with $X_j = x_j$ belongs to the class $C_k$, $P(x_j|C_k)$, is determined as follows:

- If $X_j$ is categorical:
  \[
P(x_j|C_k) = \frac{\text{# of observations in } x_j|C_k}{\text{# of observations in } C_k}
\]
- If $X_j$ is continuous:
  \[
P(x_j|C_k) = \frac{1}{s_{jk}} \phi((x_j - m_{jk})/s_{jk})
\]
Here, $\phi$ is the standard normal density function, and $m$ and $s$ are the mean and standard deviation, respectively, of the predictor values within the class $C_k$.

The unconditional probability that an observation belongs in class $C_k$, $P(C_k)$, is computed as follows:

$$P(C_k) = \frac{\text{# of observations in } C_k + (0.5/K)}{\text{Total # of observations} + 0.5}$$

An observation is classified into the class for which its conditional probability is the largest.

**Note:** In the formula for $P(C_k)$, 0.5 is the prior bias factor. This value is the default value. To change the prior default factor, go to File > Preferences > Platforms > Naive Bayes, select the Prior Bias check box and change the value.

### Saved Probability Formulas

This section describes the formulas saved using the Save Probability Formula option. The conditional probability that an observation with predictor values $x_1, x_2, \ldots, x_p$ belongs in the class $C_k$ differs slightly from that given by $P(C_k | (x_1, \ldots, x_p))$, shown in the section “Algorithm” on page 152. This is done for computational efficiency.

### Naive Score Formulas

The Naive Score formula for a given class $C_k$, $S(C_k)$, is a variation of the numerator in the expression for $P(C_k | (x_1, \ldots, x_p))$ and is computed as follows:

$$S(C_k) = \exp \left( \sum_{j=1}^{p} \ln(1/s_{jk}) + P(C_k) + \sum_{j=1}^{p} \text{Normal Log Density} \left( \frac{x_j - m_{jk}}{s_{jk}} \right) - \ln(R) \right)$$

### Naive Score Sum Formulas

The Naive Score Sum formula, $S$, sums the Naive Score formulas over all classes. This is a variation of the denominator in the expression for $P(C_k | (x_1, \ldots, x_p))$.

$$S = \sum_{k=1}^{K} S(C_k)$$
Naive Prob Formulas

The Naive Prob formula for a given class $C_k$ equals $P(C_k|x_1, ..., x_p)$. In the JMP formulas,

$$P(C_k|x_1, ..., x_p) = \frac{S(C_k)}{S}$$

Naive Predicted Formula

The Naive Predicted Formula for an observation classifies that observation into the class for which $P(C_k|x_1, ..., x_p)$ is the largest. This is equivalent to classifying an observation into the class for which its Naive Score formula is the largest.
The Support Vector Machines platform is available only in JMP Pro.

In JMP Pro, the Support Vector Machines (SVM) platform provides a machine learning tool for both nonlinear regression and classification. The SVM algorithm is a supervised learning algorithm that uses the training data to build a model to predict or classify new observations.

If you have a categorical response, you can visualize the model classification in the Response Profile Plot. The SVM platform also provides misclassification rates, confusion matrices, and ROC and Lift curves to help you determine how well your model fits the data. If you have a continuous response, fit statistics and actual by predicted plots are used to determine how well the model fits the data.

Overview of Support Vector Machines

A support vector machine (SVM) model is a supervised learning algorithm that is used to predict or classify new observations. A model is fit on a set of training data where the responses are known. Then, the model is used to predict the responses of new observations.

When the response is categorical, SVM models classify data by optimizing a hyperplane that separates the classes. This can also be viewed as finding the hyperplane that maximizes the margin between the classes. In simple problems, this hyperplane is linear. However, more complicated data often cannot be separated linearly. For these scenarios, the SVM platform provides the option to use a radial basis function kernel to map the points to a nonlinear dimension that can make the classes easier to separate.

When the response is continuous, the models that are fit are known as support vector regression (SVR) models. In a typical regression problem, the goal is to fit a model that minimizes the error between a predicted response and the actual response. In an SVR problem, the goal is to fit a model such that the error between a predicted response and the actual response falls within a range of \( -\varepsilon \) to \( \varepsilon \). This provides a more flexible fit. In JMP Pro, \( \varepsilon \) is equal to 0.1. The SVR algorithm doubles the data by creating two classes, \( Y + \varepsilon \) and \( Y - \varepsilon \). Then the same algorithm that is used for the classification problem is also used for the prediction (SVR) problem.

The maximization in SVM algorithms is performed by solving a quadratic programming problem. In JMP Pro, the algorithm used by the SVM platform is based on the Sequential Minimal Optimization (SMO) algorithm introduced by John Platt in 1998. Typically, the SVM quadratic programming problem is very large. The SMO algorithm splits the overall quadratic programming problem into a series of smaller quadratic programming problems. Smaller quadratic programming problems are solved analytically instead of numerically, meaning they produce closed-form solutions. Therefore, the SMO algorithm is more efficient than solving the overall quadratic programming problem (Platt 1998).

Example of Support Vector Machines

You have baseline medical data for 442 diabetic patients. You also have a binary measure of diabetes disease progression obtained one year after each patient’s initial visit. This measure quantifies disease progression as either Low or High. You want to construct a classification model to predict the disease progression for future patients as High or Low. You explore both kernel function options.

1. Select Help > Sample Data Library and open Diabetes.jmp.
2. Select Analyze > Predictive Modeling > Support Vector Machines.
3. Select Y Binary and click **Y, Response**.
4. Select Age through Glucose and click **X, Factor**.
5. Select Validation and click **Validation**.
6. Click **OK**.
7. In the Model Launch control panel, check that the kernel function is a Radial Basis Function and select Tuning Design.
8. Enter 10 next to Number of Runs.
9. Click **Go**.
10. Click the gray triangle next to Model Launch to open the Model Launch control panel.
11. Change the kernel function to a Linear function and select Tuning Design.
12. Enter 10 next to Number of Runs.
13. Click **Go**.

</table>

The Model Comparison report shows that the best model in terms of misclassification rate and R-Square is Model 20. This model has a linear kernel function with cost parameter 0.04975. This is the model to further analyze.
The Model Summary report shows that the misclassification rates for the training and validation sets are very similar. This is a good indication that the model did not overfit the data. The confusion matrices provide more information about the types of observations that are misclassified by the model. In the confusion matrices, the upper left corner shows that the model correctly categorizes the Low responses most of the time (96% in training and 92.6% in validation). However, fewer of the High responses are correctly categorized (53% in training and 68.4% in validation). Therefore, most of the misclassifications are the High responses being misclassified as Low.
The Support Vector Machines Launch Window

Use the SVM launch window to specify your response and model factors. If used, validation and by columns are also specified in the launch windows.

Figure 9.4 Support Vector Machines Launch Window

For more information about the options in the Select Columns red triangle menu, see Using JMP.

The Support Vector Machines launch window provides the following options:

**Y, Response**  The response variable that you want to analyze.

**X, Factor**  The predictor variables.

**Freq**  A column whose numeric values assign a frequency to each row in the analysis.

**Validation**  A numeric column that defines the validation sets. See “Validation Method” on page 162. If you click the Validation button with no columns selected in the Select Columns list, you can add a validation column to your data table. For more information about the Make Validation Column utility, see the “Make Validation Column” chapter on page 201.

**By**  A column or columns whose levels define separate analyses. For each level of the specified column, the corresponding rows are analyzed using the other variables that you have specified. The results are presented in separate reports. If more than one By variable is assigned, a separate report is produced for each possible combination of the levels of the By variables.
Model Launch Control Panel

When you click OK in the launch window, the Support Vector Machine report window appears, showing a Model Launch control panel for fitting models. Use the Model Launch control panel to specify the kernel function and associated parameter values, as well as the validation method.

Figure 9.5 The Model Launch Control Panel

The Model Launch control panel contains the following options:

**Kernel Function** Specifies the kernel function used in the model. Choose from the following kernel functions:

- **Radial Basis Function** Selects the radial basis function kernel to create a nonlinear hyperplane to separate the classes.
  - The Cost parameter is the penalty associated with misclassifying an observation in the training set. A higher cost parameter implements an algorithm that is less likely to misclassify a point in the training set, whereas a lower cost parameter produces a wider margin. The Cost parameter must be greater than 0, and the default value is 1.
  - The Gamma parameter is the parameter in the kernel function. This parameter determines the amount of curvature there is to the decision line; a higher Gamma value indicates more curvature. A nonlinear decision line provides a more flexible fit, but too much curvature can lead to overfitting. The Gamma parameter must be greater than 0, and the default value is \(1/(\text{# of predictors})\).

- **Linear** Selects the linear kernel function to create a linear hyperplane to separate the classes.
  - The Cost parameter is the penalty associated with misclassifying an observation in the training set. A higher cost parameter implements an algorithm that is less likely to misclassify a point in the training set, whereas a lower cost parameter produces a wider margin. The Cost parameter must be greater than 0, and the default value is 1.
**Note:** If you specify parameter values that are out of range, the default values are used.

**Tip:** To find the best fitting model, fit a range of kernel functions and parameter values and use the Model Comparison report.

**Tuning Design** Enables you to fit a range of parameter values for the specified kernel. The models with the largest RSquare and the smallest Misclassification Rate or RASE are identified in the Model Comparison report. After you select Tuning Design, you must specify minimum and maximum values for the parameters. Default values are provided based on the data and the minimum must be greater than zero. You must also specify a value for the Number of Runs. The SVM platform fits that many models over a grid of parameter values determined by the minimum and maximum values.

**Validation Method** Specifies the model validation method. When you click the Go button for the first time, the first SVM model is fit using the specified validation method. This Validation Method is then used for all SVM models fit from within the SVM window. This ensures that all models in the report window are fit using the same validation method and validation set.

**Holdback** Randomly divides the original data into training and validation sets. You can specify the proportion of the original data to use as the validation set (holdback).

**KFold** (Available only when Y is continuous or nominal.) Randomly divides the original data into K subsets. In turn, each of the K sets is used to validate the model fit on the rest of the data, fitting a total of K models. If Y is continuous, the model that has the best validation RASE statistic is chosen as the final model. If Y is nominal, the model that has the best validation misclassification rate is chosen as the final model.

**Validation Column** (Available only if you specified a Validation column in the launch window.) Uses the values in the specified Validation column to divide the data into parts. The column’s values determine how the data are split, and what method is used for validation:

- If there are two values, the smaller value defines the training set and the larger value defines the validation set.
- If there are three values, these values define the training, validation, and test sets in order of increasing size.
If the validation column has more than three levels, then Validation Column K Fold is used.

The SVM platforms uses the validation column to train and evaluate the model, unless a Tuning Design is used. If the Tuning Design option is selected, the SVM platform uses the validation column to train and tune the model or to train, tune, and evaluate the model. For more information about validation, see “Validation in JMP Modeling” on page 541 in the “Statistical Details” appendix.

Note: If the validation column does not lead to a valid partition of the data, the Holdback validation method is used instead.

Validation Column K Fold (Available only when the Y, Response column has exactly two levels and a Validation column is specified in the launch window.) Uses the values in the specified Validation column to divide the data into $K$ sets, where $K$ is the number of unique values in the column. Then, K-Fold validation is performed.

None No validation used.

Go Fits the specified SVM model and shows the model report.

Note: If you have a large data table, a progress bar is shown for each model that is fit to the data. The total number of models fit is $k!/2(k-2)!$, where $k$ is the number of levels of the response variable. Each progress bar has an Accept Current Estimates button. Click this button if you want to stop the fitting algorithm early and accept the current estimates. Because prediction calculations are performed after you click this button, it may take some time for the report to appear.

The Support Vector Machine Report

When you click Go in the Model Launch control panel, a Model Comparison report appears above the control panel and a model report appears below the control panel. The model reports are numbered sequentially. Each time a new model is fit, it is added to the Model Comparison report and a new model report is added to the window. See “Model Comparison Report” on page 164 and “Support Vector Machine Model Report” on page 165. Click on the column headings to sort the models by any of the columns in the Model Comparison report. The first click sorts in ascending order; click the column heading a second time to sort in descending order.
Model Comparison Report

The Model Comparison Report contains the following information:

**Show**  A check box that indicates whether the Support Vector Machine Model report for the corresponding fit should appear in the report window.

**Method**  The model number.

**Kernel Function**  The kernel function for the corresponding model.

**Cost**  The value of the cost parameter for the corresponding model.

**Gamma**  The value of the gamma parameter for the corresponding model. If the model uses a linear kernel, this value is missing.

**# SV**  The number of support vectors used in the corresponding model.

**Training Misclassification Rate**  (Appears only if the response is categorical.) The misclassification rate for the observations in the training set. This rate is based on the classification decision rule that is calculated by the platform.

**Validation Misclassification Rate**  (Appears only if the response is categorical and validation is used.) The misclassification rate for the observations in the validation set. This rate is based on the classification decision rule that is calculated by the platform.

**Test Misclassification Rate**  (Appears only if the response is categorical and a test set is specified using a validation column.) The misclassification rate for the observations in the test set. This rate is based on the classification decision rule that is calculated by the platform.

**Training RASE**  (Appears only if the response is continuous.) The square root of the mean squared prediction error (Root Average Square Error) for the observations in the training set. See “RASE” on page 166.

**Validation RASE**  (Appears only if the response is continuous and validation is used.) The square root of the mean squared prediction error (Root Average Square Error) for the observations in the validation set. See “RASE” on page 166.

**Test RASE**  (Appears only if the response is continuous and a test set is specified using a validation column.) The square root of the mean squared prediction error (Root Average Square Error) for the observations in the test set. See “RASE” on page 166.

**Validation Generalized RSquare**  (Appears only if validation is used.) The Generalized RSquare value for observations in the validation set. See “Fit Details” on page 166.

**Probability Threshold**  (Appears only if the response is binary and validation is used.) The cutoff probability determined by the classification decision rule that is calculated by the
platform. An observation is classified into the target level when its predicted probability exceeds this value.

**Tip:** You can change this value by using the Set Probability Threshold option in the Confusion Matrix report. See “Confusion Matrix” on page 167.

**Conditional Validation Misclassification Rate**  (Appears only if the response is binary and validation is used.) The misclassification rate for the observations in the validation set, conditioned on the probability threshold value.

**Best**  Indicates which model fit has the smallest misclassification rate. If validation is used without a test set, this is the model with the smallest validation misclassification rate. If validation is used with a test set, this is the model with the smallest test misclassification rate.

**Model Comparison Plot**

Shows a contour plot of the model performance of the validation set over the grid of parameter values. This report is available only if Tuning Design is specified in the Model Launch Control Panel.

**Support Vector Machine Model Report**

**Response Profile Plot**  (Available only when the response is categorical.) Gives a visual representation of the classification model. The points on the plot are the actual data observations and are on by default only when there are exactly two continuous variables. For the two variables plotted, the shaded contours represent a plane of the prediction space determined by fixed values of the remaining model factors. The predictions are based on the classification decision rule that is calculated by the platform. Controls for the fixed values are located above the plot. When you change the fixed values of the factors, using either the slider or number box, the prediction space for the plotted variables is automatically updated. You can also change the axes of the plot to display any continuous factor using the red triangles on each axis.

The Response Profile Plot red triangle menu contains the following options:

**Grid Density**  Determines the fineness of the prediction grid underlying the shaded contours. A higher grid density provides a smoother decision line.

**Show Points**  Shows or hides the points on the plot. On by default when there are only two variables.

**Model Summary**  Gives the name of the response column, the validation method, and the type of kernel function used in the model fit. The Model Summary table also contains information about the model fit for the training, validation, and test sets. The number of
observations and the number of support vectors are reported for each set. If the response is
categorical, the misclassification rate is reported for each set. The misclassification rate is
the proportion of observations misclassified by the model. This is calculated as the number
of misclassifications divided by the total number of observations. If the response is
continuous, the RASE and R Square values are reported for each set.

**Estimation Details**  Gives the values of the parameters used in the model.

**Fit Details**  (Available only if the response is categorical.) Gives the following statistics for the
training set, and for the validation and test sets if they are specified:

- **Entropy RSquare**  A measure of fit that compares the log-likelihoods from the fitted
  model and the constant probability model. Entropy RSquare ranges from 0 to 1, where
  values closer to 1 indicate a better fit. See “Entropy RSquare” on page 541 in the
  “Statistical Details” chapter.

- **Generalized RSquare**  A measure that can be applied to general regression models. It is
  based on the likelihood function L and is scaled to have a maximum value of 1. The
  Generalized RSquare measure simplifies to the traditional RSquare for continuous
  normal responses in the standard least squares setting. Generalized RSquare is also
  known as the Nagelkerke or Craig and Uhler $R^2$, which is a normalized version of Cox
  and Snell’s pseudo $R^2$. See Nagelkerke (1991). Values closer to 1 indicate a better fit.

- **Mean -Log p**  The average of $-\log(p)$, where $p$ is the fitted probability associated with the
  event that occurred. Smaller values indicate a better fit.

- **RASE**  The square root of the mean squared prediction error (Root Average Square Error). RASE is computed as follows, where *Source* indicates the Training, Validation, or Test
  set.

  \[
  \text{RASE}_{\text{Source}} = \sqrt{\frac{\text{SSE}_{\text{Source}}}{n}}
  \]

- **Mean Abs Dev**  The average of the absolute values of the differences between the
  response and the predicted response. The differences are between 1 and $p$, the fitted
  probability for the response level that actually occurred. Smaller values indicate a
  better fit.

- **Misclassification Rate**  The rate for which the response category with the highest fitted
  probability is not the observed category.

**Note:** The misclassification rates in the Fit Details report might not match the
misclassification rates in the Confusion Matrix report. When the response is binary, the
rates in the Fit Details report use a probability cutoff of 0.5, but the rates in the
Confusion Matrix report use the probability threshold value as the cutoff.
N  The number of observations.

Confusion Matrix   (Available only if the response is categorical.) A confusion matrix is shown for each set (training, validation, and test) specified in the model. A confusion matrix is a two-way classification of actual and predicted responses. Use the confusion matrices and the misclassification rates to evaluate your model.

The confusion matrices and the misclassification rates use the value in the probability threshold box as the cutoff value. By default, this value is based on the classification decision rule that is calculated by the platform. You can change the cutoff value by dragging the slider or entering a new value in the box next to Probability Threshold. If you change the probability threshold, the confusion matrices and misclassification rates automatically update. The probability threshold and conditional validation misclassification rate columns in the Model Comparison report are also updated.

Actual by Predicted Plot   (Available only if the response is continuous.) Plots the actual response versus the predicted response. The diagonal line is the Y = X line. The closer the points are to this line, the better the model fits the data. When validation is used, plots are shown for the training, validation, and, if specified, test sets.

Support Vector Machines Platform Options

See Using JMP for more information about the following options:

Local Data Filter   Shows or hides the local data filter that enables you to filter the data used in a specific report.

Redo   Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

Save Script   Contains options that enable you to save a script that reproduces the report to several destinations.

Save By-Group Script   Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.

Support Vector Machine Model Report Options

Each Support Vector Machine Model report contains the following options:

Response Profile Plot   (Available only if the response is categorical.) Shows or hides the Response Profile Plot.
Support Vector Coefficients  Shows or hides the table of support vector coefficients. Select rows in the table to highlight the support vectors in the original data table and the Response Profile Plot.

Confusion Matrix  (Available only if the response is categorical.) Shows or hides the confusion matrix. See “Confusion Matrix” on page 167.

ROC Curve  (Available only if the response is categorical.) Shows or hides the ROC Curve. If you use validation, ROC Curves for the validation and, if specified, test sets appear in addition to the curve for the training set. For more information, see “ROC Curve” on page 72 in the “Partition Models” chapter.

Lift Curve  (Available only if the response is categorical.) Shows or hides the Lift Curve. If you use validation, Lift Curves for the validation and, if specified, test sets appear in addition to the curve for the training set. For more information, see “Lift Curve” on page 73 in the “Partition Models” chapter.

Plot Actual by Predicted  (Available only if the response is continuous.) Shows or hides a plot of the actual values versus the predicted values.

Plot Residual by Predicted  (Available only if the response is continuous.) Show or hides a plot of the residuals versus the predicted values.

Profiler  Shows or hides the Prediction Profiler. Each response level is represented by a separate row in the Prediction Profiler. For more information about the options in the red triangle menu, see Profilers.

Contour Profiler  (Available only when the model contains more than one continuous factor.) Shows or hides the Contour Profiler. For more information about the options in the red triangle menu, see Profilers.

Surface Profiler  (Available only when the model contains at least one continuous factor.) Shows or hides a surface profiler. For more information about the options in the red triangle menu, see Profilers.

Save Predicteds  Saves the predicted classifications based on the threshold probability cutoff value to the data table in a column called Predicted <Y, Response>.

Save Prediction Formula  Saves the prediction formulas based on the threshold probability cutoff value to the data table. If the response is binary, a single prediction formula column is added to the data table. If the response has more than two levels, a prediction formula column is added to the data table for each pairwise model, in addition to a formula column for the final prediction.

Publish Prediction Formula  Creates probability formulas based on the threshold probability cutoff value and saves them as formula column scripts in the Formula Depot platform. If a
Formula Depot report is not open, this option opens the Formula Depot window. See the “Formula Depot” chapter on page 213.

**Save Probabilities** Saves the probability of each response level as a separate column in the data table, as well as a column called Most Likely \(<Y, \text{Response}\>\).

**Save Probability Formula** (Available only if the response is binary.) Saves the following formula columns to the data table:

- **Decision Value** A hidden column that contains the formula for the decision value.
- **Probability** Two probability formula columns, one for each level of the binary response.
- **Most Likely** The predicted classification based on which probability value is higher.
- **Threshold Predicted** The predicted classification based on the threshold probability cutoff value obtained from the confusion matrix. By default, this value is based on the classification decision rule that is calculated by the platform. If the threshold value is changed to 0.5, the Threshold Predicted column is not saved to the data table because it would be equivalent to the Most Likely column.

**Publish Probability Formula** (Available only if the response is binary.) Creates probability formulas and saves them as formula column scripts in the Formula Depot platform. If a Formula Depot report is not open, this option opens the Formula Depot window. See the “Formula Depot” chapter on page 213.

**Save Validation** (Available only when the Holdback or KFold validation methods are used.) Creates a new column in the data table that identifies which rows were used in the training and validation sets.

**Remove Fit** Removes the entire model report.

---

**Additional Example of the SVM Platform**

**Example of Support Vector Regression for Continuous Response**

Support vector regression (SVR) models use the SVM algorithm to predict continuous response data. This example uses the same medical data on diabetic patients that was used in “Example of Support Vector Machines” on page 157. Instead of a binary measure of diabetes disease progression, you now have a continuous measure. Higher values correspond to more disease progression. Vary the cost parameter of the radial basis function to find the best fitting model.

1. Select **Help > Sample Data Library** and open Diabetes.jmp.
2. Select **Analyze > Predictive Modeling > Support Vector Machines.**
3. Select **Y** and click **Y, Response.**
4. Select **Age** through **Glucose** and click **X, Factor.**
5. Select **Validation** and click **Validation.**
6. Click **OK.**
7. In the Model Launch control panel, check that the kernel function is a Radial Basis Function with Cost parameter 1 and Gamma parameter 0.1.
8. Click **Go.**
9. Click the gray triangle next to Model Launch to open the Model Launch control panel.
10. Change the cost parameter to 0.1.
11. Click **Go.**
12. Click the gray triangle next to Model Launch to open the Model Launch control panel.
13. Change the cost parameter to 2.
14. Click **Go.**

The Model Comparison report contains the results of the models using different cost parameters. Recall that a higher cost parameter implements an algorithm that is less likely to misclassify a point, whereas a lower cost parameter implements a more flexible algorithm. In this scenario, the more flexible model (cost parameter equal to 0.1) produces the best model fit.

15. In the Show column of the Model Comparison report, deselect Model 1 and Model 3.
The model report for a continuous response contains the Model Summary, Estimation Details, and Actual by Predicted Plot. In the Model Summary report, the RASE is 52.58 for the training set and 57.50 for the validation set.
Support Vector Machines
Additional Example of the SVM Platform

Chapter 9
Predictive and Specialized Modeling
The Model Screening platform is available only in JMP Pro.

The Model Screening platform in JMP Pro enables you to run multiple predictive modeling platforms from one launch window and assemble summaries from the different methods. This helps you pick the best performing model without launching each individual model platform. You can also easily launch an individual platform report for any of the models from the Model Screening report window for further refinement.

**Figure 10.1** Model Screening Report
## Contents

- Example of Model Screening for Continuous Response ........................................... 175
- Launch the Model Screening Platform ........................................................................ 177
- The Model Screening Report ....................................................................................... 180
  - Summary Across the Folds Report .............................................................................. 181
  - Training, Validation, and Test Measures of Fit ......................................................... 182
- Model Screening Platform Options ............................................................................. 183
- Decision Thresholds Report .......................................................................................... 185
Example of Model Screening for Continuous Response

You have baseline medical data for 442 diabetic patients. You also have a continuous measure of diabetes disease progression obtained one year after each patient’s initial visit. Higher values correspond to more disease progression. You want to assess various models for their ability to predict diabetes disease progression.

1. Select Help > Sample Data Library and open Diabetes.jmp.
2. Select Analyze > Predictive Modeling > Model Screening.
4. Select Age through Glucose and click X, Factor.
5. In the Folded Crossvalidation section, select the box next to K Fold Crossvalidation.
6. (Optional) In the Options section, type 42920 next to Set Random Seed.
   Use the random seed in order to match the example output.
7. Click OK.
8. Click the red triangle next to Model Screening for Y and select Optional Reports > Elapsed Time.
The best performing model based on the Validation RSquare averaged across the folds, is Neural Boosted. The average Validation RSquare for Neural Boosted is 0.5503. The Elapsed Time report shows that the Neural Boosted models also took the longest to fit. In this case, the elapsed time was only 5 seconds, but this information could be important for larger data sets or more complex models.

**Tip:** To see performance metrics for the individual models, click the gray disclosure icon next to Validation.
Launch the Model Screening Platform

To launch the Model Screening platform, select **Analyze > Predictive Modeling > Model Screening**.

**Figure 10.3** The Model Screening Launch Window

For more information about the options in the Select Columns red triangle menu, see *Using JMP*.

**Y, Response**  The response variable or variables that you want to analyze.

**X, Factor**  The predictor variables.

**Weight**  (Not applicable to the K Nearest Neighbors, Support Vector Machines, or Neural modeling platforms.) A column whose numeric values assign a weight to each row in the analysis.
Launch the Model Screening Platform

Predictive and Specialized Modeling

**Freq**  (Not applicable to the K Nearest Neighbors modeling platform.) A column whose numeric values assign a frequency to each row in the analysis.

**Validation**  (Not applicable if any of the Crossvalidation options are selected in the launch window.) A numeric column that defines the validation sets. If you click the Validation button with no columns selected in the Select Columns list, you can add a validation column to your data table. For more information about the Make Validation Column utility, see the “Make Validation Column” chapter on page 201.

**Note:** If you specify a validation column with more than three levels, this column is used to perform K Fold crossvalidation.

**By**  A column or columns whose levels define separate analyses. For each level of the specified column, the corresponding rows are analyzed using the other variables that you have specified. The results are presented in separate reports. If more than one By variable is assigned, a separate report is produced for each possible combination of the levels of the By variables.

**Methods**  Enables you to select the desired modeling platforms. By default, the modeling platforms that are fit are Decision Tree (Partition), Bootstrap Forest, Boosted Tree, K Nearest Neighbors, Neural, Support Vector Machines, Discriminant, Fit Least Squares, Fit Stepwise, Logistic Regression, and Generalized Regression. Naive Bayes, Partial Least Squares, and XGBoost are also available.

**Notes:**
- XGBoost is not supported by JMP and is available only if the XGBoost add-in is installed. For more information about XGBoost, see https://community.jmp.com.
- Decision Tree (Partition), Discriminant, and Partial Least Squares all require some type of validation set in order to fit a model.
- If there are fewer than 20 observations in a validation set, a Decision Tree (Partition) model cannot be fit.
- The modeling platforms use default options in model fitting. You can try to improve the fit past what the default yields by calling platforms directly and choosing different options.

**Options**

Provides additional options.

**Remove Live Reports**  Does not include the individual model platform reports in the Model Screening report window.
Tip: Select this option to free up memory when you have a large problem with many methods and fits.

Log Methods  Writes out a progress message to the log each time a fitting platform is called.

Time Limit Each  Specifies a time limit, in seconds, for each fit. For platforms that support early stopping, the best estimates up to that point are provided. For platforms that do not support early stopping, no result is provided.

Set Random Seed  Sets a random seed that is used for any random components of the model fit routines. This enables you to rerun the platform and obtain the same model fits.

Folded Crossvalidation

Provides options for various types of crossvalidation.

K Fold Crossvalidation  Divides the data randomly into $K$ parts or folds. Each model is fit to the data $K$ times, each time with a different fold held out as a crossvalidation set. A total of $K$ models are fit. The default value of $K$ is 5.

- $K$ specifies the number of folds for K Fold Crossvalidation. The default is 5 and $K$ must be greater than 1.

Nested Crossvalidation  Divides the data into nested folds for crossvalidation. First, the data are divided into $k = 1, \ldots, K$ equals parts, or folds. For each fold, the $k^{th}$ fold is used as a test set and the remaining data are divided further into $L$ equal parts. These $L$ subdivisions are called inner folds. Then, a model is fit to the data $L$ times with a different inner fold held out each time as a crossvalidation set. The $L$ models then use the $k^{th}$ fold as a common test data set. In all, a total of $K \times L$ models are fit. The default value of $K$ is 4 and the default value of $L$ is 5.

For example, set $K = 2$ and $L = 3$. The data are initially divided into two folds. The first fold is held out as a test set and the second fold is divided into 3 inner folds. Three models are fit to the data, each time with a different inner fold held out as a crossvalidation set. Then, all three models are tested on the first fold.

The second fold is then held out as a test set and the first fold is divided into 3 inner folds. Three models are fit to the data, each time with a different inner fold held out as a crossvalidation set. Then, all three models are tested on the second fold.

- $K$ specifies the number of folds for Nested Crossvalidation. The default is 4 and $K$ must be greater than 1.
- $L$ specifies the number of inner folds for Nested Crossvalidation. The default is 5 and $L$ must be greater than 1.
Note: If both K Fold Crossvalidation and Nested Crossvalidation are selected, Nested Crossvalidation is performed.

Repeated K Fold  Specifies the number of times the K Fold Crossvalidation or Nested Crossvalidation process is repeated.

Modeling Options

Provides additional options for the modeling platforms.

Add Two Way Interactions  Adds all two way interaction effects to linear models.

Add Quadratics  Adds effects for the squares of continuous variables to linear models.

Informative Missing  Enables informative missing for all platforms.

Additional Methods  Calls several additional methods, such as Ridge, Elastic Net and Lasso, in the Generalized Regression platform. See the “Generalized Regression Models” chapter on page 283.

Caution: This results in additional model fits.

When you click OK, the specified models are fit and a set of progress bars are shown. The upper progress bar reports the progress across all fits. The lower progress bar reports the progress for the current individual model fit. You can stop the lower progress bar to employ early stopping and the upper progress bar will continue to run.

The Model Screening Report

The content of the Model Screening report depends on both the type of crossvalidation implemented and the modeling type of the response variable. At the top of the Model Screening report, the name of the data table and column name of the response variable are shown. If a validation column is specified, the name of that column is also shown.

By default, the Details report appears next. This report contains the individual model reports for all of the models for each fold and trial. These reports are the actual output from each platform and contain all reports and command features. For example, if you decide on a model that is best, you can go to the corresponding platform report in the Details report and save the desired prediction formula column. You can hide the Details report by selecting the Remove Live Reports option in the launch window.

If either the K Fold Crossvalidation option or the Nested Crossvalidation option is specified in the launch window, the Summary Across the Folds report appears. This report is a summary of the measures of fit averaged across the test folds.
Measures of fit are shown for each individual model fit, for the training, validation, and test sets if applicable. If crossvalidation is used by specifying a validation column in the launch window, only the individual model fit measures of fit are shown in the report.

**Summary Across the Folds Report**

The Summary Across the Folds report contains a summary of the measures of fit across the folds, as well as across the trials if Repeated K Fold is specified. If the K Fold Crossvalidation option is specified, the measures of fit are summarized across the validation sets. If the Nested K Fold Crossvalidation option is specified, the measures of fit are summarized across the test sets. The report contains a table with the following columns:

- **Method**: The name of the method used to fit the model.
- **N Trials Folds**: The total number of models that were fit across all folds and trials, if applicable.
- **Sum Freq**: The average number of observations in the validation or test sets. The test sets are used to estimate model performance.
- **RSquare**: The mean RSquare across all validation or test set folds. This column contains the Entropy RSquare when the response is categorical.
- **Mean RASE**: The mean RASE (Root Average Square Error) across all validation or test set folds.
- **StdDev RASE**: The standard deviation of the RASE across all validation or test sets.
- **Mean AUC**: (Available only for categorical responses.) The mean area under the ROC curve (AUC) across all validation or test sets.
- **Mean MR**: (Available only for categorical responses.) The mean misclassification rate (MR) across all validation or test sets.

The following options are available below the table:

- **Select Dominant**: Selects each model that is better than or equal to all of the other models in terms of a combination of model fitting criteria. This is also referred to as selecting the Pareto Frontier. For continuous responses, RSquare and Sum Freq are considered when determining the dominant model. For categorical responses, Entropy RSquare, Misclassification Rate, AUC, and Sum Freq are considered when determining the dominant model.

- **Run Selected**: Runs the individual model for each selected row. When you click Run Selected, you are prompted to select a validation column for each selected row. This specifies the validation sets that are used to fit the models.
Save Script Selected  Saves a model script to the script window for each selected row. When you click Save Script Selected, you are prompted to select a validation column for each selected row. This specifies the validation sets that are saved in the scripts.

Training, Validation, and Test Measures of Fit

There is a measures of fit report for each model data set that is specified. These could be Training, Training and Validation, or Training, Validation, and Test sets. Each report contains a table with the following columns:

**Method**  The name of the method used to fit the model.

**N**  The number of observations in the set.

**Sum Wgt**  The sum of the weights.

**RSquare**  (Available only for continuous responses.) The RSquare value of the fitted model.

**Entropy RSquare**  (Available only for categorical responses.) A measure of fit that compares the log-likelihoods from the fitted model and the constant probability model. Entropy RSquare ranges from 0 to 1, where values closer to 1 indicate a better fit. See “Entropy RSquare” on page 541 in the “Statistical Details” chapter.

**Misclassification Rate**  (Available only for categorical responses.) The proportion of observations misclassified by the model. Smaller values indicate a better fit.

**Note:** In these tables, the misclassification rate is always calculated using a probability threshold of 0.5.

**AUC**  (Available only for categorical responses.) The area under the ROC curve. Values closer to 1 indicate a better fit.

**RASE**  The square root of the mean squared prediction error (Root Average Square Error). RASE is computed as follows, where Source indicates the Training, Validation, or Test set.

\[
\text{RASE}_{Source} = \sqrt{\frac{\text{SSE}_{Source}}{n}}
\]

**Generalized RSquare**  (Available only for categorical responses.) A measure that can be applied to general regression models. It is based on the likelihood function \(L\) and is scaled to have a maximum value of 1. The value is 1 for a perfect model, and 0 for a model no better than a constant model. The Generalized RSquare measure simplifies to the traditional RSquare for continuous normal responses in the standard least squares setting. Generalized RSquare is also known as the Nagelkerke or Craig and Uhler \(R^2\), which is a normalized version of Cox and Snell’s pseudo \(R^2\). See Nagelkerke (1991).
Fold (Available only if the K Fold Crossvalidation option or the Nested Crossvalidation option is specified in the launch window.) Identifies the fold that is held out for the model fit in that row.

Inner Fold (Available only if the Nested Crossvalidation option is specified in the launch window.) Identifies the inner fold that is held out for the model fit in that row.

Trial (Available only if the Repeated K Fold option is specified in the launch window.) Identifies the trial number for the model fit in that row.

The following options are available below each table:

Select Dominant Selects each model that is better than or equal to all of the other models in terms of a combination of model fitting criteria. For continuous responses, RSquare and Sum Freq are considered when determining the dominant model. For categorical responses, Entropy RSquare, Misclassification Rate, AUC, and Sum Freq are considered when determining the dominant model.

Run Selected Runs the individual model for each selected row.

**Caution:** If any form of K Fold Crossvalidation is specified, Run Selected runs the selected models on the training and validation sets that are determined by the last fold.

Save Script Selected Saves a model script to the script window for each selected row.

**Caution:** If any form of K Fold Crossvalidation is specified, Save Script Selected saves the script for the selected models on the training and validation sets that are determined by the last fold.

### Model Screening Platform Options

**Plot Actual by Predicted** (Available only for continuous responses.) Shows or hides a report of plots that overlay the actual by predicted points from all of the model fits. There are separate plots for the Training, Validation, and Test sets. The report contains a Methods legend with check boxes that enable you to specify which fits appear on the plots based on the method, fold, inner fold, and trial combination. Click the Deselect All button at the bottom of the legend to remove all model fits from the plots.

**Notes:**

- If you select a subset of models from the Training, Validation, or Test reports and then select Plot Actual by Predicted, only the plots for the selected models are shown.
- The actual by predicted plots are not supported by all of the modeling platforms. A list of unsupported platforms is shown below the plots.
**ROC Curve**  (Available only for categorical responses.) Shows or hides a report of plots that overlay the ROC curves for all of the model fits. There are separate plots for the Training, Validation, and Test sets. The report contains two legends with check boxes that enable you to specify which fits appear on the plots. Click the Deselect All button at the bottom of the legend to remove all model fits from the plots. For more information about ROC Curves, see “ROC Curve” on page 72 in the “Partition Models” chapter.

**Notes:**
- If you select a subset of models from the Training, Validation, or Test reports and then select ROC Curves, only the plots for the selected models are shown.
- The ROC plots are not supported by all of the modeling platforms. A list of unsupported platforms is shown below the plots.

**Show Profit**  (Available only for binary categorical responses that have a Profit Matrix column property.) Shows or hides the expected profit for each model.

**Decision Threshold**  (Available only for binary categorical responses.) Shows or hides Decision Thresholds reports for the training, validation, and test sets, if specified. Each report contains a graph of the distribution of fitted probabilities for each model, confusion matrices for each model, and classification graphs to adjust thresholds and compare the model fits. See “Decision Thresholds Report” on page 185.

**Note:** If you select a subset of models from the Training, Validation, or Test reports and then select Decision Threshold, only the information for the selected models is shown.

**Save Results Table**  Saves the information in the Validation report to a new data table titled Model Screening Statistics Validation Set. If there is a test set, such as when the Nested Crossvalidation option is specified, the information in the Test report is also saved to a new data table titled Model Screening Statistics Test Set.

**Save KFold Results Table**  (Available only if a Crossvalidation option is specified in the launch window.) Saves the information in the Summary Across the Folds report to a new data table titled KFold Results.

**Optional Reports**  Shows a submenu of additional report options.

- **Elapsed Time**  Shows or hides a report that contains the total elapsed time that was spent fitting each type of model.

- **Cardinality of Predictors**  Shows or hides a report of the number of levels and how many parameters are used in the linear model fit for each categorical predictor.

See *Using JMP* for more information about the following options:

**Local Data Filter**  Shows or hides the local data filter that enables you to filter the data used in a specific report.
Redo  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

Save Script  Contains options that enable you to save a script that reproduces the report to several destinations.

Save By-Group Script  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.

Decision Thresholds Report

The Decision Thresholds report enables you to explore thresholds for binary classification models. There is a Decision Thresholds report for each model data set that is specified by the validation method. These could be Training, Training and Validation, or Training, Validation, and Test sets. Each Decision Thresholds report contains a graph of the distribution of fitted probabilities, a bar chart of classifications, and confusion matrices. All are organized by model fit, fold, trial, and class level. The report also contains a tabbed section on classification accuracy measures and an option to set the profit matrix. The report updates as you adjust the probability threshold.

Distribution of Fitted Probabilities

The distribution of fitted probabilities, or model scores, enables you to see how each individual model fit differentiates between the two classes. A vertical line on the graph represents the probability threshold, which determines the classification of each observation. By default, the probability threshold is 0.5. You can change the probability threshold by dragging the vertical line or by clicking the Probability Threshold value and entering a new value. This changes the probability threshold value across the whole Decision Thresholds report. The value of the probability threshold must be between 0 and 1.

Classification Counts

The bar chart of classifications shows the classification counts for each level of the response variable at the current threshold. Green bars represent correctly classified observations; red bars represent incorrectly classified observations.
Confusion Matrices

The confusion matrices, also known as contingency tables, show the two-way classification of actual and predicted responses for each individual model fit. Confusion rates matrices are shown as well. The rates are equal to the values in the confusion matrices divided by the row totals.

Classification Accuracy Measures

False Classification by Threshold  Shows a plot of the misclassification count by probability threshold and a plot of the misclassification rate by probability threshold. Each plot contains two curves for each individual model fit. The curves for the low response category are solid and the curves for the high response category are dashed. The curves intersect at the threshold that yields equal misclassification, counts or rates, of each response level. There is also a vertical line on each graph that represents the current probability threshold value. You can change the probability threshold value by dragging the vertical line. This changes the probability threshold value across the whole report.

False Classification by Portion  Shows a plot of the misclassification count or rate by the portion of the rank ordered scores. Each plot contains two curves for each individual model fit. The curves for the low response category are solid and the curves for the high response category are dashed.

True Classification by Threshold  Shows a plot of the true count by the probability threshold and a plot of the true rate by the probability threshold. Each plot contains two curves for each individual model fit. The curves for the low response category are dashed and those for the high response level are solid. The curves intersect at the threshold that yields equal correct classifications, counts or rates, for each response. There is also a vertical line on each graph that represents the current probability threshold value. You can change the probability threshold value by dragging the vertical line. This changes the probability threshold value across the whole report.

True Classification by Portion  Shows a plot of the true count or rate by the portion of the rank ordered scores. Each plot contains two curves for each individual model fit. The curves for the low response category are dashed and the curves for the high response category are solid.

Profit by Threshold  (Available only if a profit matrix is specified.)Shows a plot of the average profit by the probability threshold. There is a curve for each individual model fit and a vertical line that represents the current probability threshold value. The specified profit matrix is also shown next to the plot.

Metrics  Shows a table of classification accuracy metrics for each model. A legend is provided to describe how the metric in each column is calculated.
Set Profit Matrix

Enables you to assign costs to undesirable outcomes and profits to desirable outcomes. See “Specify Profit Matrix” on page 67 in the “Partition Models” chapter. If you change the probability threshold in the profit matrix window and click OK, the Decision Thresholds report is updated using that value as the probability threshold.
The Model Comparison platform is available only in JMP Pro.

The Model Comparison platform in JMP Pro lets you compare the predictive ability of different models. Measures of fit are provided for each model along with overlaid diagnostic plots.

Additional Example of Model Comparison ........................................... 198
Example of Model Comparison

This section provides an example of using the Model Comparison platform. The example uses demographic data to build a model for median home price. A regression model and a bootstrap forest model are compared.

Begin by selecting Help > Sample Data Library and opening Boston Housing.jmp.

Create a Validation Column

1. Select Analyze > Predictive Modeling > Make Validation Column.
2. Do not select any columns in the launch window.
   This indicates that the platform will create a simple random validation column
3. Click OK.
4. In the box next to New Column Name, type Create Validation.
5. In the box next to Random Seed, enter 1234.
6. Click Go.
   A new Validation column is created. The rows assigned a 0 are the training set. The rows assigned a 1 are the validation set.

Create the Regression Model and Save the Prediction Formula to a Column

1. Select Analyze > Fit Model.
2. Select mvalue and click Y.
3. Select crim through lstat and click Add.
4. Select Create Validation and click Validation.
5. Select Stepwise in the Personality list.
6. Click the Run button.
7. Select P-value Threshold from the Stopping Rule list.
8. Click the Go button.
9. Click the Run Model button.
10. To save the prediction formula to a column, click the Response red triangle and select **Save Columns > Prediction Formula**.

Create the Bootstrap Forest Model and Save the Prediction Formula to a Column

1. Select **Analyze > Predictive Modeling > Bootstrap Forest**.
2. Select mvalue and click **Y, Response**.
3. Select crim through lstat and click **X, Factor**.
4. Select Create Validation and click **Validation**.
5. Click **OK**.
6. Select the **Early Stopping** check box.
7. Select the **Multiple Fits over number of terms** check box.
8. Enter 617 in the box next to **Random Seed**.
9. Click **OK**.
Chapter 11
Predictive and Specialized Modeling

Model Comparison 193

Predictive and Specialized Modeling Example of Model Comparison

Figure 11.3 Bootstrap Forest Model

10. To save the prediction formula to a column, click the Bootstrap Forest red triangle and select **Save Columns > Save Prediction Formula**.

**Compare the Models**

1. Select **Analyze > Predictive Modeling > Model Comparison**.
2. Select the two prediction formula columns and click **Y, Predictors**.
3. Select **Create Validation** and click **Group**.

**Tip:** If a **Group** column is not specified, JMP automatically recognizes when the same validation column has been used for all predictors and prompts you to add it as a grouping variable.

4. Click **OK**.

**Figure 11.4 Model Comparison Report**

The rows in the training set were used to build the models, so the RSquare statistics for Create Validation = Training might be artificially inflated. In this case, the statistics are not representative of the models’ future predictive ability. This is especially true for the bootstrap forest model.
Compare the models using the statistics for Create Validation = Validation. In this case, the bootstrap forest model predicts better than the regression model.

5. Click the Model Comparison red triangle and select Profiler.

**Figure 11.5 Prediction Profiler for All Models**

The prediction profiler enables you to compare the impact of each factor in the different models. The profiler is especially interesting when comparing different types of models such as here where you have a regression model and a partition model.

Related Information

- *Fitting Linear Models*
- The "Partition Models" chapter on page 51

---

**Launch the Model Comparison Platform**

To launch the Model Comparison platform, select *Analyze > Predictive Modeling > Model Comparison.*

**Figure 11.6 The Model Comparison Launch Window**
For more information about the options in the Select Columns red triangle menu, see *Using JMP*.

**Y, Predictors**  The columns that contain the predictions for the models that you want to compare. They can be either formula columns or just data columns. Prediction formula columns created by JMP platforms have either the Predicting or Response Probability column property. If you specify a column that does not contain one of these properties, the platform prompts you to specify which column is being predicted by the specified Y column.

For a categorical response with \( k \) levels, most model fitting platforms save \( k \) columns to the data table, each predicting the probability for a level. All \( k \) columns need to be specified as **Y, Predictors**. For platforms that do not save \( k \) columns of probabilities, the column containing the predicted response level can be specified as a **Y, Predictors** column.

If you do not specify any **Y, Predictors** columns, JMP uses the prediction formula columns in the data table that have either the Predicting or Response Probability column property.

**Group**  The column that separates the data into groups, which are evaluated separately. If a **Group** column is not specified, JMP automatically recognizes when the same validation column has been used for all predictors and prompts you to add it as a grouping variable.

The other role buttons are common among JMP platforms. See *Using JMP*.

The Model Comparison Report

Figure 11.7 shows an example of the initial Model Comparison report for a continuous response.

**Figure 11.7** Initial Model Comparison Report

The Predictors report shows all responses and all models being compared for each response. The fitting platform that created the predictor column is also listed.

The Measures of Fit report shows measures of fit for each model. The columns are different for continuous and categorical responses.
Measures of Fit for Continuous Responses

**RSquare**  The $r$-squared statistic. In data tables that contain no missing values, the $r$-squared statistics in the Model Comparison report and original models match. However, if there are any missing values, the $r$-squared statistics differ.

**RASE**  The square root of the mean squared prediction error. This is computed as follows:

- Square and sum the prediction errors (differences between the actual responses and the predicted responses) to obtain the $SSE$.
- Denote the number of observations by $n$.
- RASE is:

\[
RASE = \sqrt{\frac{SSE}{n}}
\]

**AAE**  The average absolute error.

**Freq**  The column that contains frequency counts for each row.

Measures of Fit for Categorical Responses

**Entropy RSquare**  One minus the ratio of the negative log-likelihoods from the fitted model and the constant probability model. It ranges from 0 to 1.

**Generalized RSquare**  A measure that can be applied to general regression models. It is based on the likelihood function $L$ and is scaled to have a maximum value of 1. The value is 1 for a perfect model, and 0 for a model no better than a constant model. The Generalized RSquare measure simplifies to the traditional RSquare for continuous normal responses in the standard least squares setting. Generalized RSquare is also known as the Nagelkerke or Craig and Uhler $R^2$, which is a normalized version of Cox and Snell’s pseudo $R^2$. See Nagelkerke (1991).

**Mean $-\log p$**  The average of $-\log(p)$, where $p$ is the fitted probability associated with the event that occurred.

**RASE**  The root average squared error, adjusted for degrees of freedom. For categorical responses, the differences are between 1 and $p$ (the fitted probability for the response level that actually occurred).

**Mean Abs Dev**  The average of the absolute values of the differences between the response and the predicted response. For categorical responses, the differences are between 1 and $p$ (the fitted probability for the response level that actually occurred).

**Misclassification Rate**  The rate for which the response category with the highest fitted probability is not the observed category.
N  The number of observations.

Related Information

“Training and Validation Measures of Fit” on page 45 in the “Neural Networks” chapter provides more information about measures of fit for categorical responses.

Model Comparison Platform Options

Continuous and Categorical Responses

Model Averaging  Makes a new column of the arithmetic mean of the predicted values (for continuous responses) or the predicted.probabilities (for categorical responses).

Continuous Responses

Plot Actual by Predicted  Shows a scatterplot of the actual versus the predicted values. The plots for the different models are overlaid.

Plot Residual by Row  Shows a plot of the residuals by row number. The plots for the different models are overlaid.

Profiler  Shows a profiler for each response based on prediction formula columns in your data. The profilers have a row for each model being compared.

Categorical Responses

ROC Curve  Shows ROC curves for each level of the response variable. The curves for the different models are overlaid.

AUC Comparison  Provides a comparison of the area under the ROC curve (AUC) from each model. The area under the curve is the indicator of the goodness of fit, where 1 is a perfect fit.

The report includes the following information:

– standard errors and confidence intervals for each AUC
– standard errors, confidence intervals, and hypothesis tests for the difference between each pair of AUCs
– an overall hypothesis test for testing whether all AUCs are equal
Lift Curve  Shows lift curves for each level of the response variable. The curves for the different models are overlaid.

Cum Gains Curve  Shows cumulative gains curves for each level of the response variable. A cumulative gains curve is a plot of the proportion of a response level that is identified by the model against the proportion of all responses. A cumulative gains curve for a perfect model would reach 1.0 at the overall proportion of the response level. The curves for the different models are overlaid.

Confusion Matrix  Shows confusion matrices for each model. A confusion matrix is a two-way classification of actual and predicted responses. Count and rate confusion matrices are shown. Separate confusion matrices are produced for each level of the Group variable.

If the response has a Profit Matrix column property, then Actual by Decision Count and Actual by Decision Rate matrices are shown to the right of the confusion matrices. For more information about these matrices, see “Additional Examples of Partitioning” on page 76 in the “Partition Models” chapter.

Profiler  Shows a profiler for each response based on prediction formula columns in your data. The profilers have a row for each model being compared.

Decision Threshold  (Available only for binary categorical responses.) Shows or hides Decision Thresholds reports for the training, validation, and test sets, if specified. Each report contains a graph of the distribution of fitted probabilities for each model, confusion matrices for each model, and classification graphs to compare the model fits. See “Decision Thresholds Report” on page 185 in the “Model Screening” chapter.

- “Lift Curve” on page 73 in the “Partition Models” chapter

Additional Example of Model Comparison

This example uses automobile data to build a model to predict the size of the purchased car. A logistic regression model and a decision tree model are compared.

Begin by selecting Help > Sample Data Library and opening Car Physical Data.jmp.

Create the Logistic Regression Model

1. Select Analyze > Fit Model.
2. Select Type and click Y.
3. Select the following columns and click **Add**: Country, Weight, Turning Cycle, Displacement, and Horsepower.

4. Click **Run**.

   The Nominal Logistic Fit report appears.

5. To save the prediction formulas to columns, click the Nominal Logistic red triangle and select **Save Probability Formula**.

**Create the Decision Tree Model and Save the Prediction Formula to a Column**

1. Select **Analyze > Predictive Modeling > Partition**.

2. Select **Type** and click **Y, Response**.

3. Select the Country, Weight, Turning Cycle, Displacement, and Horsepower columns and click **X, Factor**.

4. Make sure that **Decision Tree** is selected in the Method list.

5. Click **OK**.

   The Partition report appears.

6. Click **Split** 10 times.

7. To save the prediction formulas to columns, click the Partition red triangle and select **Save Columns > Save Prediction Formula**.

**Compare the Models**

1. Select **Analyze > Predictive Modeling > Model Comparison**.

2. Select all columns that begin with **Prob** and click **Y, Predictors**.

3. Click **OK**.

**Figure 11.8 Initial Model Comparison Report**

![Initial Model Comparison Report]

The report shows that the Partition model has slightly higher values for Entropy RSquare and Generalized RSquare and a slightly lower value for Misclassification Rate.

4. Click the Model Comparison red triangle and select **ROC Curve**.

   ROC curves appear for each Type, one of which is shown in Figure 11.9.
Examining all the ROC curves, you see that the two models are similar in their predictive ability.

5. Click the Model Comparison red triangle and select **AUC Comparison**.

AUC Comparison reports appear for each Type, one of which is shown in Figure 11.10.

**Figure 11.10** AUC Comparison for Medium

The report shows results for a hypothesis test for the difference between the AUC values (area under the ROC curve). Examining the results, you see there is no statistical difference between the values for any level of Type.

You conclude that there is no large difference between the predictive abilities of the two models for the following reasons:

- The R Square values and the ROC curves are similar.
- There is no statistically significant difference between AUC values.
The Make Validation Column platform is available only in JMP Pro.

Validation is the process of using part of a data set to estimate model parameters and using another part to assess the predictive ability of a model. You can partition the data into two or three sets. The Make Validation Column platform provides five different methods to create these partitions.

Additional Example of the Make Validation Column Platform ......................... 210
Overview of the Make Validation Column Platform

Validation is the process of using part of a data set to estimate model parameters and using another part to assess the predictive ability of a model. With complex data, this can reduce the risk of model overfitting.

A validation column partitions the data into two or three parts.

- The training set is used to estimate the model parameters.
- The validation set is used to help choose a model with good predictive ability.
- The testing set checks the model’s predictive ability after a model has been chosen.

A validation column can be used as a validation method in many JMP platforms. See “Validation in JMP Modeling” on page 541 in the “Statistical Details” appendix.

The Make Validation Column platform enables you to create training, validation, and test sets using a variety of methods. You can specify stratification, grouping, or cutpoint columns to determine the method used to create the validation column.

Example of Make Validation Column

The Lipid Data.jmp data table contains blood measurements, physical measurements, and questionnaire data from 95 subjects at a California hospital. You are interested in creating a validation column to use during future analyses.

1. Select Help > Sample Data Library and open Lipid Data.jmp.
2. Select Analyze > Distribution.
4. Click OK.
Figure 12.1 illustrates the distribution of Gender in the data set. Notice that there is not an equal proportion of males and females represented. Because there are fewer females within the data, you want to be sure to balance the genders across the validation and training sets.

5. Select Analyze > Predictive Modeling > Make Validation Column.
6. Select Gender and click Stratification Columns.
7. Click OK.

The Make Validation Column report appears with a description of the validation method you selected. There are also options to change the rates, column types, or set a seed.

8. (Optional) Type 1234 next to Random Seed in the Options section of the report.
9. Click Go.

A Validation column is added to the data table. You can explore the distribution of the validation and training sets by creating a Mosaic Plot.

10. Select Analyze > Fit Y by X.
11. Assign Validation to Y, Response, and Gender to X, Factor.
12. Click OK.
Figure 12.2 Distribution of Gender across Validation and Training Sets

Figure 12.2 illustrates the distribution of Gender across each of the validation and training sets. Note that about 75% of both females and males are in the training set and about 25% of both females and males are in the validation set.

Launch the Make Validation Column Platform

Launch the Make Validation Column platform by selecting Analyze > Predictive Modeling > Make Validation Column.

Figure 12.3 Make Validation Column Launch Window

For more information about the options in the Select Columns red triangle menu, see Using JMP.

The Make Validation Column launch window provides the following options:

**Stratification Columns** Assigns one or more stratification columns.

**Grouping Columns** Assigns one or more grouping columns.
**Cutpoint Column**  Assigns a numeric cutpoint column.

**Cutpoint Batch ID**  When a cutpoint column is assigned, you can also assign a column for cutpoint batch IDs. This enables you to determine cutpoint values within each level of the Cutpoint Batch ID column.

**Selected Method**

Provides two methods for validation.

**Make Validation Column** creates a validation column based on the specified stratification, grouping, and cutpoint columns. The validation column method determined by the specified stratification, grouping, and cutpoint columns is described below the box. After a method is selected and you click OK, you specify the allocations for each set in the Make Validation Column report. See “Specify Rates or Relative Rates” on page 208 and “Set Cutpoints” on page 208. There are five methods for constructing the holdback sets.

**Random Validation Column**  The default method if there are no column assignments in the launch window. This method partitions the data into sets based on the allocations entered in the Make Validation Column report.

**Stratified Validation Column**  The selected method if one or more stratification columns are assigned. This method partitions the data into balanced sets based on the levels of the specified stratification columns. As in the Random Validation Column method, rows are randomly assigned to the holdback sets based on the allocations entered in the Make Validation Column report. However, this is done at each level or combination of levels of the stratifying columns. Use this method when you want a balanced representation of the levels of a column in each of the training, validation, and test sets.

**Grouped Validation Column**  The selected method if one or more grouping columns are specified. This method partitions the data into sets in such a way that entire levels of a specified column or combinations of levels of two or more columns are placed in the same set. Because of this, the sizes of the resulting sets vary slightly from the sizes that you specified. Use this option when splitting levels across holdback sets is not desirable.

**Stratify by Group Validation Column**  The selected method if both stratification and grouping columns are specified. This method partitions the data to balance the levels across the stratification column while requiring that the specified groups stay together in the same holdback sets. As in Grouped Validation Column, groups can be created as levels of a specified column or combination of levels of two or more columns. The sizes of the resulting sets vary slightly from the sizes you specified.
**Cutpoint Validation Column**  The selected method if a cutpoint column is specified. This method partitions the data into sets based on the time series cutpoints. Use this option when you want to assign your data to holdback sets based on time periods. The training set consists of rows between the first cutpoint and the second cutpoint. The validation set consists of rows between the second and third cutpoints. The test set consists of the remaining rows. These sets are chosen based on options in the Set Cutpoints report.

**Make Autovalidation Table**  Creates a new data table that contains a duplication of the rows in the original data table concatenated to the rows in the original data table. The new data table, which can be used for crossvalidation, has four additional columns:

- **Valid Set**  Assigns a value of 0 to the original data and a value of 1 to the duplicated data. The values in this column designate the training and validation sets. Use this column in the Validation role in the launch window of an analysis.

- **Valid ID**  Assigns the row number of the original observation. This allows matching of training and validation set rows for each original observation.

- **Valid Weight**  Assigns the autovalidation weight, to be used in the Freq role in the launch window of an analysis. For each value of Valid ID, the same uniform random number is generated for the training observation and the validation observation. For the training set, Valid Weight is calculated as follows:
  \[
  \text{Valid Weight} = -\log(1 - \text{Valid Uniform})
  \]
  For the validation set, Valid Weight is calculated as follows:
  \[
  \text{Valid Weight} = -\log(\text{Valid Uniform})
  \]
  The Valid Weight column is constructed so that the training data weights are negatively correlated with the validation data weights. This ensures that the difference in the fit of the validation data yields an effective crossvalidation of the fitting method.

- **Null Factor**  Assigns the same normal random number for each value of Valid ID.

**Tip:** Use Make Autovalidation Table for small data tables, where using a subset as the training data could cause estimation problems.
Make Validation Column Report

When you click OK in the launch window, the Make Validation Column report window appears. The report contains a description of the validation method you selected and relevant options for rates, cutpoints, column type, and setting a random seed.

Specify Rates or Relative Rates

This report enables you to specify the allocations for the training, validation, and test sets. In the boxes next to Training Set, Validation Set, and Test Set, enter values that represent the proportions or numbers of rows that you would like to include in each of these sets. The default values construct a training set that contains about 75% of the rows and a validation set that contains about 25% of the rows.

Depending on the number of rows in the data table and the selected validation method, the actual sizes of the resulting sets might vary slightly from the sizes that you specified. The Adjusted Rates, Row Counts, and Group Count columns provide the actual sizes of the sets.

Set Cutpoints

This report is shown only when a cutpoint column is specified in the launch window. The cutpoints are determined by one of the following four methods:

Proportions  Determines the cutpoints based on the proportions of rows specified for each set. In the boxes next to Training Set, Validation Set, and Test Set, enter values that represent the proportions that you would like to include in each of these sets. Depending on the number of rows and the proportions, the actual sizes of the resulting sets might vary slightly from the sizes you specified.

Number of Rows  Determines the cutpoints based on the number of rows specified for each set. In the boxes next to Training Set, Validation Set, and Test Set, enter values that represent the number of rows that you would like to include in each of these sets. This option enables you to specify the sets exactly.

Fixed Time or Date  Determines the cutpoints based on fixed data points in the specified cutpoint column. If you select this option, the minimum and maximum values for the cutpoint column are shown for reference. In the boxes next to Training Set, Validation Set, and Test Set, enter the value that represents the minimum value that you would like to include in each of these sets.

Elapsed Time  Determines the cutpoints based on the amount of time that has elapsed since the first timestamp in the cutpoint column. If you select this option, the total elapsed time from the first value to the last value is shown for reference. In the boxes next to Training
Set, Validation Set, and Test Set, enter the values that represent the amounts of elapsed time that you would like to include in each of these sets.

**Options**

You can also specify the following additional options:

**New Column Name**  Enables you to specify the name of the validation column.

**Validation Column Type**  (Not available for the Cutpoint Validation Column method.) Enables you to specify the validation column type as fixed or formula.

- The fixed column type produces a column with fixed values.
- The formula column type produces a formula column as the validation column.

**Random Seed**  (Not available for the Cutpoint Validation Column method or if a formula column type is specified.) Enables you to set a random seed to reproduce the same validation column in the future.

**Go**

Click **Go** in the Make Validation Column report to add the validation column to the data table. The validation column has a Notes property that gives the stratifying, grouping, or cutpoint variables.

**Make Validation Column Platform Options**

The Make Validation Column Utility has the following red triangle menu options:

See *Using JMP* for more information about the following options:

**Redo**  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

**Save Script**  Contains options that enable you to save a script that reproduces the report to several destinations.
Additional Example of the Make Validation Column Platform

This example uses weekly weather data collected over one year from 16 weather stations across the United States. Run the Weather Station Locations script in the data table to view a map of the locations. Not every weather station has a weekly temperature measurement for every week of the year. You are interested in creating a validation column for this data table based on the dates of data collection. For each weather station, you want to use the first 60% of observations for training, the next 25% of observations for validation, and the final 15% of observations for testing. This example shows the importance of using a Batch ID column in this type of scenario.

Create Validation Column with Cutpoints

2. Select Analyze > Predictive Modeling > Make Validation Column.
3. Select Week of Year and click Cutpoint Column.
4. Click OK.
5. In the list next to Determine cutpoints using, select Proportions.
6. In the boxes next to Training Set, Validation Set, and Test Set, enter 0.60, 0.25, and 0.15, respectively.
7. In the box next to New Column Name, type Cutpoint Validation.
8. Click Go.

A validation column called Cutpoint Validation is added to the data table.

9. Select Analyze > Tabulate.
10. Click ID and drag it to the Drop zone for rows.
11. Click Cutpoint Validation and drag it on top of N.
12. Click Row% and drag it on top of the cells.
Create Validation Column with Cutpoints and Batch ID

1. Select **Analyze > Predictive Modeling > Make Validation Column.**
2. Select **Week of Year** and click **Cutpoint Column.**
3. Select **ID** and click **Cutpoint Batch ID.**
4. Click **OK.**
5. In the list next to Determine cutpoints using, select **Proportions.**
6. In the boxes next to Training Set, Validation Set, and Test Set, enter 0.60, 0.25, and 0.15, respectively.
7. In the box next to New Column Name, type Cutpoint Batch Validation.
8. Click **Go.**
   
   A validation column called Cutpoint Batch Validation is added to the data table.
9. Select **Analyze > Tabulate.**
10. Click ID and drag it to the Drop zone for rows.
11. Click Cutpoint Batch Validation and drag it on top of N.
12. Click Row% and drag it on top of the cells.

</table>

Figure 12.5 shows that using a Cutpoint Batch ID column ensures that each weather station has proportions for the training, validation, and test sets that are much closer to the specified values.
The Formula Depot Platform is available only in JMP Pro.

The Formula Depot is a repository to organize, compare, and profile models. Scoring code for deployment within or outside of JMP can be generated for models published to the Formula Depot. For model exploration work, you can use the Formula Depot to store candidate models outside of your JMP data table. The model profiler and model compare platforms are accessible from the Formula Depot. A model that is selected for further use can be saved to your JMP table or saved to a JMP table with new data for scoring. For use in an environment outside of JMP, you can generate scoring code in C, Python, JavaScript, SAS, or SQL.

Generating Scoring Code from the Formula Depot Platform ...................... 219
Overview of the Formula Depot Platform

The Formula Depot is a repository to organize, compare, profile, and score models for deployment. Models are prediction formulas. Prediction formulas are saved to the Formula Depot as column scripts. You can add prediction formulas to JMP tables to score data. You can also use the Formula Depot to generate scoring code for prediction formulas to facilitate the deployment of models in environments outside of JMP.

The Formula Depot enables you to perform the following tasks:

- save prediction formulas outside of data tables
- save prediction formulas from multiple data tables in a common location
- save intermediate cleaning formulas within a prediction formula
- compare models
- profile models
- add prediction formulas to a data table for scoring of new data within JMP
- generate scoring code (C, Python, JavaScript, SAS, or SQL) for deploying models outside of JMP
- The Formula Depot includes intermediate formulas in the generated scoring code. A model constructed from inputs with column formulas includes the corresponding formulas in the scoring code. For example, if your model includes a recoded variable the recode formula is included in the scoring code. This enables you to apply your prediction formula to raw data that has not been processed.

**Note:** Informative missing is not a supported intermediate formula.

Example of Formula Depot

The Liver Cancer.jmp sample data table contains data on the severity of liver cancer in patients when they entered a study. The file also contains a number of table scripts for models. This example uses these scripts to generate models to demonstrate the Formula Depot.

1. Select Help > Sample Data Library and open Liver Cancer.jmp.
2. Click the green triangle next to the Lasso Poisson, Validation Column script.
3. Click the red triangle next to Poisson Adaptive Lasso with Validation Column and select Save Columns > Publish Prediction Formula.

This option opens a Formula Depot that contains the prediction formula for the Fit Generalized model.
4. To add the prediction formula to the data table, select Run Script from the Fit Generalized - Node Count red triangle in the Formula Depot.

**Note:** The result of step 3 and step 4 can be obtained using the Save Columns > Save Prediction Formula at step 3. However, then the prediction formula is not part of the Formula Depot.

5. To generate scoring code for use outside of JMP select a code type from the Fit Generalized - Node Count red triangle. A script window appears containing the code. See “Generating Scoring Code from the Formula Depot Platform” on page 219.

6. To save the Formula Depot, select File > Save.

**Note:** The Formula Depot is saved as a JMP Report File (*.jrp).

---

**Launch the Formula Depot Platform**

Launch the Formula Depot by selecting Analyze > Predictive Modeling > Formula Depot.

**Figure 13.3** Empty Formula Depot from Launch

Alternatively, if there is not an open Formula Depot then a Formula Depot opens when you select a Publish command.
Platforms That Publish Prediction Formulas to the Formula Depot

The platforms that publish prediction formulas and generate scoring code include:

- Discriminant
- Least Squares Regression
- Logistic Regression
- Partition
- Uplift
- K Nearest Neighbors
- Naive Bayes
- Neural
- Latent Class Analysis
- Principal Components
- Generalized Regression
- PLS
- Gaussian Process

In platforms that do not publish prediction formulas to the Formula Depot, you can save the prediction formula to the data table. From the data table, add it to the Formula Depot by selecting **Add Formula from Column**. However, the scoring code might not be fully functional for such models. For more information about scoring code see “Generating Scoring Code from the Formula Depot Platform” on page 219.

In addition, you can publish a formula directly from the formula editor. Select the formula, right-click, and select **Publish expression to formula depot**.

---

Formula Depot Platform Options

**Add Formula From Column**  Enables you to add existing prediction formulas from data table columns to the current formula depot. If your table has only one formula, that formula is added to the depot. If you have multiple column formulas, a dialog box enables you to select the formulas of interest. If your formula columns are selected in your data table, they will be pre-selected in the dialog box.

**Show Scripts**  Opens a new Formula Window (or appends to an open Formula Window) that contains scripts for all of the formulas that are in the current formula depot.
Copy Scripts  Copies all scripts from the current formula depot to the clipboard.

Copy Formulas as Functions  Enables you to select models from the current formula depot to be copied as functions for use in JSL. Selected models are copied onto the clipboard. The functions act on scalar variables rather than columns. One Namespace is generated for each selected model. Each Namespace has one function, called predict, that takes the model inputs as parameters and returns the model predictor.

Copy Formulas as Transforms  Enables you to select models from the current formula depot to be copied. Selected models are copied onto the clipboard within a Transform Columns() statement.

Run Scripts  Enables you to save models from the current formula depot to new columns in your JMP data table. Formulas with intermediate column formulas will add the intermediate columns to your JMP data table.

**Note:** If you have more than one data table open, a Choose Table window appears that enables you to specify which data table to use for Run Scripts.

Generate C Code, Generate Python Code, Generate JavaScript Code, Generate SAS Code, and Generate SQL Code  Enables you to select models from the current formula depot for code generation. A new script window appears that contains scoring code for the selected models in C, Python, JavaScript, SAS DS2, or SQL, respectively. You can use this code to facilitate the deployment of the model in the environment or framework of your choice. See “Generating Scoring Code from the Formula Depot Platform” on page 219.

Model Comparison  Enables you to select models from the current formula depot to be compared using the model comparison utility. If models from multiple tables are stored in the depot, first select the table of interest and then the models of interest. Hold the shift key when selecting the Model Comparison option to launch the Model Comparison in a new window. See the “Model Comparison” chapter on page 189.

**Note:** If you have more than one data table open, a Choose Table window appears that enables you to specify which data table to use for the Model Comparison.

Remove Model Comparison  Removes all Model Comparison reports from the current formula depot.

Profiler  Enables you to select models from the current formula depot to be profiled using the profiler. If models from multiple tables are stored in the depot you first select the table of interest and then the models of interest. Hold the shift key when selecting the profiler option to launch the profiler in a new window. See Profilers.
Note: If you have more than one data table open, a Choose Table window appears that enables you to specify which data table to use for the Profiler.

Remove Profiler  Removes all Profilers from the current formula depot.

See Using JMP for more information about the following options:

Redo  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

Save Script  Contains options that enable you to save a script that reproduces the report to several destinations.

Formula Depot Model Options

Each prediction formula that is saved in the Formula Depot has an individual options menu. In addition to Show, Copy, Run, and Code Generation options that correspond to the main menu options, the individual menus include the following options:

Rename New Column  Enables you to rename the model. This new name is applied as the column name if you run the script to add the prediction formula to a JMP data table. In addition, this name is included in generated code.

Remove  Removes the model from the Formula Depot. This command cannot be undone.

Generating Scoring Code from the Formula Depot Platform

Scoring code generation is intended to facilitate using models built in JMP in a production environment or other framework of your choice. Many platforms publish prediction formulas to the Formula Depot, however; not all prediction formulas generate complete code. Code can be complete, it can be a code fragment, or the code can include unsupported functions that require additional programming for implementation. Error messages often indicate an unsupported function call that requires additional programming in the targeted language. Target language specific libraries might be required for the implementation of more complex functions. These libraries are discussed in the language specific sections below. For example, you can perform the following tasks:

- Deploy your model to SAS Model Manager using the generated SAS code.
- Augment your ETL process with in-database scoring using the generated SQL code.
• Create a node for a data transformation pipeline with an application built with the generated C code.
• Create a Jupyter notebook to show live scoring results using the generated Python code.
• Enable customers to score their own data with a web application that includes the generated JavaScript.

For the C, Python, and JavaScript languages, you must include supporting code such as .h files and utility libraries when deploying or compiling the generated code. These files are available in your JMP installation folder inside the Scoring folder.

**Tip:** To find the location of installation folder on your machine, use the JSL command `Get Path Variable("$ALL_HOME/Scoring");`

---

**C Code** The C scoring code that is generated must be compiled into a library and then linked into an application. You might use either a static or a dynamic link approach. The files `jmp_lib.h`, `jmp_parms.h`, and `jmp_score.h` needed for compiling and linking can be found in the Scoring/C folder in your JMP installation folder.

**Python Code** The file `jmp_score.py` that is needed to run your Python scoring application can be found in the Scoring/Python folder in your JMP installation folder. When deploying your models, copy `jmp_score.py` to the same location as your executable scoring code.

When calling the generated code to score your data, it is important that the input data is passed in a data structure compatible with the code generated by JMP. The Python scoring code expects the input and output arguments to be of a dictionary-like type. Values can be accessed and written by key, such as DataFrame row objects from the Spark, Dask and Pandas frameworks, or the standard Python “dict” class.

Use of linear algebra operators or advanced operators such as Vec Quadratic and Design Norm require the NumPy Python library.

**JavaScript Code** The file `jmp_score.js` that is needed to run your JavaScript scoring application can be found in Scoring/JavaScript folder.

**SAS Code** The generated code fragment that once wrapped by PROC DS2 statements can be used in SAS applications including the SAS In-Database Code Accelerator. The code is added to a SAS Window and includes a variable name mapping section in the comment block that precedes the code. Any temporary variable names associated with intermediate columns are deleted at the end of the DATA Step by the drop command.

**Tip:** For models with an ifmax call, such as logistic or neural models for a categorical response, move temporary variable declarations before the `method run()` statement.

**SQL Code** The SQL code fragment that once wrapped in a select statement can be used in SQL queries against most major database servers.
Note: Code that contains “placeholder” or “ERROR” indicates an unsupported function call.
In many situations, especially in the physical and biological sciences, well-known nonlinear equations describe the relationship between variables. For example, pharmacological bioassay experiments can demonstrate how the strength of the response to a drug changes as a function of drug concentration. Sigmoid curves often accurately model response strength as a function of drug concentration. Another example is exponential growth curves, which can model the size of a population over time.

The Fit Curve platform does not require you to specify starting values for parameter estimates or create model formulas. To specify your own starting values and create model formulas, use the more powerful custom Nonlinear platform, which can also fit any nonlinear model. See the “Nonlinear Regression” chapter on page 247.

Overview of the Fit Curve Platform

Some models are linear in the parameters (for example, a quadratic or other polynomial); others can be transformed to be such (for example, when you use a log transformation of $x$). The Fit Model or Fit Y by X platforms are more appropriate in these situations. An example in Fitting Linear Models shows a significant linear relationship between oxygen uptake and time spent running. For more information about Fit Model, see Fitting Linear Models. For more information about Fit Y by X, see Basic Analysis.

The Fit Curve platform enables you to fit models that are nonlinear in the parameters. The initial example in this chapter shows the analysis of a nonlinear relationship: drug toxicity as a function of concentration. The effect of concentration on toxicity changes from low to high doses, so this relationship is nonlinear.

The following are examples of equations for linear and nonlinear functions.

Linear function: \[ Y = \beta_0 + \beta_1 e^{x} \]

Nonlinear function: \[ Y = \beta_0 + \beta_1 e^{\beta_2 x} \]

The Fit Curve platform provides predefined models, such as polynomial, logistic, probit, Gompertz, exponential, peak, and pharmacokinetic models. Specifying a grouping variable lets you estimate separate model parameters for each level of the grouping variable. The fitted models and estimated parameters can be compared across the levels of the grouping variable.

Fit Curve also enables you to build a model to create the prediction formula. Then you set upper and lower parameter limits in Nonlinear. See “Example of Setting Parameter Limits” on page 268 in the “Nonlinear Regression” chapter. In JMP Pro, you can also specify a set of supplementary variables and fit a generalized regression model within the Fit Curve platform to determine how these variables affect the response.

Example Using the Fit Curve Platform

This example shows how to build a model for toxicity as a function of the concentration of a drug. You have a standard formulation of the drug and want to compare it to three new formulations.

You are interested in a toxicity ratio of non-surviving to surviving cells at a specific concentration of each drug. From prior research, you know the toxicity ratios for 16 different concentrations of each drug formulation. A higher ratio indicates more toxicity, which could be detrimental to development of the drug. Log concentration was calculated to decrease the range of concentration values and make it easier to detect differences in the curves.
Follow these steps to build the model:

1. Select **Help > Sample Data Library** and open Nonlinear Examples/Bioassay.jmp.
2. Select **Analyze > Specialized Modeling > Fit Curve**.
3. Assign Toxicity to the **Y, Response** role.
4. Assign log Conc to the **X, Regressor** role.
5. Assign Formulation to the **Group** role.
6. Click **OK**.

   The Fit Curve Report appears. The Plot report contains an overlaid plot of the fitted model of each formulation.

**Figure 14.2** Initial Fit Curve Report

7. To see a legend identifying each drug formulation, right-click one of the graphs and select **Row Legend**. Select **Formulation** for the column and click **OK**.
The curves appear S-shaped, so a sigmoid curve would be an appropriate fit. Table 14.1 shows formulas and graphical depictions of the different types of models that the Fit Curve platform offers.

8. Click the Fit Curve red triangle and select **Sigmoid Curves > Logistic Curves > Fit Logistic 4P**.
Figure 14.4  Logistic 4P Report

The Logistic 4P report appears. There is also a separate plot for each drug formulation. The plot of the fitted curves suggests that formulation B might be different, because the test B curve starts to rise sooner than the others. Inflection point parameters cause this rise.

9. Click the Logistic 4P red triangle and select Compare Parameter Estimates.

Figure 14.5  Parameter Comparison Report

Notice that the Inflection Point parameter for the test B formulation is significantly lower than the average inflection point. This agrees with the plots shown in Figure 14.4. Drug formulation B has a higher toxicity ratio than the other formulations.
Launch the Fit Curve Platform

To launch the Fit Curve platform, select **Analyze > Specialized Modeling > Fit Curve**. The launch window is shown in Figure 14.6.

**Figure 14.6** Fit Curve Platform Launch Window

For more information about the options in the Select Columns red triangle menu, see *Using JMP*.

The Fit Curve platform launch window has the following features:

**Y, Response** Specify the Y variable.

**X, Regressor** Specify the X variable.

**Group** Specify a grouping variable. The fitted model has separate parameters for each level of the grouping variable. This enables you to compare fitted models and estimated parameters across the levels of the grouping variable.

**Z, Supplementary** Specify one or more supplementary variables. Supplementary variables are not used in any of the calculations in the Fit Curve platform and including them does not affect the results. Supplementary variables are variables you might want to use in future analyses of the results from Fit Curve. When you specify supplementary variables, they are included in the table that is created by the Make Parameter Table option. In JMP Pro, if you specify one or more supplementary variables and a grouping variable, a Curve DOE Analysis option is made available for the fitted models. See “Curve DOE Analysis” on page 234.

**Weight** Specify a variable that contains the weights of the observations.

**Freq** Specify a variable that contains the frequencies of the observations.

**By** Specify a variable to perform a separate analysis for every level of the variable.
The Fit Curve Report

The Fit Curve report initially contains only a plot of Y versus X. If you specify a Group variable, the report includes overlaid and individual plots for each group of the fitted model.

Figure 14.7  Fit Curve Reports: No Grouping Variable (left) and with Group Variable (right)

After fitting a model, the fitted model appears on the plot (when no grouping variable is specified on the platform launch window). A Model Comparison report appears above the plots and a Model Report appears below the plot. Each time a new model is fit, it appears in the Model Comparison report and a new model report appears in the report window. See “Model Comparison Report” on page 231 and “Model Fit Report” on page 233.

Note: Any rows that are excluded in the data table are also hidden in the Fit Curve plot.

Fit Curve Options

Select any of the following built-in models from the Fit Curve red triangle menu. See “Model Formulas” on page 240.

Polynomials  Fits first degree to fifth degree polynomials.

Sigmoid Curves  Fits Logistic, Probit, Gompertz, and Weibull models. These models are S-shaped and have both upper and lower asymptotes. The Logistic 2P, 3P, and 4P and Probit 2P and 4P models are symmetric. The Logistic 5P and both Gompertz models are not symmetric. The Logistic 2P is available only when the response is between 0 and 1. The Weibull Growth is available only when both the response values and regressor values are
non-negative. Examples of Sigmoid curves include learning curves and modeling tumor growth, both of which increase initially and then taper off.

**Exponential Growth and Decay**  Fits Exponential, Biexponential, Mechanistic Growth, and Cell Growth models. The Exponential 2P and 3P are similar, but the 3P model has an asymptote. The Biexponential models assume there are two separate growth or decay processes. The Mechanistic Growth and Exponential 3P models always increase (or decrease), but the rate of growth (or decay) slows so that the model has an asymptote. Examples of exponential growth and decay functions are virus spread and drug half-life, respectively.

**Peak Models**  Fits Gaussian Peak and Lorentzian Peak models. These models increase up to a peak and then decrease. The Gaussian Peak model is a scaled version of the Gaussian probability density function (PDF). The Lorentzian Peak model is a scaled version of the Cauchy distribution, a continuous probability distribution. These models can be used for some chemical concentration assays and artificial neural networks.

**Pharmacokinetic Models**  Fits the One Compartment Oral Dose model, the Two Compartment IV Bolus Dose model, and the Biexponential 4P model. This option is used to model the concentration of drugs in the body.

**Fit Michaelis-Menten**  Fits the Michaelis-Menten biochemical kinetics model, which relates the rate of enzymatic reactions to substrate concentration.

See *Using JMP* for more information about the following options:

**Local Data Filter**  Shows or hides the local data filter that enables you to filter the data used in a specific report.

**Redo**  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

**Save Script**  Contains options that enable you to save a script that reproduces the report to several destinations.

**Save By-Group Script**  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.

**Model Comparison Report**

To create the report shown in Figure 14.8, select *Sigmoid Curves > Logistic Curves > Fit Logistic 4P* and *Sigmoid Curves > Fit Gompertz 4P* from the Fit Curve red triangle menu.
Figure 14.8 Model Comparison Report

The Model Comparison report shows fit statistics used for comparing multiple models. The statistics are AICc, AICc Weight, BIC, SSE, MSE, RMSE, and R-Square, and are defined below.

**AICc**  Gives a measure of the goodness of fit of an estimated statistical model that can be used to compare two or more models. AICc is a modification of the AIC adjusted for small samples. AICc can be computed only when the number of data points is at least two greater than the number of parameters. The model with the lowest AICc value is the best, which is the Logistic 4P in our example. See *Fitting Linear Models*.

**AICc Weight**  Gives normalized AICc values that sum to one. The AICc weight can be interpreted as the probability that a particular model is the true model given that one of the fitted models is the truth. Therefore, the model with the AICc weight closest to one is the best fit. In our example, the Logistic 4P model is clearly the better fit. The AICc weights are calculated using only nonmissing AICc values:

\[
\text{AICc Weight} = \frac{\exp[-0.5(AICc-min(AICc))] / \text{sum}(\exp[-0.5(AICc-min(AICc))])}
\]

where min(AICc) is the smallest AICc value among the fitted models. The AICc Weight column is then sorted in decreasing order.

**BIC**  Gives a measure based on the likelihood function of model fit that is helpful when comparing different models. The model with the lower BIC value is the better fit. See *Fitting Linear Models*.

**SSE**  The sum of the squared differences between each observation and its predicted value.

**MSE**  Gives the average of the squares of the errors of each value.

**RMSE**  The square root of the MSE that estimates the standard deviation of the random error.

**R-Square**  Estimates the proportion of variation in the response that can be attributed to the model rather than to random error. The model with the R-Square value closest to one is the better fit.

The Model Comparison platform provides additional options, such as plotting residual and actual values. See the “Model Comparison” chapter on page 189.
Model Fit Report

A report is created for each fitted model. The red triangle menu for each model report contains the following options.

**Prediction Model**  Gives the algebraic form of the prediction formula and the parameters.

**Summary of Fit**  Gives the same fit statistics as the Model Comparison report.

**Parameter Estimates**  Gives the estimates of the parameters, standard errors, Chi-squared statistics, \( p \)-values, and confidence intervals. The correlations and covariances of the estimates are given also.

**Tip:** You can sort the Parameter Estimates report table by clicking on the column that you want to sort by.

**Plot**  Gives plots of the data with the fitted model (Figure 14.7). The plots are shown only when you select a Grouping variable on the platform launch window.

Model Fit Options

Each model report contains a red triangle menu with some or all of the following options:

**Test Parallelism**  Helps determine whether the curves are similar in shape when they are shifted along the X axis. In certain situations, it is important to establish parallelism before making further comparisons between groups. This option is available only when a Group variable is specified on the platform launch window. This option is available for the Sigmoid models (Logistic and Gompertz), as well as the Linear Regression model, with the exception of higher-order polynomials. See “Test Parallelism” on page 235.

**Area Under Curve**  Gives the area under the fitted curve. This option is available for the following models: One Compartment, Two Compartment, Gaussian Peak, and Lorentzian Peak. This option is also available for Bi-Exponential 4P Models, but only when all parameters are positive. The range of integration depends on the type of model and is specified in the report.

If a Grouping variable is specified on the platform launch window, an Analysis of Means is performed for comparing the estimates across groups. If the result for a group exceeds a decision limit, the result is considered different from the overall mean of AUC.

**Time to Peak Response**  Displays the estimate of the regressor, \( X \), at the peak of the fitted curve. The standard error of the estimate is also shown. This option is available for Cell Growth 4P and One Compartment models.
Peak Response  Displays the estimate of the response, \( Y \), at the peak of the fitted curve. The standard error of the estimate is also shown. This option is available for Cell Growth 4P and One Compartment models.

Compare Parameter Estimates  Gives an analysis for testing the equality of parameters across levels of the grouping variable. This option is available only when a Group variable is specified on the platform launch window. See “Compare Parameter Estimates” on page 238.

Equivalence Test  Gives an analysis for testing the equivalence of models across levels of the grouping variable. This option is available only when a Group variable is specified on the platform launch window. See “Equivalence Test” on page 238.

Curve DOE Analysis  (Available only if a grouping variable and at least one supplementary variable are specified in the launch window.) Launches a Generalized Regression report within the Fit Curve platform. A generalized regression model is fit to each parameter of the nonlinear model using the supplementary variables as model effects. By default, a two degree factorial model is fit and the Estimation Method is Forward Selection. These models are then combined to create a profiler of the response as a function of the regressor variable and the supplementary variables. You can then use the CDOE Profiler to explore how the supplementary variables affect the response.

The Curve DOE Analysis report contains the following red triangle menu options:

Generalized Regression for Model Parameters  Shows or hides the Generalized Regression reports for each model parameter. For more information on Generalized Regression model reports, see Fitting Linear Models.

Diagnostic Plots  Shows or hides actual by predicted and residual plots for the response variable.

CDOE Profiler  Shows or hides the CDOE Profiler, which enables you to explore how the response changes based on the supplementary variables. For more information about the CDOE Profiler red triangle menu options, see Profilers.

Save Prediction Formula  Saves the prediction formula for the response to a new column in the data table.

Make Parameter Table  Saves the parameter estimates, standard errors, and t-ratios in a data table. This option is available only when a Group variable is specified on the platform launch window.

Plot Actual by Predicted  Plots actual \( Y \) values on the vertical axis and predicted \( Y \) values on the horizontal axis.

Plot Residual by Predicted  Plots the residuals on the vertical axis and the predicted \( Y \) values on the horizontal axis.
Profiler  Shows or hides a profiler of the fitted prediction function. The derivatives are derivatives of the prediction function with respect to the X variable. For more information about profilers, see Profilers.

Save Formulas  Contains options for saving a variety of formula columns in the data table.

  Save Prediction Formula  Saves the prediction equation.

  Save Std Error of Predicted  Saves the standard error of the predicted values.

  Save Parametric Prediction Formula  Saves the prediction equation in parametric form. This is helpful if you want to use the fitted model in the custom Nonlinear platform.

  Save Residual Formula  Saves the residuals.

  Save Studentized Residual Formula  Saves the studentized residual formula, a standard residual that is divided by its estimated standard deviation.

  Save First Derivative  Saves the derivative of the prediction function with respect to the X variable.

  Save Std Error of First Derivative  Saves the equation of the standard error of the first derivative.

  Save Inverse Prediction Formula  Saves the equation for predicting X from Y.

Custom Inverse Prediction  Predicts an X value for a specific Y value. For more information about inverse prediction, see Fitting Linear Models.

Remove Fit  Removes the model report, the entry from the Model Comparison report, and the fitted line from the plot.

Test Parallelism

The Test Parallelism option provides an analysis for testing if the fitted models between groups have the same shape, but are shifted along the X axis (Figure 14.9). In the Bioassay example, the curve for drug formulation B is shifted to the left of the other three curves. However, you do not know whether the curves still have the same shape (are parallel), or if formulation B is different. The Parallelism Test tells us if the shapes for the different drug formulations have similar shapes and are shifted along the horizontal axis. Select Test Parallelism from the fitted model’s red triangle menu to add the report.
The report gives the following results:

**Test Results**  Gives the results of an $F$ Test and a Chi-Square Test for parallelism. The tests compare the error sums-of-squares for a full model (Full SSE) and a reduced model (Fit SSE). The full model gives each group different parameters. The reduced model forces the groups to share every parameter except for the inflection point. A small $p$-value indicates that the group models are significantly different from one another. Therefore, the reduced model with shared parameters is insufficient and the full model should be used. In Figure 14.9, the $p$-value is greater than 0.05, indicating that there is not enough evidence to conclude that differences exist between the curves. In this case, the reduced model with shared parameters is appropriate.

The fit statistics are calculated as follows:

**F Ratio**  $\frac{(\text{Fit SSE} - \text{Full SSE}) / \text{NDF}}{\text{Full SSE} / \text{DDF}}$

**ChiSquare**  $\text{Fit SSE} - \text{Full SSE}$
**Parallel Fit Parameter Estimates**  Gives the parameter estimates under the reduced model (same parameters, except for inflection point). A plot of the fitted curves under the reduced model is provided. The inflection point for drug formulation B is much lower than that of the other three drug formulations.

**Relative Potencies**  Gives the potency and relative potency for each level of the grouping variable. The potency is $10^{\text{EC}_{50}}$, where $\text{EC}_{50}$ is the concentration at which the response half way between baseline and maximum is obtained. For the Logistic 2P, 3P, and 4P, the potency is $10^{\text{inflection point parameter}}$. The relative potency is the potency of one level of the grouping variable divided by the potency of another level. For example, in Figure 14.10, the relative potency of test A to standard is $\text{Potency}_{\text{test A}}/\text{Potency}_{\text{standard}}$.

**Figure 14.10** Relative Potencies by Group

In the **Relative Potency versus standard** panel from Figure 14.10, note that the relative potencies for drug formulations A and C are nearly one. This indicates that their potencies are similar to that of the standard formulation. The potency for drug formulation B is lower than that of the standard. This means that drug formulation B increases in toxicity as a function of concentration faster than the standard.

In the parallelism test, the curves are parallel, which enables you to calculate relative potencies. Based on the relative potencies, you conclude that formulation B is more potent than the other drug formulations. Taken with the prior findings, drug formulation B appears to be more toxic.
Compare Parameter Estimates

The Compare Parameter Estimates report gives results for testing the equality of parameters across the levels of the grouping variable. There is an Analysis of Means (ANOM) report for each parameter, which tests whether the parameters are equal to an overall mean. If the result for a parameter exceeds the decision limits, then the parameter is different from the overall mean. Figure 14.11 shows the ANOM report for growth rate estimates. Select Compare Parameter Estimates from the fitted model’s red triangle menu to add the report.

**Figure 14.11** Parameter Comparison for Growth Rate Estimates

The Analysis of Means red triangle menu contains the following options:

**Set Alpha Level**  Sets the alpha level for the test.

**Show Summary Report**  Shows or hides a report containing the parameter estimates, the decision limits, and whether the parameter exceeded the limits.

**Display Options**  Contains options for showing or hiding decision limits, shading, and the center line. Also contains options for changing the appearance of the points.

For more information about the Analysis of Means report, see Basic Analysis.

Equivalence Test

The Equivalence Test report gives an analysis for testing the equivalence of models across levels of the grouping variable (Figure 14.12). After selecting the option, you specify the level of the grouping variable that you want to test against every other level. There is a report for every level versus the chosen level. Select Equivalence Test from the fitted model’s red triangle menu to add the report.
The equality of the parameters is tested by analyzing the ratio of the parameters. The default decision lines are placed at ratio values of 0.8 and 1.25, representing a 25% difference.

If all of the confidence intervals are inside the decision lines, then the two groups are practically equal. If a single interval falls outside the lines (Figure 14.12), then you cannot conclude that the groups are equal. The inflection point for drug formulation B is lower than the standard, which agrees with the previous findings.

**Figure 14.12** Equivalence Test

The inflection point is outside the decision limits, so you cannot conclude that the groups are equal.

The Equivalence red triangle menu contains the following options:

**Set Alpha Level**  Sets the alpha level for the test. The default value is 0.05.

**Set Decision Lines**  Changes the decision limits for the ratio. The default values are set at 0.8 and 1.25, representing a 25% difference.

**Show Summary Report**  Shows or hides a report containing the parameter estimates, the decision limits, and whether the parameter exceeded the limits.

**Display Options**  Contains options for showing or hiding decision limits, shading, and the center line. Also contains options for changing the appearance of the points. For additional formatting options, right-click the graph and select **Customize**.

The Nonlinear platform is a good choice for models that are *nonlinear* in the parameters. This chapter focuses on custom nonlinear models, which include a model formula and parameters to be estimated. Use the default least squares loss function or a custom loss function to fit models. The platform minimizes the sum of the loss function across the observations.

**Figure 15.1** Example of a Custom Nonlinear Fit

The Nonlinear platform also provides predefined models, such as polynomial, logistic, Gompertz, exponential, peak, and pharmacokinetic models. See the "Fit Curve" chapter on page 223.

**Note:** Some models are *linear* in the parameters (for example, a quadratic or other polynomial) or can be transformed to be such (for example, when you use a log transformation of \( x \)). The Fit Model or Fit Y by X platforms are more appropriate in these situations. For more information about these platforms, see *Fitting Linear Models* and *Basic Analysis*.

Example of Fitting a Custom Model

To fit a custom model, you must first create a model column with initial parameter estimates. This method does require a few more steps than fitting a built-in model, but it does allow any nonlinear model to be fit. Also, you can provide a custom loss function, and specify several other options for the fitting process.

This section provides an example of creating the formula column for a model, and fitting the model in the Nonlinear platform. The data is in the US Population.jmp data table. The response variable is the population (in millions) of the Unites States and the predictor is the year.

2. Create a new column called Model.
3. Right-click the Model column and select Column Properties > Formula.
   The Formula Editor appears.
4. Select Parameters from the list below the list of columns.
5. Select New Parameter.
6. Type B0 for Name.
7. Type 3.9 for Value. This is the initial estimate of the parameter.
8. Click OK.
10. Type B1 for Name and enter 0.022 for Value.
11. Click OK.
12. Enter the model formula using the Formula Editor functions, the column year, and the parameters.

Figure 15.2 Completed Model Formula

Tip: Click the gray triangle next to Transcendental to find the Exp command.

13. Click OK.
15. Assign Model to the X, Predictor Formula role.
16. Assign pop to the Y, Response role.
17. Click **OK**.

18. Click **Go** on the Control Panel to fit the model.

**Figure 15.3** Plot and Solution Report

![Solution report and plot](image)

The final parameter estimates are shown in the **Solution** report, along with other fit statistics. The fitted model is shown on the plot.

**Parameters for Models with a Grouping Variable**

In the formula editor, when you add a parameter, note the check box for **Expand Into Categories, selecting column**. This option is used to add several parameters (one for each level of a categorical variable for example) at once. When you select this option, a dialog appears that enables you to select a column. After selection, a new parameter appears in the Parameters list with the name `D_column`, where `D` is the name that you gave the parameter. When you use this parameter in the formula, a Match expression is inserted, containing a separate parameter for each level of the grouping variable.
Launch the Nonlinear Platform

To launch the Nonlinear platform, select Analyze > Specialized Modeling > Nonlinear.

Figure 15.4  Nonlinear Platform Launch Window

The Nonlinear platform launch window has the following features:

**Y, Response**  Select the Y variable.

**X, Predictor Formula**  Select either the X variable or a column containing the model formula with parameters.

**Note:** If you select a column that does not contain a model formula with parameters and you also do not specify a custom formula, the Fit Curve platform is launched instead.

**Note:** If you select a formula column that contains a parameter list item that does not have an assignment, JMP automatically sets that parameter to zero and displays a message in the log.

**Group**  Specify a grouping variable. The fitted model has separate parameters for each level of the grouping variable. This enables you to compare fitted models and estimated parameters across the levels of the grouping variable.
Note: If the formula does not have separate parameters for each group level, the Group variable is ignored by JMP.

Weight Specify a variable containing the weights of observations.
Freq Specify a variable representing the frequency of an observation.
Loss Specify a formula column giving a loss function.
By Specify a variable to perform a separate analysis for every level of the variable.

Model Library Launches the Model Library tool, which helps you choose initial values to create a formula column. See “Create a Formula Using the Model Library” on page 260.

Options for fitting custom formulas If you specify a column in the X, Predictor Formula role that does not contain a model formula with parameters, you can use this option to create a custom formula. In the Predictor field, specify parameters, parameter values, and a custom formula that uses the selected X variable. Then, click the Reset button and launch the platform.

Numeric Derivatives Only Uses numeric derivatives only. This option is useful when you have a model for which it is too messy to take analytic derivatives. It can also be valuable in obtaining convergence in tough cases. This option is used only when a formula column is provided in the X, Predictor Formula role.

Expand Intermediate Formulas Tells JMP that if an ingredient column to the model is a column that itself has a formula, to substitute the inner formula, as long as it refers to other columns. To prevent an ingredient column from expanding, use the Other column property with a name of “Expand Formula” and a value of 0. This option is used only when a formula column is provided in the X, Predictor Formula role.

The Nonlinear Fit Report

The initial Nonlinear Fit report includes the following items, shown in Figure 15.5.

Control Panel Provides options for controlling the fitting process.

Go Starts the fitting process.
Stop Stops the fitting process.
Step Proceeds through the fitting process one iteration at a time.
Reset Resets the editable values into the formula, resets the iteration values, and calculates the SSE at these new values.
**Criterion**  Shows iteration measures from the fitting process.

**Current**  Shows the current value of each Criterion.

**Stop Limit**  Sets limits on the measures listed under Criterion.

**Plot**  Shows a plot of the X and Y variables for models with only one X variable. The model based on the current values is shown on the plot. To change the current values of the parameters, use the sliders or edit boxes beneath the plot.

**Figure 15.5** Initial Nonlinear Fit Report

After you click **Go** to fit a model, the report includes the following additional items, shown in Figure 15.6.

**Save Estimates**  Saves the current parameter values to the parameters in the formula column.
Confidence Limits  Computes confidence intervals for all parameters. The intervals are profile likelihood confidence intervals, and are shown in the Solution report. The confidence limit computations involve a new set of iterations for each limit of each parameter, and the iterations often do not find the limits successfully. The Edit Alpha and Convergence Criterion options are for the confidence interval computations. For more information about the Goal SSE for CL, see “Profile Likelihood Confidence Limits” on page 272.

Solution  Shows the parameters estimates and other statistics.

SSE  Shows the residual sum of squared errors. SSE is the objective that is to be minimized. If a custom loss function is specified, this is the sum of the loss function.

DFE  Shows the degrees of freedom for error, which is the number of observations used minus the number of parameters fitted.

MSE  Shows the mean squared error. It is the estimate of the variance of the residual error, which is the SSE divided by the DFE.

RMSE  Estimates the standard deviation of the residual error, which is square root of the MSE.

RSquare  (Available only if the model has an intercept and the sum of the residuals is close to zero.) Shows the RSquare value.

Parameter  Lists the names that you gave the parameters in the fitting formula.

Estimate  Lists the parameter estimates produced. Keep in mind that with nonlinear regression, there might be problems with this estimate even if everything seems to work.

ApproxStdErr  Lists the approximate standard error, which is computed analogously to linear regression. It is formed by the product of the RMSE and the square root of the diagonals of the derivative cross-products matrix inverse.

Note: If the number of observations is less than or equal to the number of parameters in the fitted model, ApproxStdErr is not reported.

Lower CL and Upper CL  Shows the confidence limits for the parameters. They are missing until you click the Confidence Limits on the Control Panel. For more information about the confidence intervals, see “Profile Likelihood Confidence Limits” on page 272.

Excluded Data  Shows a report showing fit statistics for excluded rows. This is useful for validating the model on observations not used to fit the model. You can use this feature in conjunction with the Remember Solution option to change the exclusions, and get a new report reflecting the different exclusions.
**Correlation of Estimates**  Displays the correlations between the parameter estimates.

**Covariance of Estimates**  Displays the covariances between the parameter estimates.

**Figure 15.6**  Fitted Model Report
Nonlinear Platform Options

The Nonlinear Fit red triangle menu contains the following options:

**Parameter Bounds**  Sets bounds on the parameters. When the option is selected, editable boxes appear in the Control Panel. Unbounded parameters are signified by leaving the field blank.

**Plot**  Shows or hides a plot of the $X$ and $Y$ variables for models with only one $X$ variable. The model shown on the plot is based on the current values of the parameters. To change the current values of the parameters, use the sliders or edit boxes beneath the plot. If you specify a Group variable at launch, then a curve shows for each group.

**Iteration Options**  Specifies options for the fitting algorithm.

- **Iteration Log**  Records each step of the fitting process in a new window.
- **Numeric Derivatives Only**  Useful when you have a model that is too messy to take analytic derivatives for. It can also be valuable in obtaining convergence in tough cases.
- **Expand Intermediate Formulas**  Tells JMP that if an ingredient column to the formula is a column that itself has a formula, to substitute the inner formula, as long as it refers to other columns. To prevent an ingredient column from expanding, use the Other column property with a name of “Expand Formula” and a value of 0.
- **Newton**  Specifies whether Gauss-Newton (for regular least squares) or Newton-Raphson (for models with loss functions) is the optimization method.
- **QuasiNewton SR1**  Specifies QuasiNewton SR1 as the optimization method.
- **QuasiNewton BFGS**  Specifies QuasiNewton BFGS as the optimization method.
- **Accept Current Estimates**  Tells JMP to produce the solution report with the current estimates, even if the estimates did not converge.
- **Show Derivatives**  Shows the derivatives of the nonlinear formula in the JMP log. See “Notes Concerning Derivatives” on page 274, for technical information about derivatives.
- **Unthreaded**  Runs the iterations in the main computational thread. In most cases, JMP does the computations in a separate computational thread. This improves the responsiveness of JMP while doing other things during the nonlinear calculations. However, there are some isolated cases (models that have side effects that call display routines, for example) that should be run in the main thread, so this option should be turned on.

**Profilers**  Provides various profilers for viewing response surfaces.
Profiler  Shows the Prediction Profiler. The Profiler lets you view vertical slices of the surface across each $x$-variable in turn, as well as find optimal values of the factors.

Contour Profiler  Shows the Contour Profiler. The Contour profiler lets you see two-dimensional contours as well as three dimensional mesh plots.

Surface Profiler  Creates a three-dimensional surface plot. This option is available only for models with two or more $X$ variables.

Parameter Profiler  Shows the Prediction Profiler and profiles the SSE or loss as a function of the parameters.

Parameter Contour Profiler  Shows the Contour Profiler and contours the SSE or loss as a function of the parameters.

Parameter Surface Profiler  Creates a three-dimensional surface plot and profiles the SSE or loss as a function of the parameters. This option is available only for models with two or more parameters.

SSE Grid  Create a grid of values around the solution estimates and compute the error sum of squares for each value. The solution estimates should have the minimum SSE. When the option is selected, the Specify Grid for Output report is shown with these features:

Parameter  Lists the parameters in the model.

Min  Displays the minimum parameter values used in the grid calculations. By default, Min is the solution estimate minus 2.5 times the ApproxStdErr.

Max  Displays the maximum parameter value used in the grid calculations. By default, Max is the solution estimate plus 2.5 times the ApproxStdErr.

Number of Points  Gives the number of points to create for each parameter. To calculate the total number of points in the new grid table, multiply all the Number of Points values. Initially Number of Points is 11 for the first two parameters and 3 for the rest. If you specify new values, use odd values to ensure that the grid table includes the solution estimates. Setting Number of Points to 0 for any parameter records only the solution estimate in the grid table.

When you click Go, JMP creates the grid of points in a new table. A highlighted row marks the solution estimate row if the solution is in the table.

Revert to Original Parameters  Resets the platform to the original parameter values (the values given in the formula column parameters).

Remember Solution  Creates a report called Remembered Models, which contains the current parameter estimates and summary statistics. Results of multiple models can be remembered and compared. This is useful if you want to compare models based on different parameter restrictions, or models fit using different options. Click the radio
button for a particular model to display that model in the Plot and the parameter estimates in the Control Panel.

**Custom Estimate**  Gives an estimate of a function of the parameters. You provide an expression involving only parameters. JMP calculates the expression using the current parameter estimates, and also calculates a standard error of the expression using a first-order Taylor series approximation.

**Custom Inverse Prediction**  Estimates the X value for a given Y value. It also calculates a standard error for the estimated X. JMP must be able to invert the model. The standard error is based on the first-order Taylor series approximation using the inverted expression. The confidence interval uses a t-quantile with the standard error, and is a Wald interval.

**Show Prediction Expression**  Shows the prediction model or the loss function at the top of the report.

**Save Pred Confid Limits**  Saves asymptotic confidence limits for the model prediction. This is the confidence interval for the average Y at a given X value.

**Save Indiv Confid Limits**  Saves asymptotic confidence limits for an individual prediction. This is the confidence interval for an individual Y value at a given X value.

**Save Formulas**  Gives options for saving model results to data table columns:

- **Save Prediction Formula**  Saves the prediction formula with the current parameter estimates.
- **Save Std Error of Predicted**  Saves the standard error for a model prediction. This is the standard error for predicting the average Y for a given X. The formula is of the form $\text{Sqrt(VecQuadratic(matrix1, vector1))}$. matrix1 is the covariance matrix associated with the parameter estimates, and vector1 is a composition of the partial derivatives of the model with respect to each parameter.
- **Save Std Error of Individual**  Saves the standard error for an individual prediction. This is the standard error for predicting an individual Y value for a given X value. The formula is of the form $\text{Sqrt(VecQuadratic(matrix1, vector1)+mse)}$. matrix1 is the covariance matrix associated with the parameter estimates, vector1 is a composition of the partial derivatives of the model with respect to each parameter, and mse is the estimate of error variance.
- **Save Residual Formula**  Saves the formula for computing the residuals.
- **Save Pred Confid Limit Formula**  Saves the formula to calculate the confidence interval for a model prediction. This is a confidence interval for the average Y for a given X.
- **Save Indiv Confid Limit Formula**  Saves the formula to calculate the confidence interval for an individual prediction. This is a confidence interval for an individual Y for a given X.
**Save Inverse Prediction Formula**  Saves formulas for the inverse of the model, the standard error of an inverse prediction, and the standard error of an individual inverse prediction.

**Save Specific Solving Formula**  Equivalent to Save Inverse Prediction Formula in simple cases. However, this command allows the formula to be a function of several variables and allows expressions to be substituted. This feature works only for solving easily invertible operators and functions that occur just once in the formula.

After selecting this command, a dialog appears that enables you to select the variable to solve for. You can also edit the names of the columns in the resulting table. You can also substitute values for the names in the dialog. In these cases, the formula is solved for those values.

**Note:** The standard errors, confidence intervals, and hypothesis tests are correct only if least squares estimation is done, or if maximum likelihood estimation is used with a proper negative log-likelihood.

**Save Estimates to Table**  Saves the parameter estimates to a new data table.
Create a Formula Using the Model Library

The Model Library can assist you in creating the formula column with parameters and initial values. Click the Model Library button on the Nonlinear launch window to open the library. Select a model in the list to see its formula in the Formula box.

Figure 15.7 Nonlinear Model Library Dialog

Click Show Graph to show a 2-D theoretical curve for one-parameter models and a 3-D surface plot for two-parameter models. No graph is available for models with more than two explanatory (X) variables. On the graph window, change the default initial values of parameters using the slider, or clicking and entering values in directly.
The **Reset** button sets the initial values of parameters back to their default values.

Click **Show Points** to overlay the actual data points to the plot. The dialog in Figure 15.9 opens, asking you to assign columns into $X$ and $Y$ roles, and an optional Group role. The Group role allows for fitting the model to every level of a categorical variable. If you specify a Group role here, also specify the Group column on the platform launch window.

**Figure 15.9 Select Roles**

For most models, the starting values are constants. Showing points enables you to adjust the parameter values to see how well the model fits for different values of the parameters. For the US population example, the points are shown in Figure 15.10.
Create a Formula Using the Model Library

Figure 15.10 Show Points

Clicking Make Formula at this point (after using Show Points) creates a new data table column named after the model that you chose from the Model Library. This column has the formula as a function of the latest parameter starting values.

Note: If you click Make Formula before using the Show Graph or Show Points buttons, you are asked to provide the X and Y roles, and an optional Group role (Figure 15.9). After that, you are brought back to the plot so that you have the opportunity to adjust the parameters starting values if desired. At that point click Make Formula again to create the new column.

Once the formula is created in the data table, continue the analysis by assigning the new column as the X, Predictor Formula in the Nonlinear launch dialog.

Customize the Nonlinear Model Library

The Model Library is created by a built-in script named NonlinLib.jsl, located in the Resources/Builtins folder in the folder that contains JMP (Windows) or in the Application Package (macOS). You can customize the nonlinear library script by modifying this script.

To add a model, you must add three lines to the list named Listofmodellist#. These three lines are actually a list themselves, which consists of the following three parts.

- Model name, a quoted string
- Model formula, an expression
• Model scale

For example, suppose you want to add a model called “Simple Exponential Growth” that has the form

\[ y = b_1 e^{kx} \]

Add the following lines to the NonlinLib.jsl script

```
{ /* Simple Exponential Growth */
  "Simple Exponential Growth",
  Expr(Parameter({b1=2, k=0.5}, b1*exp(k * :X))),
  lowx = -1; highx = 2; lowy = 0; highy = 2},
```

Some things to note:

• The first line is simply an open bracket (starting the list) and an optional comment. The second line is the string that is displayed in the model library window.

• The values of lowx, highx, logy, and highy specify the initial window for the theoretical graph.

• There is a comma as the last character in the example above. If this is the final entry in the Listofmodellist# list, the comma can be omitted.

• If the model uses more than two parameters, replace the last line (containing the graph limits) with the quoted string “String Not Available”.

To delete a model, delete the corresponding three-lined list from the Listofmodellist# list.

---

**Additional Examples**

• “Example of Maximum Likelihood: Logistic Regression”
• “Example of a Probit Model with Binomial Errors: Numerical Derivatives”
• “Example of a Poisson Loss Function”
• “Example of Setting Parameter Limits”

---

**Example of Maximum Likelihood: Logistic Regression**

This example shows how to use the Nonlinear platform to minimize a loss function. The loss function is the negative of a log-likelihood function, thus producing maximum likelihood estimates.
The Logistic w Loss.jmp data table in the Nonlinear Examples sample data folder has an example for fitting a logistic regression using a loss function. The Y column contains ones for events and zeros for non-events. The Model Y column has the linear model, and the Loss column has the loss function. In this example, the loss function is the negative log-likelihood for each observation, or the negative log of the probability of getting the observed response.

Run the model by following the steps below:

1. Select Help > Sample Data Library and open Nonlinear Examples/Logistic w Loss.jmp.
2. Select Analyze > Specialized Modeling > Nonlinear.
3. Assign Model Y to the X, Predictor Formula role.
4. Assign Loss to the Loss role.

Figure 15.11 Nonlinear Launch Window

5. Click OK.

The Nonlinear Fit Control Panel appears.
6. Click Go.

The parameter estimates are shown in the Solution report.

**Example of a Probit Model with Binomial Errors: Numerical Derivatives**

The Ingots2.jmp sample data table includes the numbers of ingots tested for readiness after different treatments of heating and soaking times. The response variable, NReady, is binomial, depending on the number of ingots tested (Ntotal) and the heating and soaking times. Maximum likelihood estimates for parameters from a probit model with binomial errors are obtained using:

- numerical derivatives
- the negative log-likelihood as a loss function
- the Newton-Raphson method.
The average number of ingots ready is the product of the number tested and the probability that an ingot is ready for use given the amount of time it was heated and soaked. Using a probit model, the P column contains the model formula:

$$\text{Normal Distribution}(b_0 + b_1 \times \text{Heat} + b_2 \times \text{Soak})$$

The argument to the Normal Distribution function is a linear model of the treatments.

To specify binomial errors, the loss function, Loss, has the formula

$$-(N_{\text{ready}} \times \log(p) + (N_{\text{total}} - N_{\text{ready}}) \times \log(1 - p))$$

Follow these steps to fit the model:

1. Select Help > Sample Data Library and open Ingots2.jmp.
2. Select Analyze > Specialized Modeling > Nonlinear.
3. Assign P to the X, Predictor Formula role,
4. Assign Loss to the Loss role.
5. Select the Numeric Derivatives Only option.
6. Click OK.
7. Click Go.

The platform used the Numerical SR1 method to obtain the parameter estimates shown in Figure 15.14.

Solved By: Numerical SR1

**Example of a Poisson Loss Function**

A Poisson distribution is often used to model count data.

$$P(Y = n) = e^{-\mu} \frac{\mu^n}{n!}, \quad n = 0, 1, 2, \ldots$$
where \( \mu \) can be a single parameter, or a linear model with many parameters. Many texts and papers show how the model can be transformed and fit with iteratively reweighted least squares (Nelder and Wedderburn 1972). However, in JMP it is more straightforward to fit the model directly. For example, McCullagh and Nelder (1989) show how to analyze the number of reported damage incidents caused by waves to cargo-carrying vessels.

The data are in the Ship Damage.jmp sample data table. The model formula is in the model column, and the loss function (or negative log-likelihood) is in the Poisson column. To fit the model, follow the steps below:

1. Select Help > Sample Data Library and open Ship Damage.jmp.
2. Select Analyze > Specialized Modeling > Nonlinear.
3. Assign model to the X, Predictor Formula role.
4. Assign Poisson to the Loss role.
5. Click OK.
6. Set the Current Value (initial value) for \( b_0 \) to 1, and the other parameters to 0.

**Figure 15.15** Enter New Parameters

7. Click Go.
8. Click the Confidence Limits button.

The Solution report appears. The results include the parameter estimates and confidence intervals, and other summary statistics.

Note: The standard errors, confidence intervals, and hypothesis tests are correct only if least squares estimation is done, or if maximum likelihood estimation is used with a proper negative log-likelihood.

Example of Setting Parameter Limits

The Fit Curve personality enables you to fit a model and then use the prediction equation in the full personality of the Nonlinear platform. This method requires more steps and user input but allows any nonlinear model to be fit.

Complete “Example Using the Fit Curve Platform” on page 225 in the “Fit Curve” chapter to fit the model. This example shows how to save the prediction formula from Fit Curve and then set parameter limits in Nonlinear.

1. Click the Logistic 4P red triangle and select **Save Formulas > Save Parametric Prediction Formula**.

   A new column named Toxicity Predictor appears in the data table.

2. Select **Analyze > Specialized Modeling > Nonlinear**.

3. Assign Toxicity to the **Y, Response** role.

4. Assign Toxicity Predictor to the **X, Predictor Formula** role.

5. Assign Formulation to the **Group** role.

6. Click **OK**.

   The Nonlinear Fit window appears. In the Control Panel, parameter values and locking options are shown. The letters listed before each parameter correspond to variables from the Prediction Model in the Fit Curve function.
Tip: You can lock parameters if you know the values from prior information.

7. Click the Nonlinear Fit red triangle and select **Parameter Bounds**.
   Options for setting the lower and upper parameters appear next to the parameters.

8. Set the lower bounds for the parameters as shown in Figure 15.18. You know from prior experience that the maximum toxicity of the drug is at least 1.1.
Figure 15.18 Setting Parameter Bounds

9. Click Go.

The final parameter estimates are shown in the Solution report, along with other fit statistics. The fitted model is shown on the plot.
Figure 15.19 Nonlinear Fit Plot and Parameter Estimates

Options below the plot allow for adjusting parameter limits and estimates.

Statistical Details for the Nonlinear Platform

- “Profile Likelihood Confidence Limits”
- “How Custom Loss Functions Work”
- “Notes Concerning Derivatives”
- “Notes on Effective Nonlinear Modeling”
Profile Likelihood Confidence Limits

The upper and lower confidence limits for the parameters are based on a search for the value of each parameter after minimizing with respect to the other parameters. The search looks for values that produce an SSE greater by a certain amount than the solution’s minimum SSE. The goal of this difference is based on the $F$-distribution. The intervals are sometimes called likelihood confidence intervals or profile likelihood confidence intervals (Bates and Watts 1988; Ratkowsky 1990).

Profile confidence limits all start with a goal SSE. This is a sum of squared errors (or sum of loss function) that an $F$ test considers significantly different from the solution SSE at the given alpha level. If the loss function is specified to be a negative log-likelihood, then a Chi-square quantile is used instead of an $F$ quantile. For each parameter’s upper confidence limit, the parameter value is increased until the SSE reaches the goal SSE. As the parameter value is moved up, all the other parameters are adjusted to be least squares estimates subject to the change in the profiled parameter. Conceptually, this is a compounded set of nested iterations. Internally there is a way to do this with one set of iterations developed by Johnston and DeLong. See the SAS/ETS User’s Guide (SAS Institute Inc. 2020).

Figure 15.20 shows the contour of the goal SSE or negative likelihood, with the least squares (or least loss) solution inside the shaded region:

- The asymptotic standard errors produce confidence intervals that approximate the region with an ellipsoid and take the parameter values at the extremes (at the horizontal and vertical tangents).
- Profile confidence limits find the parameter values at the extremes of the true region, rather than the approximating ellipsoid.

Figure 15.20  Diagram of Confidence Limits for Parameters

Likelihood confidence intervals are more trustworthy than confidence intervals calculated from approximate standard errors. If a particular limit cannot be found, computations begin for the next limit. When you have difficulty obtaining convergence, try the following:

- use a larger alpha, resulting in a shorter interval, more likely to be better behaved
• relax the confidence limit criteria.

How Custom Loss Functions Work

The nonlinear facility can minimize or maximize functions other than the default sum of squares residual. This section shows the mathematics of how it is done.

Suppose that \( f(\beta) \) is the model. Then the Nonlinear platform attempts to minimize the sum of the loss functions defined as follows:

\[
L = \sum_{i=1}^{n} \rho(f(\beta))
\]

The loss function \( \rho(\bullet) \) for each row can be a function of other variables in the data table. It must have nonzero first- and second-order derivatives. The default \( \rho(\bullet) \) function, squared-residuals, is

\[
\rho(f(\beta)) = (y - f(\beta))^2
\]

To specify a model with a custom loss function, construct a variable in the data table and build the loss function. After launching the Nonlinear platform, select the column containing the loss function as the loss variable.

The nonlinear minimization formula works by taking the first two derivatives of \( \rho(\bullet) \) with respect to the model, and forming the gradient and an approximate Hessian as follows:

\[
\frac{\partial L}{\partial \beta_j} = \sum_{i=1}^{n} \frac{\partial \rho(f(\beta))}{\partial f} \frac{\partial f}{\partial \beta_j}
\]

\[
\frac{\partial^2 L}{\partial \beta_j \partial \beta_k} = \sum_{i=1}^{n} \left[ \frac{\partial^2 \rho(f(\beta))}{\partial (\partial f)^2} \frac{\partial f}{\partial \beta_j} \frac{\partial f}{\partial \beta_k} + \frac{\partial \rho(f(\beta))}{\partial f} \frac{\partial^2 f}{\partial \beta_j \partial \beta_k} \right]
\]

If \( f(\bullet) \) is linear in the parameters, the second term in the last equation is zero. If not, you can still hope that its sum is small relative to the first term, and use

\[
\frac{\partial^2 L}{\partial \beta_j \partial \beta_k} \approx \sum_{i=1}^{n} \frac{\partial^2 \rho(f(\beta))}{\partial (\partial f)^2} \frac{\partial f}{\partial \beta_j} \frac{\partial f}{\partial \beta_k}
\]

The second term is probably small if \( \rho \) is the squared residual because the sum of residuals is small. The term is zero if there is an intercept term. For least squares, this is the term that distinguishes Gauss-Newton from Newton-Raphson.
Note: The standard errors, confidence intervals, and hypothesis tests are correct only if least squares estimation is done, or if maximum likelihood estimation is used with a proper negative log-likelihood.

Notes Concerning Derivatives

The nonlinear platform takes symbolic derivatives for formulas with most common operations. This section shows what type of derivative expressions result.

If you open the Negative Exponential.jmp nonlinear sample data example, the actual formula for the Nonlinear column looks something like this:

\[
\text{Parameter}([\{b0=0.5, b1=0.5\}, b0*(1-\text{Exp}(-b1*X))])
\]

The Parameter block in the formula is hidden if you use the formula editor. That is how it is stored in the column and how it appears in the Nonlinear Launch dialog. Two parameters named \(b0\) and \(b1\) are given initial values and used in the formula to be fit.

The Nonlinear platform makes a separate copy of the formula, and edits it to extract the parameters from the expression. Then it maps the references to them to the place where they are estimated. Nonlinear takes the analytic derivatives of the prediction formula with respect to the parameters. If you use the Show Derivatives command, you get the resulting formulas listed in the log, like this:

Prediction Model:

\[
b0 * \text{First}(T#1=1-(T#2=\text{Exp}(-b1*X)), T#3=-(1*T#2*X))
\]

The Derivative of Model with respect to the parameters is:

\[
\{T#1, T#3*b0\}
\]

The derivative facility works like this:

- In order to avoid calculating subexpressions repeatedly, the prediction model is threaded with assignments to store the values of subexpressions that it needs for derivative calculations. The assignments are made to names like \(T#1\), \(T#2\), and so on.
- When the prediction model needs additional subexpressions evaluated, it uses the First function, which returns the value of the first argument expression, and also evaluates the other arguments. In this case additional assignments are needed for derivatives.
- The derivative table itself is a list of expressions, one expression for each parameter to be fit. For example, the derivative of the model with respect to \(b0\) is \(T#1\); its thread in the prediction model is \(1-(\text{Exp}(-b1*X))\). The derivative with respect to \(b1\) is \(T#3*b0\), which is \(-(1*\text{Exp}(-b1*X))*b0\) if you substitute in the assignments above. Although many optimizations are made, it does not always combine the operations optimally. You can see this by the expression for \(T#3\), which does not remove a double negation.
If you specify a loss function, then the formula editor takes derivatives with respect to parameters, if it has any. And it takes first and second derivatives with respect to the model, if there is one.

If the derivative mechanism does not know how to take the analytic derivative of a function, then it takes numerical derivatives, using the `NumDeriv` function. If this occurs, the platform shows the delta that it used to evaluate the change in the function with respect to a delta change in the arguments. You might need to experiment with different delta settings to obtain good numerical derivatives.

**Tips**

There are always many ways to represent a given model, and some ways behave much better than other forms. Ratkowsky (1990) covers alternative forms in his text.

If you have repeated subexpressions that occur several places in a formula, then it is better to make an assignment to a temporary variable. Then refer to it later in the formula. For example, one of the model formulas above was this:

```plaintext
If(Y==0, Log(1/(1+Exp(model))), Log(1 - 1/(1 + Exp(model))));
```

This could be simplified by factoring out an expression and assigning it to a local variable:

```plaintext
temp=1/(1+Exp(model));
If(Y==0, Log(temp), Log(1-temp));
```

The derivative facility can track derivatives across assignments and conditionals.

**Notes on Effective Nonlinear Modeling**

We strongly encourage you to *center polynomials*.

Anywhere you have a complete polynomial term that is linear in the parameters, it is always good to center the polynomials. This improves the condition of the numerical surface for optimization. For example, if you have an expression like the following:

\[
a_1 + b_1x + c_1x^2
\]

you should transform it to

\[
a_2 + b_2(x - \bar{x}) + c_2(x - \bar{x})^2
\]

The two models are equivalent, apart from a transformation of the parameters, but the second model is far easier to fit if the model is nonlinear.
The transformation of the parameters is easy to solve.

\[
\begin{align*}
    a_1 &= a_2 - b_2 \bar{x} + c_2 \bar{x}^2 \\
    b_1 &= b_2 - 2c_2 \bar{x} \\
    c_1 &= c_2
\end{align*}
\]

If the number of iterations still goes to the maximum, increase the maximum number of iterations or relax one of the convergence criteria.

There is really no one omnibus optimization method that works well on all problems. JMP has options like **Newton**, **QuasiNewton BFGS**, **QuasiNewton SR1**, and **Numeric Derivatives Only** to expand the range of problems that are solvable by the Nonlinear Platform.

If the default settings are unable to converge to the solution for a particular problem, using various combinations of these settings to increase the odds of obtaining convergence.

Some models are very sensitive to starting values of the parameters. Working on new starting values is often effective. Edit the starting values and click **Reset** to see the effect. The plot often helps. Use the sliders to visually modify the curve to fit better. The parameter profilers can help, but might be too slow for anything but small data sets.
The Functional Data Explorer platform is available only in JMP Pro.

The Functional Data Explorer (FDE) platform is designed for data that are functions, signals, or series. It can be used as an exploratory data analysis tool or as a dimension-reduction technique. In the case of dimension reduction, the FDE platform converts functional data into a form that can be analyzed in another JMP platform.

Data preprocessing tools are available in the FDE platform, including several types of transformations for output data and alignments for input data. A functional model is created by fitting a B-spline, P-spline, or Fourier basis model to the data. When a model is fit, functional principal components analysis (functional PCA) is automatically performed on the functional model. Results from the functional PCA, such as the functional principal component scores, are saved to a separate data table for feature extraction or dimension reduction.

Overview of the Functional Data Explorer Platform

Functional data can be defined as data that are recorded over a continuous domain, where a set of measurements form a curve or image. Often, the domain is time and the sets of measurements are defined by an ID variable. A functional data observation for ID level \( i \) at a specific point \( t \) on the domain is written as \( f_i(t) \). The Functional Data Explorer platform enables you to explore and analyze functional data.

The form of functional data can be dense or sparse. Dense functional data occur when observations are on the same equally spaced grid of points for all levels of the ID variable. Sparse functional data occur when ID levels have different numbers of observations that are unequally spaced across the domain. The Functional Data Explorer platform can handle both forms of functional data.

Although functional data can be expressed in many ways, it can generally be classified into the following two cases:

- The response of interest, \( f(t) \), has a functional form.
- There are one or more covariates, \( f(t)'s \), that have functional forms. These are sometimes referred to as functional or signal processes.

The Functional Data Explorer platform is useful as an exploratory tool for any type of functional data. However, the strength of the platform is taking many functional processes (that might be associated with a scalar response) and extracting key features to use in further modeling. This can be done by first fitting a functional model to the data using a B-spline, P-spline, or Fourier basis model. Then, a functional principal components analysis (functional PCA) is performed on the functional model. Results from the functional PCA, such as the functional principal component (FPC) scores, are saved and used for feature extraction and analysis in another modeling platform, such as the Generalized Regression personality of the Fit Model platform. Alternatively, you can specify a set of supplementary variables and fit a generalized regression model within the FDE platform to determine how these variables affect the response.

For more information about functional data analysis, see Ramsay and Silverman (2005).
Example of Functional Data Explorer

This example analyzes weekly weather data collected from 16 weather stations across the United States. Run the Weather Station Locations script in the data table to view a map of the locations. Daily temperatures are summarized as weekly averages. Not every weather station has a weekly temperature measurement for every week of the year. This is an example of sparse functional data.

2. Select Analyze > Specialized Modeling > Functional Data Explorer.
3. Select TMAX and click Y, Output.
4. Select Week of Year and click X, Input.
5. Select ID and click ID, Function.
6. Click OK.

Figure 16.2 Initial Functional Data Explorer Report

The initial Functional Data Explorer report contains plots of the raw data, summary statistics, and summary plots for the functional mean and functional standard deviation of the data. There are also buttons for data processing options. Data processing options are
also accessible from the Data Processing red triangle menu. Prior to modeling, it is often a good idea to standardize your output data.

7. Click the **Standardize** button under the Transform menu.

   The data plots and summary statistics are updated based on the specified transformation. Standardized is added to the Steps list.

8. Click the Functional Data Explorer red triangle and select **Models > Fourier Basis**.

**Figure 16.3** Fourier Basis Model Report

The Fourier Basis report includes several reports that contain information about the selected model. In the Model Selection report, the displayed model is the best fitting model according to the BIC fit criterion. For the weather data, the Fourier Basis model that is chosen has a period of 53 and three basis function pairs. Fit statistics and coefficients are also available for the model. Scroll down to view the Functional PCA report.
The Functional PCA report shows that the first two eigenvalues explain nearly 97% of the variation in the data. In the Model Selection graph, click and drag the red dashed line to 3 FPCs to see that the first three eigenvalues explain 99% of the variation in the data. However, the first eigenvalue alone explains 92%. You can use the Score Plot to detect individual functions that are outliers from the other functions. In the Score Plot, most of the locations are clustered together except for the Miami Beach, FL and Greenville, ME
locations. Scroll up to the individual function plots. The function for the Miami Beach location is flatter, indicating less temperature variability than the rest of the locations. The function for the Greenville location has a lower maximum, indicating consistently colder temperatures than the rest of the locations.

**Tip:** Deselect the Label variables option in the Score Plot report to better identify outliers.

Launch the Functional Data Explorer Platform

Launch the Functional Data Explorer platform by selecting **Analyze > Specialized Modeling > Functional Data Explorer**.

**Figure 16.5** Functional Data Explorer Launch Window

For more information about the options in the Select Columns red triangle menu, see **Using JMP**.

The Functional Data Explorer launch window includes tabs for different types of data formats. Select the tab based on your data format.

**Stacked Data Format**  Select for data tables where each row corresponds to a single observation. There are separate columns for the output, input, and ID variables.

**Note:** The Stacked Data Format is the only data format that enables you to specify multiple functional processes. If you assign more than one column to **Y, Output** in the Stacked Data Format tab, each Y variable is analyzed separately. A Fit Group report contains the individual reports for the Y variables.
**Rows as Functions**  Select for data tables where each row corresponds to the full output function for one level of the ID variable. Each column is a level of the input variable.

**Caution:** The Rows as Functions format assumes that your observations are equally spaced in the input domain unless the FDE X column property is used. The FDE X column property enables this data format to use input variables specified in the column names.

**Columns as Functions**  Select for data tables where each column corresponds to the entire output function for one level of the ID variable. Each row corresponds to a level of the input variable.

**Launch Window Options**

**Y, Output**  Assigns the functional process, $f(t)$. There must be at least two observed output values for each level of the ID variable.

**Note:** Functions with fewer than two observed output values are removed from the analysis.

**X, Input**  (Available for Stacked Data Format and Columns as Functions.) Assigns the input variable $t$. If no variable is specified for X, Input, the row number is used. Using the row number assumes that the observations are equally spaced in the input domain.

**ID, Function**  (Available for Stacked Data Format and Rows as Functions.) Assigns the ID variable to each function. For Stacked Data, if no ID variable is assigned all observations are assumed to come from one function.

**Z, Supplementary**  (Available for Stacked Data Format and Rows as Functions.) Assigns one or more supplementary variables. Supplementary variables are not used in any of the calculations in the Functional Data Explorer platform and including them does not affect the results. Supplementary variables are variables you might want to use in future analyses of the results from Functional Data Explorer. When you specify supplementary variables, they are included in a Supplementary column group in the tables that are created by the Save Data and Save Summaries options. These columns retain any column properties that were specified in the original data table. A Functional DOE Analysis option is also made available for the fitted models. See “Functional DOE Analysis” on page 297.

**Freq**  (Available only for Stacked Data Format.) Assigns a column whose numeric values represent a frequency for each row in the analysis. The effect of a frequency column is to expand the data table, so that any row with integer frequency $k$ is expanded to $k$ identical rows.

**Validation**  Assigns an optional numeric column that defines the validation sets. This column should contain only two distinct values. The smaller value defines the training set and the
larger value defines the validation set. If there are more than two values, the smallest value defines the training set and all other values define the validation set. The FDE platform uses the validation column to train and evaluate the model. For more information about validation, see “Validation in JMP Modeling” on page 541 in the “Statistical Details” appendix.

**Note:** The Validation option enables you to hold out complete functions, not a sample of observations from each function. Therefore, all observations that have the same ID value must be classified as either test or validation. You cannot have observations with the same ID value in both sets. For more information about this type of validation column, see “Grouped Validation Column” on page 206 in the “Make Validation Column” chapter.

**Caution:** If you click the Validation button with no columns selected in the Select Columns list, and add a validation column to your data table it will not be a grouped validation column. Instead, use the Make Validation Column Platform, see “Grouped Validation Column” on page 206 in the “Make Validation Column” chapter.

**By** Assigns a column that creates a report consisting of separate analyses for each level of the variable. If more than one By variable is assigned, a separate analysis is produced for each possible combination of the levels of the By variables.
The initial Functional Data Explorer report contains a Data Processing report and a Summaries report.

**Figure 16.6** Initial Functional Data Explorer Report

The Data Processing Report includes an initial data plot of all observations, as well as a grid of individual data plots that correspond to levels of the ID variable. The maximum number of individual plots shown in the grid is twenty. There are drop-down menus and arrows above the grid to interactively select which individual plots are shown. If you specified a validation set, the first drop-down menu enables you to select if the individual plots shown are from the training set or the validation set. If there are more than twenty functions, the second drop-down menu and the arrows enable you to view different groups of plots. All graphs plot the functional response data over the values of the input variable. The Data Processing Report also contains data processing buttons.

The Summaries report contains a table of overall summary statistics, including the number of observations, number of functions, and the overall mean, standard deviation, minimum, and maximum values. There are also plots of the functional mean and functional standard deviation. The functional summary statistics displayed in the plots are computed at each unique value of the input variable.
The Data Processing and Summaries reports are useful for preprocessing your data prior to fitting a model or performing direct functional principal components analysis. There are data cleaning, transformation, and alignment buttons available in the Data Processing Report that correspond to the options in the Data Processing red triangle menu. See “Data Processing Report Options” on page 294. Each time you perform a preprocessing step, the graphs and summary results are automatically updated. You can perform multiple preprocessing steps in sequence. Each step is added to the Steps list of the Data Processing report. To remove the most recent step, click the Remove Last Step button below the Steps outline.

**Model Reports**

Use the options in the Models submenu in the Functional Data Explorer red triangle menu to fit models to your data. See “Models” on page 292 for the available models. Each time you fit a different type of model to the data, a model report appears. Each model report contains the following reports:

- “Model Controls” on page 287
- “Model Selection” on page 288
- “Diagnostic Plots” on page 289
- “Function Summaries” on page 289
- “Basis Function Coefficients” on page 290
- “Random Coefficients by Function” on page 290
- “Functional PCA” on page 290

**Model Controls**

The Model Controls report enables you to define parameters of models to compare in the Model Selection report. The appearance of the Model Controls report depends on the type of model that is fit.

**B-Spline and P-Spline Model Controls**

When a B-Spline or P-Spline model is fit, you can specify the following parameters:

**Number of Knots**  Add, remove, or specify a range for the number of knots in each spline. The knots must be non-zero integers.

Note: The maximum number of knots allowed for B-Spline models is the maximum number of observations per function or the number of unique inputs. The maximum number of knots allowed for P-Spline models is two less than the number of unique inputs. If you specify a number larger than the maximum, a warning message appears.
Spline Degree  Add or remove spline degree fits from the Model Selection report.

Fourier Basis Model Controls

When a Fourier Basis model is fit, you can specify the following parameters:

Number of Fourier Pairs  Add, remove, or specify a range for the number of Fourier pairs to compare.

Period  Change the period of the function.

After you specify the model controls, click Go to view the updated models in the Model Selection report.

Tip: To specify the Model Controls prior to fitting a model, press Shift, click the Functional Data Explorer red triangle, and select the desired model. See “Models” on page 292.

Model Selection

The Model Selection report contains an overall prediction plot, a grid of individual prediction plots, a solution path plot, and a table of fit statistics. The grid of individual prediction plots has the same layout and controls as the grid of individual plots in the Data Processing report. At most, there are twenty plots shown at a time. There are drop-down menus and arrows that enable you to view different groups of individual prediction plots. The solution path plot shows a model selection criterion plotted over values of a model parameter. The Bayesian Information Criterion (BIC) is the default fitting criterion. See “Model Report Options” on page 297. For B-Spline and P-Spline models, there is a separate solution path for each spline degree plotted across the defined number of knots. For Fourier Basis models, the solution path is plotted across the number of Fourier pairs for a defined period. Use the Model Selection option to change the solution path plot parameters.

The current solution is designated by the dotted vertical line in the solution path plot. By default, the slider is placed at the number of knots or Fourier pairs that corresponds to the model that has the smallest model selection criterion value. You can drag the slider at the top of the dotted vertical line to change the number of knots or Fourier pairs in the current model. Dragging the slider automatically updates the prediction plots in the Model Selection report, as well as the information in all other reports.

The Fit Statistics table contains a description of the current solution model. It also displays the -2 Log Likelihood, the values for the AICc, BIC, and GCV model fitting criterion, and a value for the response standard deviation, denoted as <Y, Output> Std Dev. The response standard deviation is defined as the residual sigma from the fitted model. When a P-Spline model is selected, the penalty parameter \( \lambda \) (Lambda) is also displayed.
The prediction plots show the raw data and prediction curves that correspond to the current model. If there is a validation set, the predicted curves are not shown for functions that are in the validation set. For spline models, the default model selected is the degree of spline with the best fit. Click a specific spline in the solution path plot or the legend to change the current model selection. The curve in the overall prediction plot is a prediction of the mean curve. The curves in the individual prediction plots are prediction curves for each specific function. For B-Spline models, the overall prediction plot also displays the location of the knots. You can change the location of the knots by dragging the blue slider bars to different locations. To update the model reports according to the new knot locations, click the **Update Models** button. To reset the knots to their default locations, click the **Reset Knots** button.

### Diagnostic Plots

The Diagnostic Plots report contains the Actual by Predicted plot and the Residual by Predicted plot. These plots help assess how well the current model fits the data. The Diagnostic Plots report is closed by default.

### Function Summaries

Displays summaries from the Functional PCA for each level of the ID variable. The functional principal components associated with eigenvalues that explain more than 1% variation in the data are displayed by default. The mean, standard deviation, median, minimum, maximum, integrated difference, root integrated square error (RISE), and root integrated function square (RIFS) are also shown. The integrated difference and RISE summary values are used to determine how much the ID specific function differs from the overall mean function. The RIFS summary value is used for optimal curve fitting. See “Function Summaries Details” on page 306. The Function Summaries red triangle menu contains the following options:

**Customize Function Summaries** Displays a window that enables you to select the number of FPCs and the summary statistics that are shown in the Function Summaries report. If the number of FPCs to be shown is specified, the Functional PCA report is also updated. There is also a checkbox, Save Graphs, that determines whether a graph for each function is included in the data table produced by the Save Summaries option.

**Tip:** If you have multiple functional processes, you can customize all Function Summaries reports to show the same summary values by clicking Ctrl and selecting Customize Function Summaries.

**Save Summaries** Saves the summary statistics specified in the Function Summaries report to a new data table. The name of the new data table describes the model fit. This data table contains formula columns for the eigenfunctions, mean function, prediction function, and conditional prediction function. There is also a column that contains the image of a graph of the raw data and the specified model fit for each function. In the data table, there is a
profiler script that launches the prediction profilers for the prediction and conditional prediction formulas. These formulas are functions of the input variable, the ID variable, and the eigenfunctions.

### Basis Function Coefficients

Displays the estimated basis function coefficients and their standard deviations. These are common across all levels of the ID variable and are fixed estimates in the mixed model framework. To view standard errors and confidence intervals for the coefficients, right-click in the table and select **Columns**.

### Random Coefficients by Function

Displays the estimated random coefficients for each basis function and functional process combination. These are unique to each level of the ID variable and are random effects estimates in the mixed model framework.

### Functional PCA

Functional principal components analysis (functional PCA) is performed on the fitted functional model. The Functional PCA report lists the eigenvalues that correspond to each functional principal component (FPC) in order from largest to smallest. The percent of variation accounted for by each FPC and the cumulative percent is listed and shown in a bar chart. There is a graph of the mean function as well as a graph for each component. The component graphs show the values of the eigenfunction.

You can perform model selection in the Functional PCA report to refine the selected number of functional principal components. There is a solution path plot that shows the Bayesian Information Criterion (BIC) plotted versus the number of FPCs. The current number of FPCs is designated by the dotted vertical line in the solution path plot. It is possible that models with different numbers of FPCs might have similar fits. Therefore, the solution path plot provides zones, which are intervals of values of the BIC statistic. There is a green zone and a yellow zone. The green zone contains values in the interval of the minimum BIC to the minimum BIC plus four and the yellow zone contains values in the interval of the minimum BIC plus four to the minimum BIC plus 10. By default, the model with the smallest number of FPCs within the green zone is selected. You can drag the slider at the top of the vertical line to change the number of FPCs. Dragging the slider automatically updates the other information in the Functional PCA report.

**Note:** The zones may appear small on your plot. Zoom in on the y-axis to better visualize the zones.
When Direct Functional PCA is performed, there is also an overall prediction plot and a grid of individual prediction plots. The grid of individual prediction plots has the same layout and controls as the grid of individual plots in the Data Processing report. At most, there are twenty plots shown at a time and there are drop-down menus and arrows that enable you to view different groups of individual prediction plots. Updating the number of FPCs automatically updates the prediction plots as well.

The prediction plots show the raw data and prediction curves that correspond to the current model. If there is a validation set, the predicted curves are not shown for functions that are in the validation set. The curve in the overall prediction plot is a prediction of the mean curve, given the specified number of FPCs. The curves in the individual prediction plots are prediction curves for each specific function, given the specified number of FPCs.

**Note:** The Functional PCA report is not shown if only a single function is modeled. Otherwise, if JMP is unable to perform Functional PCA, an error message appears in the Functional PCA report.

The following options are available in the Functional PCA red triangle menu:

**Diagnostic Plots**  Shows or hides the Actual by Predicted and the Residual by Predicted plots. Use these plots help assess how well the model fits the data, given the selected number of functional principal components.

**Score Plot**  Shows or hides a score plot of the FPC scores. Use the lists under Select Component to specify which FPCs are plotted on each axis of the Score Plot. If there is only one FPC, the FPC scores are plotted on the line $y = x$ and the lists to change the components are not shown. Score plots are useful for detecting outliers. In the case of FPC scores, the Score Plot is useful for detecting levels of the ID variable that have outlier functions. If you select a point in the score plot, the FPC Profiler is set to the scores for that function.

**Tip:** Hover over a point in the score plot to view a prediction plot of the fitted curve for that level of the ID variable.

**FPC Profiler**  Shows or hides a profiler of the FPC scores. The FPC Profiler includes a column for the input variable and a column for each FPC score. For each target function that is specified, there are two additional profilers. One measures the difference from the target function, and the other measures the integrated error from the target function. For more information about FPC Profiler red triangle menu options, see *Profilers*.

**Customize Number of FPC’s**  Specifies the number of FPC scores to show in the Functional PCA. Specifying the number of FPC scores in this option also updates the Function Summaries report.
The Functional Data Explorer red triangle menu contains the following options:

**Summaries**  A submenu of the following options for functional summary statistics:

- **Plot Mean**  Shows or hides a plot of the functional mean in the Summaries report. On by default.

- **Plot Standard Deviation**  Shows or hides a plot of the functional standard deviation in the Summaries report. On by default.

- **Plot Median**  Shows or hides a plot of the functional median in the Summaries report.

**Models**  A submenu of the following model options:

- **B-Splines**  Fits a basis spline (B-Spline) model to the data. Use the B-Spline model for non-periodic data.

- **P-Splines**  Fits a penalized basis spline (P-Spline) model to the data.

- **Fourier Basis**  Fits a Fourier Basis model to the data. Use the Fourier Basis model for periodic data. A periodic model assumes that the function finishes where it starts. See “Fourier Basis Model” on page 305.

**Note:** If there are fewer than three unique input values, neither a Fourier basis model or a P-Spline model can be fit to the data, and a warning message appears.

**Model Controls**  Shows a submenu that enables you to open the Model Controls panel prior to fitting a model. See “Model Controls” on page 287.

**Direct Functional PCA**  (Not available if there is only a single function.) Performs functional principal components analysis directly on the data, without fitting a basis function model first. This reduces computation time, particularly for large data sets. The implementation of Direct Functional PCA is as follows:

1. Align the input data to be between 0 and 1 and interpolate the observations to a common grid of input values.

2. Perform functional principal components analysis on the data.

3. Smooth the first eigenfunction using a P-Spline model with a knot at each grid point.

4. Remove the first smoothed eigenfunction from the data and repeat step 2 to step 4 until a large amount of the variation in the data is explained.

Once you perform a Direct Functional PCA, a Functional PCA report is shown. See “Functional PCA” on page 290.
**Save Data**  Saves the processed data to a new data table. The processed data are saved in the stacked data format.

See *Using JMP* for more information about the following options:

**Local Data Filter**  Shows or hides the local data filter that enables you to filter the data used in a specific report.

**Redo**  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

**Save Script**  Contains options that enable you to save a script that reproduces the report to several destinations.

**Save By-Group Script**  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.

---

**Functional Data Explorer Group Options**

Functional Data Explorer Group options are available only when there are multiple functional processes specified in the Stacked Data Format tab in the launch window.

**Summaries**  A submenu of options to show or hide plots of functional summary statistics for all functional processes. See “Summaries” on page 292.

**Data Processing**  A submenu of data processing options that can be applied to all functional processes. See “Data Processing Report Options” on page 294.

**Models**  A submenu of model options that can be fit to all functional processes. See “Models” on page 292.

**Save Data**  Saves the processed data for all functional processes to a new data table. The processed data are saved in the stacked data format.

**Save Summaries**  Saves the summary statistics specified in each Function Summaries report to a new data table. The name of the new data table describes the model fit. This data table contains formula columns for the eigenfunctions, mean function, prediction function, and conditional prediction function for each of the Y variables. In the data table, there is a profiler script for each Y variable that launches the prediction profilers for the prediction and conditional prediction formulas. These formulas are functions of the input variable, the ID variable, and the eigenfunctions.

**Arrange in Rows**  Specifies how many reports are displayed across the window.

See *Using JMP* for more information about the following options:
Local Data Filter  Shows or hides the local data filter that enables you to filter the data used in a specific report.

Redo  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

Save Script  Contains options that enable you to save a script that reproduces the report to several destinations.

Save By-Group Script  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.

Data Processing Report Options

The Data Processing red triangle menu contains the following options:

Cleanup  A submenu of the following data cleanup options:

Remove Zeros  Removes observations with zero values. If there are no zeros in the data, an alert appears, indicating that no zero values were found.

Remove Value  Displays a specifications window that enables you to specify a value to remove from the data.

Remove Selected  Removes observations that correspond to rows that are selected in the data table.

Remove Unselected  Removes observations that correspond to rows that are not selected in the data table.

Caution: Remove Selected and Remove Unselected remove the row numbers. When Auto Recalc is enabled, you must add or delete rows before using these options.

Filter X  Removes X values that fall outside of a specified interval. When you select the Filter X option, you must specify Below and Above values. The X values that fall outside of the specified interval are not used for the analysis.

Filter Y  Removes Y values that fall outside of a specified interval. When you select the Filter Y option, you must specify Below and Above values. The Y values that fall outside of the specified interval are not used for the analysis.

Reduce  Reduces the data over the X values using one of the following techniques:

– Use the Grid tab to interpolate observations to a common grid of values. You can specify the grid size. By default, the grid size is half the number of unique input values.
and therefore reduces the number of total observations. If you are not interested in reducing the number of total observations, but simply want your observations to be on the same grid, specify the grid size to be the number of unique input values.

– Use the Bin tab to create a specified number of bins that are evenly spaced over the unique X values. For each function (or level of the ID, Function variable), the observations within a bin are averaged to produce a Y value for the corresponding bin level.

– Use the Thin tab to remove every N observation over the X values, where N is determined by the specified thinning rate. This is done for each function (or level of the ID, Function variable). By default, the thinning rate is 2, which removes half of the observations in each function.

**Note:** The Remove options exclude the specified observations from the analysis and modeling reports, but the observations remain unchanged in the data table.

### Transform

A submenu of the following options to transform the output data:

- **Center** Centers the output.
- **Standardize** Standardizes the output by centering and scaling the data to have mean 0 and variance 1.
- **Range 0 to 1** Scales the output to lie within the range of 0 and 1.
- **Square Root** Transforms the data by computing the square root of the output. The output values must be nonnegative.
- **Square** Transforms the data by computing the square of the output.
- **Log** Transforms the data by computing the natural logarithm of the output.
- **Exp** Transforms the data by computing the exponential function of the output.
- **Negation** Transforms the data by negating the output.
- **Logit** Transforms the data by computing the logit function of the output. The output values must be between 0 and 1.

### Align

A submenu of the following options to align the input data:

- **Row Alignment** Replaces the input values with the row number.
- **Align Maximum** Aligns the functions using the observed maximum output value for each ID level. The input value associated with the observed maximum output value is set to zero for each ID level and the other input values are shifted up or down based on the difference between the observed maximum and zero.
**Align Minimum**  Aligns the functions using the observed minimum output value for each ID level. The input value associated with the observed minimum output value is set to zero for each ID level and the other input values are shifted up or down based on the difference between the observed minimum and zero.

**Align 0 to 1**  Aligns the output functions such that the range of the input values is 0 to 1.

**Tip:** **Align 0 to 1** is particularly useful when you fit a P-Spline model.

**Dynamic Time Warping**  (Available only when there is more than one function.) Aligns the output functions using dynamic time warping (DTW). DTW is a function alignment technique that finds an optimal warping to align two or more functions together. When you select the DTW option, a Select Reference Function window appears. Use this to select the reference function. The reference function is the function that the remaining functions are aligned to.

Once you select a reference function and click OK, a warping function plot is shown along with a list for the remaining query functions. On the warping function plot, the reference function is on the y-axis and the selected query function is on the x-axis. Deviations from the red diagonal line ($y = x$) indicate that the inputs of the query function have been warped for better alignment.

**Target Functions**  (Available only when there is more than one function.) A submenu that enables you to load target functions.

**Load Targets**  Shows a window that enables you to specify a target function. A target function is used for curve matching, where it is desirable for all of the functions to look like the target function. You can also specify two target functions to compare the remaining curves to the “best” and “worse” case functions.

If you specify one or more target functions, the data from the functions are not used in model fitting. For each specified target function, two rows are added to the FPC Profiler. See “FPC Profiler” on page 291.

**Note:** Target functions must be loaded before any other preprocessing steps are performed.

### Dynamic Time Warping Options

**Plot Warping Functions**  Shows or hides the warping function plot. On by default.

**Save Distance Matrix**  Saves the distance matrix to a separate data table. The distance matrix can be useful for clustering the functions. The distance matrix data table contains a hierarchical clustering script.
Save Warping Functions  Saves the warping functions to a separate data table. Each row of the data table contains the DTW adjusted input variable, the original input variable, and the ID variable.

Model Report Options

Model Selection  Displays a submenu of choices to use as the model selection criteria. The choices are AICc, BIC, and GCV. See Fitting Linear Models.

Plot Basis  Shows or hides a plot of all the basis functions on one graph.

Diagnostic Plots  Shows or hides the Diagnostics Plots report. See “Diagnostic Plots” on page 289.

Function Summaries  Shows or hides the Function Summaries report. See “Function Summaries” on page 289.

Basis Function Coefficients  Shows or hides the Basis Function Coefficients report. See “Basis Function Coefficients” on page 290.

Random Coefficients by Function  Shows or hides the Random Coefficients by Function report. See “Random Coefficients by Function” on page 290.

Functional PCA  Shows or hides the Functional PCA report. See “Functional PCA” on page 290.

Functional DOE Analysis  (Available only if at least one supplementary variable is specified in the launch window.) Launches a Generalized Regression report within the FDE platform. A generalized regression model is fit to each of the FPC score functions using the supplementary variables as model effects. By default, a two degree factorial model is fit and the Estimation Method is Best Subset. Note that categorical quadratic effects are not included. If the number of terms in the model is greater than 21 or the number of functions is greater than 1000, the Estimation Method automatically switches to Pruned Forward. Alternatively, you can specify a model script in the original data table that defines the desired model fit. Modeling the FPC scores using the supplementary variables enables you to use the model fit to determine how the response changes based on the supplementary variables. Use the FDOE Profiler to explore how the supplementary variables affect the response.

The Functional DOE Analysis report contains the following red triangle menu options:

Generalized Regression for FPC Scores  Shows or hides the Generalized Regression reports for each FPC score. For more information on Generalized Regression model reports, see Fitting Linear Models.
Diagnostic Plots  Shows or hides actual by predicted and residual plots for the response variable.

FDOE Profiler  Shows or hides the FDOE Profiler, which enables you to explore how the response changes based on the supplementary variables. For more information about the FPC Profiler red triangle menu options, see Profilers.

Save Columns  Shows a list with the options Save Prediction Formula and Save Residual Formula. These options save the corresponding formula to a new column in the data table.

Save Data  Saves the modeled data to a new data table. The modeled data are saved in the stacked data format.

Remove Fit  Removes the model report for the specified fit.

Additional Examples of the Functional Data Explorer Platform

- “Example for Multiple Functional Processes”
- “Example of Functional DOE”

Example for Multiple Functional Processes

This example uses the Fermentation Process.jmp and Fermentation Process Batch Yield Results.jmp sample data tables to analyze enzyme production. Yield is the amount of an enzyme produced by genetically modified yeast. There are 100 process measurements per batch that were taken at equally spaced times over a 12-hour period.

Use the Functional Data Explorer platform to fit models to the data and save functional principal components to a new data table. The functional principal components are then analyzed in the Generalized Regression personality of the Fit Model platform.

Fit Functional Models

2. Select Analyze > Specialized Modeling > Functional Data Explorer.
3. In the Stacked Data Format tab, select Ethanol through pH and click Y, Output.
4. Select Time and click X, Input.
5. Select BatchID and click ID, Function.
6. Click **OK**.

7. Click the Functional Data Explorer Group red triangle and select **Data Processing > Align > Align 0 to 1**. This aligns the input variable to be between 0 and 1 in each Functional Data Explorer report.

8. Click the Functional Data Explorer Group red triangle and select **Models > B-Splines**. This fits a B-spline model to each of the functional processes.

**Figure 16.7** Functional Data Explorer Report for Ethanol
Figure 16.8 Model Summary Report for Ethanol

Figure 16.7 and Figure 16.8 show the model reports for one of the functional process variables, Ethanol. Scroll through the full report to view the models fit for each of the process variables. Next, use the FPCs in the Function Summaries report in an analysis.

Save FPCs and Link Yield Results

1. Press Ctrl, click any Function Summaries red triangle, and select Customize Function Summaries.

2. In the box next to Enter number of FPCs to show, type 3.

3. Click the Deselect All Summaries box.

4. Click OK.

5. Click the Functional Data Explorer Group red triangle and select Save Summaries.

7. In the Functional Data Explorer Model Summaries.jmp data table, right-click BatchID and deselect Link ID.

8. In the Functional Data Explorer Model Summaries.jmp data table, right-click BatchID and select Link Reference > Fermentation Process Batch Yield Results.jmp.

This virtually joins the yield data table and the summaries data table.
Fit a Generalized Regression Model

Use the Generalized Regression personality of the Fit Model platform to determine how Yield is affected by the functional process variables.

1. In the Functional Data Explorer Model Summaries.jmp data table, select Analyze > Fit Model.
2. Click the triangle next to referenced by BatchID to Fermentation Process Batch Yield Results.
3. Select Yield[BatchID] and click Y.
4. Select the remaining columns, except Time and BatchID, and click Add.
5. Change the Personality to Generalized Regression.
6. Click Run.
7. Select the Adaptive box.
8. Click Go.

Figure 16.9 Generalized Regression Report for Batch Yield
The Generalized Regression report shows that Yield is significantly affected by certain components of Ethanol, Molasses Feed, NH3 Feed, and Air. The RSquare for the model is 0.73225. By using FDE to perform dimension reduction on the functional processes first, you greatly reduce the number of variables, while still retaining the ability to build a reasonable prediction models.

Example of Functional DOE

This example uses the Formulation For Homogeneity DOE.jmp data table to explore how combinations of ingredients effect the homogeneity grade of a compound across different temperatures. The three ingredients that form the compound are the primary ingredient labeled Active, Water, and Solvent. There are 32 combinations of ingredients; these combinations are denoted by the values in the Formulation column. For each formulation, the Homogeneity Grade is measured from 20 to 70 degrees Celsius at 5 degree intervals. By plotting these measurements across the different temperatures, you can form a curve for each formulation. Use the Functional Data Explorer platform to determine how the curves change depending on the values of Active, Water, and Solvent.

1. Select Help > Sample Data Library and open Functional Data/Formulation For Homogeneity DOE.jmp.
2. Select Analyze > Specialized Modeling > Functional Data Explorer.
3. In the Stacked Data Format tab, select Homogeneity Grade and click Y, Output.
4. Select T and click X, Input.
5. Select Formulation and click ID, Function.
6. Select Solvent, Active, and Water and click Z, Supplementary.
   These variables are not used in the initial functional data analysis. However, by specifying them here as supplementary variables, you can use them later when fitting models.
7. Click OK.
8. Click the Functional Data Explorer red triangle and select Models > B-Splines.
   The best fitting model is a linear spline model with one knot.
The Functional PCA report shows that two functional principal components are needed to explain the variability in the data. The FPC Profiler shows how Homogeneity Grade is affected by the FPCs across the different temperatures. However, there is no way to tell how the actual ingredients affect the Homogeneity Grade.

9. Click the red triangle next to B-Spline on Initial data and select **Functional DOE Analysis**.
The Functional DOE Analysis option fits a generalized regression model to each principal component score using the three supplementary variables as predictors. Because the data table contains a Model script, the models that are fit are based on the model defined in the script.

**Note:** If your data table does not contain a Model script, a two degree factorial model is fit.

**Figure 16.11** FDOE Profiler for Homogeneity Grade

The FDOE Profiler enables you to explore how Homogeneity Grade changes based on the predictors you are actually interested in. In general, Homogeneity Grade seems to decrease as the amount of Active increases.

**Note:** In this example, the values of Active, Solvent, and Water are constrained to sum to 1. This constraint is reflected in the profiler.

**Statistical Details for the Functional Data Explorer Platform**

- “Functional Model Fits”
- “Function Summaries Details”
Functional Model Fits

All of the model fits in the Functional Data Explorer platform rely on basis function expansion. Basis functions are a set of independent functions. Any function, \( f(t) \), can be approximated by taking a linear combination of \( K \) basis functions, denoted as \( \phi_k \). In general, a function is approximated as follows:

\[
\hat{f}(t) = \sum_{k=1}^{K} c_k \phi_k(t)
\]

where the \( c_k \) parameters are the basis coefficients. The amount of smoothing is determined by the number of basis functions, \( K \). For more information about basis function expansion, see Ramsay and Silverman (2005).

Fourier Basis Model

The \( k = 1, \ldots, K \) functions that define the Fourier basis are defined such that \( \phi_0 = 1 \), \( \phi_{2k-1} = \sin(r \omega t) \), and \( \phi_{2k} = \cos(r \omega t) \). Then, the approximated function is defined as follows:

\[
\hat{f}_i(t) = c_{i0} + c_{i1} \sin \omega t + c_{i2} \cos \omega t + c_{i3} \sin 2\omega t + c_{i4} \cos 2\omega t + \ldots
\]

This approximates a periodic function with period \( A \) defined as \( A = 2\pi/\omega \). The coefficients are a combination of fixed basis function coefficients and random coefficients by function. Each \( c \) is defined as follows:

\[
c_{ik} = \beta_k + \alpha_{ik}
\]

where \( \beta_k \) is the fixed coefficient for basis function \( k \) and \( \alpha_{ik} \) is the random coefficient for basis function \( k \) for a specific functional process \( i \). For the Fourier Basis model, the estimates for the \( \beta_k \) and \( \alpha_{ik} \) parameters are found in the Basis Function Coefficients table and Random Coefficients by Function table, respectively.

Fourier basis models have an intercept term and an equal number of sine and cosine terms, which are referred to as Fourier pairs. Therefore, \( K \) is always odd. For example, if \( K = 7 \), there is an intercept term and three Fourier pairs.
Function Summaries Details

The Function Summaries report includes the following summary statistics: integrated difference, root integrated square error (RISE), and root integrated function squared (RIFS). These summary statistics are defined in this section. For all equations in this section, it is assumed that the input values have been aligned between 0 and 1. The following notation is used for all functions:

\[ \hat{f}_i(x) \] is the estimated function for curve \( i \) at input value \( x \)
\[ \hat{m}(x) \] is the estimated mean function at input value \( x \)

Integrated Difference

The integrated difference is the average difference between points on the ID specific curve and the overall mean curve. It can be used to determine if the ID specific curve falls above or below the mean curve, on average. The integrated difference for curve \( i \) is defined as follows:

\[
\text{ID}_i = \frac{1}{1} \int_{0}^{1} (\hat{f}_i(x) - \hat{m}(x)) dx
\]

RISE

Root integrated square error (RISE) is the average distance between the ID specific curve and the overall mean curve. It can be used to determine which ID specific curves are most similar or most different from the overall mean curve. The RISE summary value for curve \( i \) is defined as follows:

\[
\text{RISE}_i = \sqrt{\frac{1}{1} \int_{0}^{1} (\hat{f}_i(x) - \hat{m}(x))^2 dx}
\]

RIFS

Root integrated function squared (RIFS) is a summary value for analyzing optimal curve scenarios. If you pre-subtract off an optimal curve, you can use the smallest values of RIFS to determine which functions are closest to the optimal curve. The RIFS summary value for curve \( i \) is defined as follows:

\[
\text{RIFS}_i = \sqrt{\frac{1}{1} \int_{0}^{1} \hat{f}_i(x)^2 dx}
\]
Use the Gaussian Process platform to model the relationship between a continuous response and one or more predictors. These types of models are common in computer simulation experiments, such as the output of finite element codes, and they often perfectly interpolate the data. Gaussian processes can deal with these no-error-term models, in which the same input values always result in the same output value.

The Gaussian Process platform fits a spatial correlation model to the data. The correlation of the response between two observations decreases as the values of the independent variables become more distant.

One purpose for using this platform is to obtain a prediction formula that can be used for further analysis and optimization.

Example of Gaussian Process

This example uses data from a space filling design in two variables with a deterministic equation for Y (the response). You can use the Gaussian Process platform to find the explanatory power of X1 and X2 on Y. You can view the equation for Y in the column formula.

1. Select Help > Sample Data Library and open 2D Gaussian Process Example.jmp.
2. Select Analyze > Specialized Modeling > Gaussian Process.
3. Select X1 and X2 and click X.
4. Select Y and click Y
5. Select Correlation Type > Cubic.
6. Deselect Fast GASP.
7. Click OK.

**Figure 17.2** Gaussian Process Report

**Note:** The estimated parameters can be different due to different starting points in the minimization routine, the choice of correlation type, and the inclusion of a nugget parameter.
Now, visualize the fitted surface compared to the original surface.

8. Click the red triangle next to Gaussian Process Model of Y and select **Save Prediction Formula**.

9. Select **Graph > Surface Plot**.

10. Select X1 through Y Prediction Formula and click **Columns**.

11. Click **OK**.

12. In the Surface column, select **Both sides** for the Y Prediction Formula.

**Figure 17.3 3D Surface Plot of the Actual and Predicted Ys**

The two surfaces are similar. The impact of X1 and X2 on the response Y can be visualized. You can rotate the plot to view it from different angles. Marginal plots are another tool to use to understand the impact of the factors on the response.
Chapter 17
Predictive and Specialized Modeling

Launch the Gaussian Process Platform

Launch the Gaussian Process platform by selecting Analyze > Specialized Modeling > Gaussian Process.

Figure 17.4  Gaussian Process Launch Window

For more information about the options in the Select Columns red triangle menu, see Using JMP.

Y  Assigns the continuous columns to analyze.

X  Assigns the columns to use as explanatory variables. Categorical variables are allowed in JMP Pro when the Fast GASP option is specified.

Estimate Nugget Parameter  Introduces a ridge parameter into the estimation procedure. A ridge parameter is useful if there is noise or randomness in the response, and you want the prediction model to smooth over the noise instead of perfectly interpolating.

Fast GASP  Option to use the Fast GASP algorithm. Fast GASP breaks the Gaussian process model into small pieces (called blocks) to speed computation time. Blocks allow for the use of multiple CPUs and parallel processing.

Note:  When there are more than 2,500 observations, the Fast GASP algorithm is required.

For more information about Fast GASP, see Parker (2015).

Correlation Type  Choose the correlation structure for the model. The platform fits a spatial correlation model to the data, where the correlation of the response between two observations decreases as the values of the independent variables become more distant.

Gaussian  Restricts the correlation between two points to always be nonzero, no matter the distance between the points.
**Cubic**  Allows the correlation between two points to be zero for points that are far enough apart. This method is a generalization of a cubic spline.

The Fast GASP algorithm does not support the cubic correlation function.

**Minimum Theta Value**  Sets the minimum theta value to use in the fitted model. The default is 0. The theta values are analogous to a slope parameter in regular regression models. Small theta values indicate that a variable has little influence on the predicted values.

**Block Size**  The number of observations in each computational block used by the Fast GASP algorithm. There must be at least 25 observations per block and a maximum of the number of rows in the data set up to a maximum of 2,500.

---

**The Gaussian Process Report**

- “Actual by Predicted Plot”
- “Model Report”
- “Marginal Model Plots”

**Actual by Predicted Plot**

The Actual by Predicted plot shows the actual Y values on the Y axis and the jackknife predicted values on the X axis. One measure of goodness-of-fit is how well the points lie along the diagonal (Y = X) of the plot.

The jackknife values are not true jackknife values in that the model is not re-fit with the associated row for each Y excluded. Rather, the row is excluded from the prediction model for each associated Y but the correlation parameters retain the contribution of the row in them. For Gaussian processes that perfectly interpolate the data this jackknife procedure provides predictions that are not equal to the input.

**Model Report**

The Model Report shows a functional ANOVA table for the model parameter estimates. Specifically, it is an analysis of variance table where the variation is computed using a function-driven method.

**Theta**  Gaussian Process model parameter estimates. See “Statistical Details for the Gaussian Process Platform” on page 318.
**Total Sensitivity**  Sum of the main effect and all interaction terms for each factor. It is a measure of the amount of influence a factor and all its two-way interactions have on the response variable.

Total variation is the integrated variability over the entire experimental space.

**Main Effect**  The functional main effect of each factor is the integrated total variation due to that factor alone. The main effect is the ratio of the functional effect and the total variation for each factor in the model.

**Interactions**  Functional interaction effects are computed in a similar way to main effects.

**Categorical Input**  When the model includes categorical factors, a correlation matrix for each categorical factor is provided. The off-diagonal entries correspond to Gaussian Process model parameter estimates. See “Models with Categorical Predictors” on page 319.

**Mu and Sigma**  The mean and variance model parameters.

**Nugget**  The estimated nugget value. A nugget value is reported if you selected estimate nugget parameter in the Gaussian Process launch window. A nugget value is also reported if JMP has added a nugget parameter in order to avoid a singular covariance matrix.

**-2LogLikelihood**  The estimated value of twice the negative log-likelihood function. See *Fitting Linear Models*.

**Marginal Model Plots**

A marginal plot appears for each factor in the model. For each plot, all factors except one are integrated out using a distribution that is uniform over the ranges of the other factors in the data. The marginal prediction of the response for the remaining factor of interest is drawn in blue. The data points for the observed response values are included to show how well the marginal model fits the data. For models with a small number of factors, these plots can be used as diagnostic plots.

**Gaussian Process Platform Options**

The Gaussian Process red triangle menu contains the following options:

**Profiler**  Opens the standard Profiler. See *Profilers*.

**Contour Profiler**  Opens the Contour Profiler. See *Profilers*.

**Surface Profiler**  Opens the Surface Profiler. See *Profilers*. 
Additional Examples of the Gaussian Process Platform

- “Example of a Gaussian Process Model”
- “Example of Gaussian Process Model with Categorical Predictors”
Example of a Gaussian Process Model

This example uses data that demonstrates the flow of water through a Borehole that is drilled from the ground surface through two aquifers. Given a specified engineering model the Gaussian process lets us understand the impact of factors included in the model on the response, Y.

1. Select Help > Sample Data Library and open Design Experiment/Borehole Latin Hypercube.jmp.
2. Select Analyze > Specialized Modeling > Gaussian Process.
3. Select log10 Rw through Kw and click X.
4. Select Y and click Y.
5. In JMP Pro, to run the analysis faster, leave the Fast GASP checked.
6. Click OK.

Figure 17.5  Borehole Latin Hypercube Report
The data on the actual by predicted plot fall along the $Y = X$ line, indicating that the Gaussian process prediction model is a good approximation of the true function. In the Model Report, you see that the first factor, log10 $R_w$, has the highest total sensitivity. The estimated total sensitivity for log10 $R_w$ explains more than 90% of the variation in the response. Factors with small theta values have little (or no) impact on the prediction formula. Use the profiler to visualize the sensitivities.

7. Click the Gaussian Process Model of $Y$ red triangle and select **Profiler**.

The desirability functions automatically appear because the response, $Y$, has a Response Limits column property.

8. Click the Prediction Profiler red triangle and select **Optimize and Desirability > Maximize Desirability**.

![Figure 17.6 Gaussian Process Model Profiler](image)

The desirability function is set to maximize the response $Y$ because $Y$ has goal set to Maximize in the Response Limits column property. Maximizing the desirability functions identifies the values of the factors that maximize the response. The shaded bands represent the 95% confidence intervals.

**Note:** Your estimates can differ from those shown in Figure 17.5, which were found using the Fast GASP algorithm.

### Example of Gaussian Process Model with Categorical Predictors

This example uses the Algorithm Data.jmp sample data table. These data are simulated CPU times from a 50 run space filling designed experiment. The Algorithm Factors.jmp sample data table provides the factors and settings for the design. The design has three continuous and two categorical factors. The goal is to predict CPU Time using a Gaussian Process model that contains both continuous and categorical factors.

1. Select **Help > Sample Data Library** and open Design Experiment/Algorithm Data.jmp.
2. Select **Analyze > Specialized Modeling > Gaussian Process**.
3. Select Alpha through Compiler and click **X**.
4. Select CPU Time and click Y.

5. To run the analysis, leave the Fast GASP checked. Click OK.

**Note:** The Fast GASP option must be used for models that contain categorical factors. See “Models with Categorical Predictors” on page 319.

**Figure 17.7 Algorithm Data Report**

The actual by predicted plot shows a strong correlation between the actual and predicted CPU times. This is an indication that the Gaussian process prediction model is a good approximation of the true function. In the Model Report, the Beta predictor has the highest total sensitivity. This indicates that of the continuous predictors, Beta explains the most variation in the response. There is a separate Categorical Input matrix for each of the categorical predictors, Algorithm and Compiler. These matrices are correlation matrices and
show the correlation between levels for each categorical predictor. The off-diagonals of the matrices are the \( \tau \) parameters.

---

**Statistical Details for the Gaussian Process Platform**

- “Models with Continuous Predictors”
- “Models with Categorical Predictors”
- “Variance Formula Parameterization”
- “Model Fit Details”

**Models with Continuous Predictors**

If the Gaussian Process model contains only continuous predictors, the Gaussian Process platform implements two possible correlation structures, the Gaussian and the Cubic.

The Gaussian correlation structure uses the product exponential correlation function with a power of 2 as the estimated model. This model assumes that \( Y \) is normally distributed with mean \( \mu \) and covariance matrix \( \sigma^2 \mathbf{R} \). The elements of the \( \mathbf{R} \) matrix are defined as follows:

\[
 r_{ij} = \exp \left( - \sum_{k=1}^{K} \theta_k (x_{ik} - x_{jk})^2 \right)
\]

where

\[ K = \# \text{ of continuous predictors} \]
\[ \theta_k = \text{theta parameter for the } k^{\text{th}} \text{ predictor} \]
\[ x_{ik} = \text{the value of the } k^{\text{th}} \text{ predictor for subject } i \]
\[ x_{jk} = \text{the value of the } k^{\text{th}} \text{ predictor for subject } j \]

The Cubic correlation structure also assumes that \( Y \) is normally distributed with mean \( \mu \) and covariance matrix \( \sigma^2 \mathbf{R} \). The \( \mathbf{R} \) matrix consists of the following elements:

\[
 r_{ij} = \prod_{k} \rho(\tau_k)
\]

where

\[ d = x_{ik} - x_{jk} \]
See Santer (2003). The theta parameter used in the Cubic correlation structure is the reciprocal of the parameter often used in the literature. The reciprocal is used so that when theta has no effect on the model, then rho has a value of zero, rather than infinity.

Models with Categorical Predictors

If the Gaussian Process model includes categorical predictors, the Gaussian correlation structure is used for the correlation structure. The elements of the R matrix are defined as follows:

\[
\rho(d; \theta) = \begin{cases} 
1 - 6(d \theta)^2 + 6(|d| \theta)^3, & |d| \leq \frac{1}{2 \theta} \\
2(1 - |d| \theta)^3, & \frac{1}{2 \theta} < |d| \leq \frac{1}{\theta} \\
0, & \frac{1}{\theta} < |d|
\end{cases}
\]

There is a \( \tau \) parameter for each combination of levels of a categorical variable, where \( \tau_{ij} \) corresponds to the unique combination formed by the observed levels of subject \( i \) and subject \( j \). Thus, the covariance element, \( r_{ij} \), depends on the combination of levels of the categorical predictors obtained from the \( i^{th} \) and \( j^{th} \) observations. See Qian et al. (2012).
Variance Formula Parameterization

The saved variance formula uses the previously defined parameterization of \( R \), except when the model includes categorical predictors. When the Gaussian Process model includes categorical predictors, the saved variance formula uses the following parameterization of \( R \):

\[
 r_{ij} = \exp \left( - \sum_{k=1}^{K} \theta_k (x_{ik} - x_{jk})^2 - \sum_{p=1}^{P} \phi_{p ij} \right)
\]

where \( \phi_{p ij} = -\ln(\tau_{p ij}) \) and all other variables are as previously defined.

Model Fit Details

The model parameters are fit via maximum likelihood. The fitted parameters are provided in the platform report. These are the parameters:

- \( \mu \) is the Gaussian Process mean,
- \( \sigma^2 \) is the Gaussian Process variance,
- Theta corresponds to the values of \( \theta_k \) in the definition of \( R \).
- The off-diagonals of the categorical input correlation matrices correspond to the values of \( \tau_{p ij} \) in the definition of \( R \).

**Note:** If your report contains the note **Nugget parameters set to avoid singular variance matrix**, JMP has added a ridge parameter to the variance matrix so that it is invertible.
The Time Series platform enables you to explore, analyze, and forecast univariate time series. A time series is a set of observations taken over a series of equally spaced time periods. Observations that are close together in time are typically correlated. Time series methodology takes advantage of this dependence between observations to better predict what the series will look like in the future.

Characteristics that are common in time series data include seasonality, trend, and autocorrelation. The Time Series platform provides options to handle these characteristics. Graphs such as variograms, autocorrelation plots, partial autocorrelation plots, and spectral density plots can be used to identify the type of model appropriate for describing and predicting (forecasting) the time series. There are also several decomposition methods in the platform that enable you to remove seasonal or general trends in the data to simplify the analysis. Alternatively, the platform can fit more sophisticated ARIMA models and State Space Smoothing models that have the ability to incorporate seasonality and long term trends all in one model. You can also perform a Box-Cox transformation and analyze and model the transformed series.

There are several methods to assess the forecasting performance of models. The Forecast on Holdback feature partitions the time series into a training portion to build models and a holdback portion to assess forecasting performance.

Overview of the Time Series Platform

A time series is a set $y_1, y_2, ..., y_N$ of observations that are observed over a series of equally spaced time periods. Some examples of time series data include quarterly sales reports, monthly average temperatures, and counts of sunspots. The Time Series platform enables you to explore patterns and trends found in these types of data. You can then use these patterns and trends to forecast, or predict, into the future.

Characteristics that are common in time series data include seasonality, trend, and autocorrelation. Seasonality refers to patterns that occur over a known period of time. For example, data that are collected monthly might look similar in summer months across all years of data collection. Trend refers to long term movements of a series, such as gradual increases or decreases of values across time. Autocorrelation is the degree to which each point in a series is correlated with earlier values in the series.

There are many different models and forecasting methods available in the Time Series platform. However, not all methods can handle trend or seasonality. In order to choose an appropriate model, it is essential to determine which characteristics are present in the series. The Time Series platform provides graphs such as variograms, autocorrelation plots, partial autocorrelation plots, and spectral density plots that can be used to identify the type of model appropriate for describing and forecasting the evolution of the time series. There are also several differencing and decomposition methods in the platform that enable you to remove seasonal or general trends in the data to explore and simplify the analysis. You can also view and apply a Box-Cox transformation to your data.

Alternatively, the platform can fit more sophisticated models that can incorporate seasonality and long term trends. One such model in the platform that has this ability is Winter’s Additive Method, which is an advanced exponential smoothing model. In addition, the platform can fit AutoRegressive Integrated Moving Average (ARIMA) models and State Space Smoothing models. Both of these types of models are the most statistically complex, but also provide the most flexibility. Advanced exponential smoothing, ARIMA, and State Space Smoothing models are harder to interpret, but they are excellent tools for forecasting.

The Time Series platform can also fit transfer function models when supplied with an input series.
Example of the Time Series Platform

This example uses the Raleigh Temps.jmp sample data table, which contains maximum monthly temperatures measured in degrees Fahrenheit from 1980 to 1990. Use the Time Series platform to examine the series and predict the maximum monthly temperatures for the next two years.

2. Select Analyze > Specialized Modeling > Time Series.
4. Select Month/Year and click X, Time ID.
5. In the box next to Forecast Periods, type 24.
   This is the number of future periods that are forecast by the models fit to the data. You want to predict the monthly temperature for the next two years, which is 24 months.
6. Click OK.

Figure 18.2 Time Series Analysis Report for Raleigh Temps.jmp
The Time Series graph shows that the series is cyclic. This cyclic component is also apparent in the autocorrelation chart. Points that are 1 lag apart are positively correlated, with an AutoCorr value of 0.8007. As points become farther apart, they become negatively correlated, then positively correlated again, and then the pattern repeats. The Time Series graph and the autocorrelation chart provide evidence of seasonality in the time series.

7. Click the Time Series red triangle and select ARIMA.
8. Set $p$, the autoregressive order, to 1 because the series showed evidence of autocorrelation.
9. Click Estimate.
10. Click the Time Series red triangle and select Seasonal ARIMA.
11. In the ARIMA box, set $p$, the autoregressive order, to 1 because the series showed evidence of autocorrelation.
12. In the Seasonal ARIMA box, set $D$, the seasonal differencing order, to 1 because the series showed evidence of seasonality.
13. Click Estimate.
14. In the Model Comparison table, check the box under Graph for both models.

Figure 18.3 Model Comparison Table for Raleigh Temps.jmp

The Model Comparison table is sorted by the AIC statistic, in decreasing order. This means that the best fitting model appears at the top of the report. The AIC value for the seasonal ARIMA model (693.4) is much smaller than the value for the regular ARIMA model (924.5). The graph shows that while the ARIMA model predicts the observed points relatively well, the residuals are larger than those from the Seasonal ARIMA model. Also, the Seasonal ARIMA model has more realistic predictions for future observations with narrower prediction intervals. These results make sense since the series showed evidence of a seasonal component.
Launch the Time Series Platform

Launch the Time Series platform by selecting **Analyze > Specialized Modeling > Time Series**. The Time Series launch window for the Seriesg.jmp sample data table is shown in Figure 18.4.

**Figure 18.4 The Time Series Launch Window**

For more information about the options in the Select Columns red triangle menu, see *Using JMP*.

The Time Series platform launch window contains the following options:

- **Y, Time Series** Assigns one or more columns as time series variables. Displayed on the Y axis.

- **Input List** Assigns one or more columns as input series variables. Displayed in the Input Time Series Panel and used in transfer function models. The input series variable must be numeric, either as a time series or an indicator.

- **X, Time ID** Assigns one variable for labeling the time axis (X axis). If no variable is specified for Time ID, the row number is used instead.

**Note:** If you use an X, Time ID variable, you can specify the time frequency by using the Time Frequency column property. You can choose Annual, Quarterly, Monthly, Weekly, Daily, Hourly, By Minute, and By Second. This helps JMP determine the spacing of the data when plotting the forecast values. If no frequency is specified, the data is treated as equally spaced numeric data.

**Caution:** It is assumed that the observations of the variable assigned to **X, Time ID** are equally spaced. However, the Time Series platform checks only whether the time stamps are increasing. The platform does not check if the observations are equally spaced.
**By** Assigns a column that creates a report consisting of separate analyses for each level of the variable. If more than one By variable is assigned, a separate analysis is produced for each possible combination of the levels of the By variables.

**Note:** If you use a By variable, you might have to change the number of autocorrelation lags depending on how many observations there are for each level of the By variable. The number of lags must be greater than one but less than the number of observations per level.

**Autocorrelation Lags** Specifies the number of lags to use in computing the autocorrelations and partial correlations. This is the maximum number of periods between points used in the computation of these correlations. It must be greater than one but less than the number of rows. The default number of lags is 25.

**Tip:** A commonly used rule for the maximum number of lags is \( n/4 \), where \( n \) is the number of observations.

**Forecast Periods** Specifies the number of observations that are forecast using each model fitted to the data. The default number of forecasts is 25.

- If you select the Forecast on Holdback option, the Forecast Periods value specifies the number of observations at the end of the series that are not included in the model fitting. These values are then forecast using the fitted model.
- If you do not select the Forecast on Holdback option, the Forecast Periods value specifies the number of future observations that are forecast after the end of the series.

**Forecast on Holdback** Determines whether forecasts are made on future observations or on the holdback observations. If the Forecast on Holdback option is selected, the forecasts are made on the holdback set that is determined by the number specified in the Forecast Periods option.

**Use Box-Cox Transformation** Transforms the original data using a Box-Cox transformation with the lambda that is specified in the Lambda for Box-Cox option. When this option is selected, all analyses in the Time Series report are performed on the transformed data. However, all forecasts are transformed back and reported on the original scale.

**Lambda for Box-Cox** (Available only when Use Box-Cox Transformation is selected.) Specifies the lambda parameter used for the Box-Cox transformation of the original data.

**Note:** In order to preserve the order and spacing of a time series, the Time Series platform treats excluded rows in the data table as missing values.
The Time Series Analysis Report

The initial Time Series report displays the time series graph, summary statistics and tests for the time series variable, and a basic diagnostics report. If a column is specified for Input List in the launch window, the Transfer Function Analysis and Input Time Series Panel reports are shown. Both the Transfer Function Analysis report and the Input Time Series Panel report contain the same initial information as the Time Series report.

- “Time Series Graph”
- “Time Series Basic Diagnostics Chart”

Time Series Graph

The Time Series graph plots each times series by the time ID. If no time ID is specified, the row number is used instead. If a holdback set is specified, there is a vertical reference line on the graph that separates the training data from the holdback data.

The platform also performs several tests for stationarity using Augmented Dickey-Fuller (ADF) tests. The following tests and summary statistics are displayed next to the time series graph:

**Lambda for Box-Cox** (Appears only if a Box-Cox Transformation is specified.) The value of lambda used in the Box-Cox transformation.

**Mean**  The sample mean.

**SD**  The sample standard deviation.

**N**  The series length.

**Zero Mean ADF**  A test against a random walk with zero mean, which is defined as follows:

\[ x_t = \phi x_{t-1} + e_t \]

**Single Mean ADF**  A test against a random walk with a non-zero mean, which is defined as follows:

\[ x_t - \mu = \phi (x_{t-1} - \mu) + e_t \]

**Trend ADF**  A test against a random walk with a non-zero mean and a linear trend, which is defined as follows:

\[ x_t - \mu - \beta t = \phi [x_{t-1} - \mu - \beta(t-1)] + e_t \]
**Time Series Basic Diagnostics Chart**

The information that is shown in the Time Series Basic Diagnostics chart depends on the Time Series Report red triangle menu options. The red triangle menu options that show or hide information from the diagnostics chart are Autocorrelation, Partial Autocorrelation, Variogram, and AR Coefficients. By default, Autocorrelation and Partial Autocorrelation are shown.

**Autocorrelation Chart**

The Autocorrelation option shows or hides the following columns in the Time Series Basic Diagnostics chart:

- **Lag** The number of periods between points.

**Note:** The number of lags begins with 0 as the default. To compute correlations beginning with lag 1, modify the JMP preferences before generating the graph. Select **File > Preferences > Platforms > Time Series**, and then select **Suppress Lag 0 in ACF and PACF**.

- **AutoCorr** The autocorrelation for the kth lag, which is computed as follows:

\[ r_k = \frac{c_k}{c_0} \quad \text{where} \quad c_k = \frac{1}{N} \sum_{t=k+1}^{N} (y_t - \bar{y})(y_{t-k} - \bar{y}) \]

and \( \bar{y} \) is the mean of the \( N \) non-missing points in the time series. By definition, the first autocorrelation (lag 0) always has length 1.

The bars graphically depict the autocorrelations. The blue curves represent twice the large-lag standard error (±2 standard errors), which is computed as follows:

\[ SE_k = \sqrt{\frac{1}{N} \left( \frac{k-1}{1 + 2 \sum_{i=1}^{k-1} r_i^2} \right)} \]

- **Ljung-Box** \( Q \) Used to test whether a group of autocorrelations is significantly different from zero, or to test that the residuals from a model can be distinguished from white noise. \( Q \) is the test statistic.

- **p-Value** The \( p \)-value from the Ljung-Box test.
Partial Autocorrelation Chart

The Partial Autocorrelation option shows or hides the following columns in the Time Series Basic Diagnostics chart:

**Lag**  The number of periods between points.

**Partial**  The partial autocorrelation for the \( k \)th lag.

The bars graphically depict the partial autocorrelations. The blue lines represent \( \pm 2 \) standard errors for approximate 95% prediction limits, where the standard error is computed as follows:

\[
SE_k = \frac{1}{\sqrt{n}} \quad \text{for all} \ k
\]

Variogram Chart

The Variogram option shows or hides the following columns in the Time Series Basic Diagnostics chart:

**Lag**  The number of periods between points.

**Variogram**  The variogram measures the variance of the differences of points \( k \) lags apart and compares it to that for points one lag apart. The variogram is computed from the autocorrelations as follows:

\[
V_k = \frac{1 - r_{k+1}}{1 - r_1}
\]

where \( r_k \) is the autocorrelation at lag \( k \).

AR Coefficients Chart

The AR Coefficients option shows or hides the following columns in the Time Series Basic Diagnostics chart:

**Lag**  The number of periods between points.

**AR Coef**  The coefficients approximate those that you would obtain from fitting a high-order, purely autoregressive model.
Chapter 18
Predictive and Specialized Modeling

Time Series Platform Options

- “Time Series Diagnostics”
- “Differencing and Decomposition”
- “ARIMA and Seasonal ARIMA Models”
- “Smoothing Models”
- “State Space Smoothing Models”
- “Transfer Function Models”
- “Smoothing Model Specification Windows”

Time Series Diagnostics

**Graph**  Shows a submenu of options to control the time series plot appearance.

**Time Series Graph**  Shows or hides the time series graph.

**Show Points**  Shows or hides the points in the time series graph.

**Connecting Lines**  Shows or hides the lines connecting the points in the time series graph.

**Mean Line**  Shows or hides a horizontal line in the time series graph that depicts the mean of the time series.

**Autocorrelation**  Shows or hides the Autocorrelation plot in the Time Series Basic Diagnostics Chart. The autocorrelation graph describes the correlation between all pairs of points in the time series for a given separation in time (lag). See “Autocorrelation Chart” on page 329.

**Tip:** The autocorrelation graph of the sample is often called the *sample autocorrelation function*.

**Partial Autocorrelation**  Shows or hides the Partial Autocorrelation plot in the Time Series Basic Diagnostics Chart. The partial autocorrelation graph describes the partial correlation between all the pairs of points in the time series for a given separation in time (lag). See “Partial Autocorrelation Chart” on page 330.

**Tip:** The Autocorrelation and Partial Autocorrelation graphs can help you determine whether the time series is stationary (meaning it has a fixed mean and standard deviation over time) and what model might be appropriate to fit the time series.
**Variogram**  Shows or hides the graph of the variogram in the Time Series Basic Diagnostics Chart. See “Variogram Chart” on page 330.

**AR Coefficients**  Shows or hides the graph of the least squares estimates of the autoregressive (AR) coefficients in the Time Series Basic Diagnostics Chart. See “AR Coefficients Chart” on page 330.

**Spectral Density**  Shows or hides graphs of the spectral density as a function of period and frequency. The spectral density option also displays the White Noise test report, which gives results from two tests on the data. See “Spectral Density Report” on page 357 and “Statistical Details for Spectral Density” on page 365.

**Differencing and Decomposition**

**Difference**  Shows the Differencing Specification window (Figure 18.5). The window enables you to specify the differencing operation that you want to apply to the time series. Differencing the values in a time series can transform a nonstationary series into a stationary series. The differenced series is given by the following equation:

\[
wt = (1 - B)^d (1 - Bs)^D y_t
\]

where \(t\) is the time index and \(B\) is the backshift operator defined by \(B y_t = y_{t-1}\).

**Note:** Many time series do not exhibit a fixed mean, such as time series with trend or seasonality. Such nonstationary series are not suitable for description by time series models that assume a stationary time series such as ARMA models. Removing the trend and/or seasonality creates a differenced series that is stationary and enables you to describe the series using the models that assume stationarity.

**Figure 18.5 Differencing Specification Window**

The Differencing Specification window enables you to specify the Nonseasonal Differencing Order, \(d\), the Seasonal Differencing Order, \(D\), and the number of Observations per Period, \(s\). Selecting zero for the value of the differencing order is equivalent to no differencing of that kind. Each time you specify a differencing operation and click **Estimate**, a new Difference Report is displayed in the report window. See “Additional Examples of the Time Series Platform” on page 358.
Decomposition (Not available when either Forecast on Holdback or Use Box-Cox Transformation are selected in the launch window.) Shows a submenu of decomposition methods. Decomposition of time series data isolates and removes linear trends and seasonal cycles from a time series. This can help with better model estimation. Three Decomposition options are provided.

Remove Linear Trend Estimates the linear trend of the time series using a linear regression model and removes the linear trend from the data. A Time Series report for the detrended series is added to the report window, along with the linear trend information. See “The Time Series Analysis Report” on page 328 and “Linear Trend Report” on page 344.

Remove Cycle Estimates the cyclic component of a time series using a single cosine wave and then removes the cyclic component from the data. When you select the Remove Cycle option, the Define Cycle dialog appears. This dialog window enables you to specify the number of units per cycle and indicate whether a constant should be subtracted from the data. A Time Series report for the decycled series is added to the report window, along with the cycle information. See “The Time Series Analysis Report” on page 328 and “Cycle Report” on page 344.

X11 Removes trend and seasonal effects using the X-11 method developed by the US Bureau of the Census (Shiskin et. al. 1967). For more information about the X-11 method, see “Statistical Details for X-11 Decomposition” on page 366. When selected, the Select Decomposition Type dialog appears. This dialog window enables you to specify a multiplicative or additive X-11 adjustment. Once you click OK, an X11 report is added to the report window. See “X11 Report” on page 345.

The X11 option is available only for monthly or quarterly data. The X, Time ID column must contain numeric values equally spaced by month or quarter without any gaps or missing values. JMP returns an error if you request X11 for a time column that does not satisfy these requirements. For an example of an appropriate time column for an X11 analysis, see “Create Appropriate Time ID Column” on page 358.

Note: When you select the Remove Linear Trend or the Remove Cycle options, JMP adds a column to the data table that contains the detrended or decycled data. If this column is already present in the data table when you select the option, JMP overwrites the existing column.

Tip: Typically, you would begin decomposition by removing any linear trend, and then removing long cycles, such as a 12-month cycle. Then you could start removing short cycles, such as 6-month cycles.

Show Lag Plot Shows or hides a plot with observations at time $t$ on the Y axis and observations at time $t +/-$ $p$ on the X axis. The $+/-$ $p$ is known as the lag. This plot is useful in
determining how an observation at time $t$ is related to another observation at time $t +/- p$. If there is not an identifiable structure to the plot, the observations are not related. However, if there is a structure to the plot, this indicates that there is some relationship between observations across time. Identifying the structure helps when building a time series model.

**Show Box-Cox Transformation Plot** (Not available if you specified Use Box-Cox Transformation in the launch window.) Shows or hides the Box-Cox Transformation plot. The Box-Cox transformation is a power transformation based on the Lambda parameter ($\lambda$) and uses the following formula:

$$Y_{\lambda} = \begin{cases} 
\lambda^{y-1} & \text{if } \lambda \neq 0 \\
\ln(y) & \text{if } \lambda = 0
\end{cases}$$

The Box-Cox Transformation Plot shows a graph of the transformed time series and options for setting the Lambda parameter ($\lambda$). The Lambda box shows the current value of the parameter. You can also use the Lambda slider to change the value of the parameter, which then automatically updates the plot. The Low and High boxes set the range of the slider.

**Tip:** Use the Box-Cox Transformation plot to see the transformed time series for different values of Lambda. Once you decide on a value, relaunch the analysis and select **Use Box-Cox Transformation** and enter the desired Lambda next to Lambda for Box-Cox. This runs the Time Series platform on the transformed series.

**Cross Correlation** (Available only in the Transfer Function Analysis red triangle menu.) Shows or hides a cross-correlation plot to the report. The length of the plot is twice that of an autocorrelation plot, or $2 \times $ACF length + 1. The plot includes plots of the output series versus all input series, in both numerical and graphical forms. The blue lines indicate two standard errors.

**Note:** For the cross correlation plot, the standard errors are calculated under the null hypothesis as $1/\sqrt{n - k}$, where $n$ is the number of nonmissing data values and $k$ is the number of autocorrelation lags.

**Prewhitening** (Available only in the Input Series red triangle menu.) Shows the Prewhitening Specification window that enables you to set the prewhitening order. Prewhitening is a technique used to help identify the transfer function model. This technique involves fitting an ARIMA model to the input series such that the residuals are equivalent to white noise. The same model is then used to estimate the output series. You can use the cross correlation between the filtered input and filtered output series to
determine an appropriate lag for the transfer function model. For information about prewhitening, see Box et al. (1994).

**ARIMA and Seasonal ARIMA Models**

**ARIMA** Shows the ARIMA Specification window, which enables you to specify the ARIMA model that you want to fit. An ARIMA model predicts future values of a time series by a linear combination of its past values and a series of errors (also known as random shocks or innovations). The ARIMA model performs a maximum likelihood fit of the specified ARIMA model to the time series. See “ARIMA Model” on page 370.

**Note:** An ARIMA model is commonly denoted ARIMA($p,d,q$). If any of $p$, $d$, or $q$ are zero, the corresponding letters are often dropped. For example, if $p$ and $d$ are zero, then the model would simply be a moving average model, denoted as MA($q$).

![ARIMA Specification Window](image)

**Figure 18.6** ARIMA Specification Window

$p$, **Autoregressive Order** The order $p$ of the polynomial $\phi(B)$ operator.

d, **Differencing Order** The order $d$ of the differencing operator.

$q$, **Moving Average Order** The order $q$ of the differencing operator $\theta(B)$.

**Prediction Interval** Enables you to set the prediction level between 0 and 1 for the forecast prediction intervals.

**Intercept** Determines whether the intercept term $\mu$ is a part of the model.

**Constrain fit** If checked, the fitting procedure constrains the autoregressive parameters to always remain within the stable region and the moving average parameters within the invertible region.
Tip: Deselect the Constrain fit option if the fitter is having difficulty finding the true optimum or if you want to speed up the fit. You can use the Model Summary table to see whether the resulting fitted model is stable and invertible.

Once you specify the model and click **Estimate**, a Model Report is added to the report window. See “Reports” on page 343.

**Seasonal ARIMA**  Shows the Seasonal ARIMA Specification window, which enables you to specify the Seasonal ARIMA model that you want to fit. This window has the same elements as the ARIMA specification window, but it also contains the seasonal element specifications. The additional Observations per Period option enables you to specify the number of observations per period, denoted as $s$. For more information about the Seasonal ARIMA model, see “Seasonal ARIMA Model” on page 371.

Note: Seasonal ARIMA models are denoted as Seasonal ARIMA$(p,d,q)(P,D,Q)s$.

Once you specify the model and click **Estimate**, a Model Report is added to the report window. See “Reports” on page 343.

### Smoothing Models

Shows a submenu of smoothing models. Once you select a smoothing model, a specification window appears. See “Smoothing Model Windows” on page 342. For each model that is specified, a Smoothing Model Report appears in the report window. See “ARIMA and Seasonal ARIMA Model Report” on page 349. Smoothing models represent the evolution of a time series by the model:

$$y_t = \mu_t + \beta_t t + s(t) + a_t$$

where

- $\mu_t$ is the time-varying mean term
- $\beta_t$ is the time-varying slope term
- $s(t)$ is one of the $s$ time-varying seasonal terms
- $a_t$ are the random shocks

For more information about the general smoothing model equation, see “Statistical Details for Smoothing Models” on page 366. The following smoothing models are available:

**Simple Moving Average**  (Not available when either Forecast on Holdback or Use Box-Cox Transformation are selected in the launch window.) A model that estimates values by using an average of several adjacent points, defined by the smoothing window. The Simple Smoothing Average Specification window enables you to specify aspects of the smoothing window. Once the smoothing window options are specified, a Simple Moving
Average report is shown. By default, this report produces plotted values that are equal to the average of consecutive observations in a time window. Multiple Simple Moving Average models can be added and shown on the same plot. See “Simple Smoothing Average Specification Window” on page 341.

**Simple Exponential Smoothing**  
A model with a level component. See “Simple Exponential Smoothing” on page 367.

**Double Exponential Smoothing**  
A model with a level component and a trend component. This is a special case of Linear Exponential Smoothing. See “Double (Brown) Exponential Smoothing” on page 367.

**Linear Exponential Smoothing**  
A model with a level component and a trend component. See “Linear (Holt) Exponential Smoothing” on page 368.

**Damped-Trend Linear Exponential Smoothing**  
A model with a level component and a damped trend component. This model is appropriate for a series that exhibits a trend more complicated than a linear trend. See “Damped-Trend Linear Exponential Smoothing” on page 368.

**Seasonal Exponential Smoothing**  
A model with a level component and a seasonal component. See “Seasonal Exponential Smoothing” on page 369.

**Winters Method**  
A model with a level component, a trend component, and a seasonal component. See “Winters Method (Additive)” on page 369.

**Note:** Each smoothing model has an ARIMA model equivalent. You might not be able to specify the equivalent ARIMA model using the ARIMA option because some smoothing models intrinsically constrain the ARIMA model parameters in ways that the ARIMA option does not allow.

### State Space Smoothing Models

Shows the Specify State Space Smoothing Models window, which enables you to fit a variety of state space smoothing models as defined by Hyndman et al. (2008). A state space smoothing model is defined based on its error, trend component, and seasonal component.

- The errors can be additive (A) or multiplicatiive (M).
- The trend component can be none (N), additive (A), additive damped (Aₜ), multiplicative (M), or multiplicative damped (Mₜ).
- The seasonal component can be none (N), additive (A), or multiplicative (M).
A specific model can be represented by its ETS (Error, Trend, Seasonal). Use the check boxes in the Specify State Space Smoothing Models window to select the error, trend, and seasonality for the desired models. Click **Select Recommended** to select the check boxes that correspond to the models recommended by the platform. The window opens with the recommended models selected. Click **Select All** to select all check boxes or **Deselect All** to deselect all check boxes. The window also contains the following options:

**Period**  Specifies seasonality values to be considered in the model fitting process.

**Constrain Parameters**  Constrains the parameters in such a way that the further an observation is from the present, the less effect it has on the present state of the model. In State Space Smoothing models, a forecast at time $t$, given all previous observations, is the same as the weighted sum of all observations up to time $t$. The weights are a function of the parameters. Therefore, constraining the parameters ensures that the weights for past observations go to zero and that the further an observation is from the present, the faster the weight goes to zero.

When you click **OK**, the specified set of models is fit. Summary values for each state space smoothing model are added to the Model Comparison table. Individual fit reports are added to the report window.

**Transfer Function Models**

**Transfer Function**  (Available only in the Transfer Function Analysis red triangle menu.) Shows the Transfer Function Model Specification window. Building a transfer function model is similar to building an ARIMA model; it is an iterative process of exploring, fitting, and comparing models. Before building a model and during the data exploration process, it is sometimes useful to prewhiten the data. See “Prewhitening” on page 334. For more information about transfer functions, see “Statistical Details for Transfer Functions” on page 371.

**Note:** Currently, the Transfer Function option has limited support of missing values. Because the Time Series platform also treats excluded rows as missing values, transfer function models cannot be fit on a data table with excluded rows.
The Transfer Function Model Specification window contains the following sections:

**Noise Series Orders**  Contains specifications for the noise series. Lowercase letters are coefficients for non-seasonal polynomials, and uppercase letters are coefficients for seasonal polynomials.

**Choose Inputs**  Enables you select the input series for the model.

**Input Series Orders**  Contains specifications for the input series. The first three orders relate to non-seasonal polynomials. The next four orders relate to seasonal polynomials. The final option is for an input lag.

There are three additional options that control model fitting:

**Intercept**  Specifies whether the model has an intercept. If unchecked, it is assumed that $\mu$ is zero.

**Alternative Parameterization**  Specifies whether the general regression coefficient is factored out of the numerator polynomials.

**Constrain Fit**  Toggles the constraining of the AR and MA coefficients.

**Forecast Periods**  Specifies the number of forecasting periods that are used for forecasting. If there are rows at the end of the data table that contain missing values for the Y variable and nonmissing values for the input variables, these rows are used in the initial forecasting settings. The values for the input variables are treated as future values of the input variables.

**Prediction Interval**  Specifies the confidence level for the prediction interval.
ARIMA Model Group  Shows the ARIMA Model Group window, which enables you to fit a range of ARIMA or Seasonal ARIMA models by specifying the range of orders. As you enter ranges into the window, the Total Number of Models updates accordingly.

Figure 18.8  ARIMA Model Group Specification Window

Once you specify the models and click **Estimate**, a Model Report for each specified model is added to the report window. See “Reports” on page 343.

**Combine and Save Forecasts from Models**  Creates a new data table with the combined results from all model fits in the report.

**Save Spectral Density**  Creates a new data table containing the spectral density and periodogram where the \((i+1)\)th row corresponds to the frequency \(f_i = i / N\) (that is, the \(i\)th harmonic of \(1 / N\)). The new data table has the following columns:

- **Period**  The period of the \(i\)th harmonic, \(1 / f_i\).
- **Frequency**  The frequency of the harmonic, \(f_i\).
- **Angular Frequency**  The angular frequency of the harmonic, \(2\pi f_i\).
- **Sine**  The Fourier sine coefficients, \(a_i\).
- **Cosine**  The Fourier cosine coefficients, \(b_i\).
- **Periodogram**  The periodogram, \(I(f_i)\).
- **Spectral Density**  The spectral density, a smoothed version of the periodogram.

**Number of Forecast Periods**  Shows a window that enables you to set the number of future periods that are forecast for the fitted models. The initial value is set in the Time Series launch window. All existing and future forecast results will use the new number of periods once it is changed.

**Maximum Iterations**  Shows a window that enables you to reset the maximum number of iterations for future optimizations used in fitting ARIMA models.

See Using JMP for more information about the following options:
Local Data Filter  Shows or hides the local data filter that enables you to filter the data used in a specific report.

Redo  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

Save Script  Contains options that enable you to save a script that reproduces the report to several destinations.

Save By-Group Script  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.

Smoothing Model Specification Windows

Simple Smoothing Average Specification Window

The Simple Smoothing Average Specification window appears when you select Simple Moving Average as the smoothing model. Let $w$ be the smoothing window width in a simple moving average (SMA) model. Let $f_t = \frac{y_t + y_{t-1} + y_{t-2} + \ldots + y_{t-(w-1)} + y_{t-(w-2)}}{w}$ be the average of $w$ consecutive observations for some time point $t$.

Figure 18.9  Simple Smoothing Average Specification Window

Enter smoothing window width  The smoothing window width, $w$, that defines the number of consecutive points to average. The larger the window width, the more the series is smoothed.

No Centering  The smoothing window is constructed from the points leading up to and including the time point, $t$, the point at which the series is being estimated. In other words, $f_t$ is the plotted value for time $t$.

Centered  The smoothing window is centered around the time point at which the series is being estimated.

– For odd $w$, $f_t$ is the plotted value for time $t-(w-1)/2$.
– For even $w$, $f_t$ is the plotted value for time $t-(w-1)/2$. When saved to a data table, $f_t$ is at $t-(w-2)/2$. 
**Centered and Double Smoothed for Even Number of Terms** For even $w$, the smoothing window cannot be centered around the time point at which the series is being estimated. This option creates two smoothing windows that are almost centered, and averages them together. The smoothing estimates are calculated as follows:

$$f_{t - \frac{w}{2}} = \frac{y_t + 2 \sum_{i=1}^{w-1} y_{t-i} + y_{t-w}}{2w}$$

**Smoothing Model Windows**

The Smoothing Model specification windows appear when you select one of the smoothing model options other than Simple Moving Average. The title of the window and the available options depend on the smoothing model option that you select.

**Figure 18.10** Smoothing Model Specification Window

**Prediction Interval** Enables you to set the prediction level for the forecast prediction intervals.

**Observations per Period** (Available only for seasonal smoothing models.) Enables you to set the number of observations per period in a seasonal smoothing model.

**Constraints** Enables you to specify what type of constraint you want to enforce on the smoothing weights during the fit. The following constraint options are available:

- **Zero To One** Constrains the values of the smoothing weights to the range zero to one.
- **Unconstrained** Allows the parameters to range freely.
- **Stable Invertible** Constrains the parameters such that the equivalent ARIMA model is stable and invertible.
- **Custom** Expands the dialog to enable you to set constraints on individual smoothing weights. Each smoothing weight can be **Bounded**, **Fixed**, or **Unconstrained** as determined by the setting of the popup menu next to the weight’s name. When entering values for fixed or bounded weights, the values can be positive or negative real numbers.
Chapter 18
Predictive and Specialized Modeling

Figure 18.11  Custom Smoothing Weights

The example shown in Figure 18.11 has the Level weight (\(\alpha\)) fixed at a value of 0.3 and the Trend weight (\(\gamma\)) bounded by 0.1 and 0.8. In this case, the value of the Trend weight is allowed to move within the range 0.1 to 0.8 while the Level weight is held constant at 0.3. Note that you can specify all the smoothing weights in advance by using these custom constraints. In that case, none of the weights would be estimated from the data although forecasts and residuals would still be computed.

Reports

- “Difference Report”
- “Decomposition Reports”
- “Model Comparison Report”
- “ARIMA and Seasonal ARIMA Model Report”
- “State Space Smoothing Report”
- “Transfer Function Report”
- “Spectral Density Report”

Difference Report

The Difference Report contains graphs of the autocorrelations and partial autocorrelations of the differenced series. These graphs can be used to determine whether the differenced series is stationary.

The ARIMA and Seasonal ARIMA models that are available in the Time Series platform accommodate a differencing operation. In a two step process, these models first difference the time series according to the differencing operation, and then fit the differenced series. The Difference option is a useful preprocessing tool for determining the order of differencing to specify for the ARIMA model.
The Difference red triangle menu contains the following options:

**Graph** Shows a submenu of options to control the appearance of the differenced series plot. See “Time Series Platform Options” on page 331.

**Autocorrelation** Shows or hides the autocorrelation of the differenced series.

**Partial Autocorrelation** Shows or hides the partial autocorrelations of the differenced series.

**Variogram** Shows or hides the variogram of the differenced series.

**Save** Saves a new column that contains the values in the differenced series to the original data table. Some of the leading elements are lost in the differencing process. They are represented as missing values in the saved Difference column.

**Remove Fit** Removes the Difference report from the report window.

---

**Decomposition Reports**

This section provides details about the reports obtained from the three decomposition options:

- “Linear Trend Report” on page 344
- “Cycle Report” on page 344
- “X11 Report” on page 345

**Linear Trend Report**

Contains the values of $\beta_0$ and $\beta_1$ from the linear regression model that is fit to the data:

$$\text{Trend}_t = \beta_0 + \beta_1 \cdot \text{time}$$

The detrended series is equal to $D_t = O_t - \text{Trend}_t$, where $O_t$ is the original time series.

**Cycle Report**

Contains the values of the cyclical component that is fit to the data:

$$\text{Cycle}_t = C + A \cdot \cos\left(2 \cdot \pi \cdot \left(\frac{1}{U} \cdot t + P\right)\right)$$

The parameter values are defined as follows:

- $C$ is the (optional) Constant
- $A$ is the Amplitude of the cosine wave
- $U$ is the number of Units per Cycle
• $P$ is the Phase of the cosine wave
• $t$ is one less than the row number of a given observation

The decycled series is equal to $D_t = O_t - \text{Cycle}_t$, where $O_t$ is the original time series.

**X11 Report**

Depending on your selection of Decomposition Type, the X11 option adds an X11-Multiplicative report or an X11-Additive report. The reports contain the same four plots:

- **Original and Adjusted** Overlays the X11-adjusted time series on the original time series, $O_t$. The X11-adjusted values are $O_t/S_t$ for the multiplicative adjustment and $O_t - S_t$ for the additive adjustment.

- **D10 - Final Seasonal Factors** Plots the seasonal factor components, $S_t$, over time.
- **D12 - Final Trend Cycle** Plots the trend cycle components, $C_t$, over time.
- **D13 - Final Irregular Series** Plots the irregular components, $I_t$, over time.

**X11 Report Options**

The X11 reports have the following red triangle options:

- **Show Tables** Shows or hides the X11 summary tables, as described in Shiskin et. al. (1967). The tables are grouped into five categories (labeled B through F), described in Table 18.1.

- **Save Columns** Saves four columns to the data table: the seasonally adjusted time series, the seasonal components ($S_t$), the trend cycle components ($C_t$), and the irregular series components ($I_t$).

- **Save All Columns** Saves columns to the data table for all of the tables produced in the report by the **Show Tables** option.

- **Remove Fit** Removes the X11 report from the report window.

**Table 18.1 Descriptions of the Categories of X11 Output Tables**

Model Comparison Report

Once a model is fit, the Model Comparison Report is displayed in the report window. This report contains the Model Comparison table and plots for the models. Each time a new model is fit, a new row is added to the Model Comparison table, with a unique color-coding. The Model Comparison table summarizes the fit statistics for each model and is used to compare several models fitted to the same time series. By default, the models are sorted by the AIC statistic, in increasing order. To sort the model by a different statistic, right-click any column in the Model Comparison Table and select Sort by Column. Alternatively, you can also click on the column header to sort. For definitions of the fit statistics, see “Model Summary Table” on page 349. The only fit statistic that is unique to the Model Comparison Table is Weights. This fit statistic is the normalized AIC Weight. The AIC Weight for a model is calculated as follows:

\[
AICWeight = \exp[-0.5(AIC - BestAIC)]/ \sum_{k=1}^{K} (\exp[-0.5(AIC_k - BestAIC)])
\]

\(K\) is the total number of models, \(AIC_k\) is the AIC value for model \(k\), and \(BestAIC\) is the AIC value for the model with the minimum AIC value.

If you specify a holdback set, the fit statistics that are computed on the training data are not shown in the Model Comparison table. Instead, the following metrics to determine the forecasting performance of the individual models on the holdback set are computed: Root Mean Square Error (RMSE), Mean Square Error (MSE), Mean Absolute Percentage Error (MAPE), and Mean Absolute Error (MAE). By default, the models are sorted by the RMSE statistic, in increasing order. To sort the model by a different statistic, right-click any column in the Model Comparison Table and select Sort by Column. Alternatively, you can also click on the column header to sort. For definitions of the fit statistics, see “Model Summary Table” on page 349.
**Caution:** If you do not specify a holdback set and fit a combination of state space smoothing models and ARIMA models, a caution message is shown at the top of the Model Comparison table. In this case, the state space smoothing models are not comparable to the ARIMA models because likelihood values and likelihood-based information criteria, such as the AIC statistic, are not comparable between the two different model classes. However, if you specify a holdback set, the models can be compared because the RMSE statistic is used.

You can select which full model reports are shown in the report window using the **Report** check box. Two model plots appear to the right of the Model Comparison table. The top plot is a time series plot of the data, forecasts, and prediction limits. Below that are plots of the autocorrelation and partial autocorrelation functions. You can select which models are displayed on the model plots using the **Graph** check box.

**Figure 18.13** Model Plots

**Model Comparison Report Options**

Each model in the Model Comparison report has the following red triangle menu options:

- **Fit New**  Opens a specification window for the model. You can change the settings to fit a different model.
Simulate Once  (Not available if a holdback set is specified.) Provides one simulation of the model to the upper end of the time axis. The simulation is shown on the Model Comparison time series plot.

Simulate More  (Not available if a holdback set is specified.) Provides the specified number of simulations of the model to the upper end of the time axis. The simulations are shown on the Model Comparison time series plot.

Remove Model Simulation  (Not available if a holdback set is specified.) Removes the simulations for the model.

Remove All Simulation  (Not available if a holdback set is specified.) Removes the simulations for all models.

Generate Simulation  (Not available if a holdback set is specified.) Generates simulations for the model, and stores the results in a data table. You can specify the random seed, number of simulations, and the number of forecast periods.

Set Seed  (Not available if a holdback set is specified.) Specifies the seed for generating the simulated trajectories.

Remove Fit  Removes the corresponding model from the report window.

Remove All Models  Removes all models that are listed in the Model Comparison table from the report window.

Remove Unselected  Removes all models that do not have the Report check box selected from the report window.

Remove Selected  Removes all models that have the Report check box selected from the report window.

Hide All Reports  Hides all of the models that are listed in the Model Comparison table from the report window. This is equivalent to deselecting all of the Report check boxes.

Hide All Graphs  Hides all of the models that are listed in the Model Comparison table from the Model Plots. This is equivalent to deselecting all of the Graph check boxes.

Note: The Time Series platform treats excluded rows as missing values. If the last several observations in the data table are excluded or missing, the simulation options in the Model Comparison Report will not work properly. The simulation procedure uses the last several observations of the time series. If the last several observations are missing, the simulation produces all missing values into the future.
ARIMA and Seasonal ARIMA Model Report

The time series modeling options are used to fit theoretical models to the series and use the fitted model to predict (forecast) future values of the series. These options also produce statistics and residuals that enable you to determine the adequacy of the model that you have chosen to use. You can select the modeling options multiple times. Each time you select a model, that model is added to the Model Comparison table. When the Report check box next to a model in the Model Comparison table is selected, a report is produced for that model. The report specifies the model in its title.

The following reports are shown by default:

- Model Summary Table
- Parameter Estimates Table
- Forecast Plot
- Residuals
- Iteration History

**Model Summary Table**  Contains fit statistics for the model. In the formulas below, \( n \) is the length of the series and \( k \) is the number of fitted parameters in the model.

- **DF**  The number of degrees of freedom in the fit, \( n - k \).
- **Sum of Squared Innovations**  The sum of the squared innovations.
- **Sum of Squared Residuals**  The sum of the squared residuals.
- **Variance Estimate**  The sum of squared innovations divided by the number of degrees of freedom \( (n - k) \). This is the sample estimate of the variance of the random shocks \( a_t \) described in the section “ARIMA Model” on page 370.
- **Standard Deviation**  The square root of the variance estimate. This is a sample estimate of the standard deviation of the random shocks \( a_t \).
- **Akaike’s ‘A’ Information Criterion**  The AIC value, computed as \(-2\log\text{likelihood} + 2k\). Smaller AIC values indicate better fit.
- **Schwarz’s Bayesian Criterion**  The SBC value, computed as \(-2\log\text{likelihood} + k\ln(n)\). Smaller SBC values indicate better fit. Schwarz’s Bayesian Criterion is equivalent to the Bayesian Information Criterion (BIC).
- **RSquare**  The R-Square value, computed as follows:

\[
R^2 = 1 - \frac{SSE}{SST}
\]

where
Time Series Analysis

Chapter 18

Reports Predictive and Specialized Modeling

are the one-step-ahead forecasts

\( \hat{y}_i \) are the one-step-ahead forecasts

\( \hat{y} \) is the mean

If the model does not fit the series well, the model error sum of squares, SSE, might be larger than the total sum of squares, SST. As a result, \( R^2 \) can be negative.

**RSquare Adj**  The adjusted \( R^2 \) value, computed as follows:

\[
1 - \left( \frac{(n-1)}{(n-k)}(1 - R^2) \right)
\]

**MAPE**  The Mean Absolute Percentage Error value, computed as follows:

\[
\frac{100}{n} \sum_{i=1}^{n} \left| \frac{y_i - \hat{y}_i}{y_i} \right|
\]

**MAE**  The Mean Absolute Error value, computed as follows:

\[
\frac{1}{n} \sum_{i=1}^{n} |y_i - \hat{y}_i|
\]

**–2LogLikelihood**  Twice the negative log-likelihood function evaluated at the best-fit parameter estimates. Smaller values are better fits. See *Fitting Linear Models*.

**Stable**  Indicates whether the autoregressive operator is stable. That is, whether all the roots of \( \phi(z) = 0 \) lie outside the unit circle.

**Invertible**  Indicates whether the moving average operator is invertible. That is, whether all the roots of \( \theta(z) = 0 \) lie outside the unit circle.

**Note:** The \( \phi \) and \( \theta \) operators are defined in the section "ARIMA Model" on page 370.

**Parameter Estimates Table**  Shows the estimates for the time series model parameters. Each type of model has its own set of parameters, which are described in the sections on specific time series models. Each Parameter Estimates table contains the following columns:
**Term**  The name of the parameter, which are described in the sections for each model type. Some models contain an *intercept* or mean term. In those models, the related *constant estimate* is also shown. The definition of the constant estimate is given under the description of ARIMA models.

**Factor**  (Shown only for multiplicative Seasonal ARIMA models.) The factor of the model that contains the parameter. In the multiplicative seasonal models, Factor 1 is nonseasonal and Factor 2 is seasonal.

**Lag**  (Shown only for ARIMA and Seasonal ARIMA models.) The degree of the lag or backshift operator that is applied to the term to which the parameter is multiplied.

**Estimate**  The parameter estimates of the time series model.

**Std Error**  The estimates of the standard errors of the parameter estimates. These estimates are used to calculate tests and prediction intervals.

**t Ratio**  The test statistics for the hypotheses that each parameter is zero. The test statistic for a parameter is the ratio of the parameter estimate to its standard error. If the hypothesis is true, then this statistic has an approximate Student’s *t* distribution. Looking for a *t*-ratio greater than 2 in absolute value is a common rule for judging significance because it approximates the 0.05 significance level.

**Prob>|t|**  The observed *p*-value calculated for each parameter. The *p*-value is the probability of getting a *t*-ratio greater (in absolute value) than the computed value, given a true hypothesis.

**Constant Estimate**  (Shown only for models that contain an intercept or mean term.) The definition of the constant estimate is given under ARIMA model.

**Mu**  (Shown only for ARIMA and Seasonal ARIMA models.) The estimate for the intercept value of an ARIMA or seasonal ARIMA model.

**Forecast**  A plot that shows both the observed and predicted values for the time series. The plot is divided by a vertical line into two regions.

If you specified a holdback set, a vertical line separates the training data from the holdback data. To the left of the vertical line, the one-step-ahead forecasts are overlaid with the training data points. To the right of the vertical line, the values forecast by the model are overlaid with the holdback data points. The prediction intervals for the forecast are also shown. You can control the number of forecast values using the Forecast Periods option in the platform launch window.

If you did not specify a holdback set, the vertical line separates the observed data from the future forecasts. To the left of the vertical line, the one-step-ahead forecasts are overlaid with the observed data points. To the right of the vertical line, the future values forecast by the model and the prediction intervals for the forecast are shown. You can control the
number of future forecast values using the Forecast Periods option in the platform launch window or by selecting Number of Forecast Periods from the Time Series red triangle menu.

**Residuals** A graph that shows the values of the residuals based on the fitted model. These values are the observed values of the time series minus the one-step-ahead predicted values. The autocorrelation and partial autocorrelation reports for these residuals are also shown. These reports can be used to determine whether the fitted model is adequate to describe the data. If the fitted model is adequate, the points in the residual plot should be normally distributed about zero and the autocorrelation and partial autocorrelation of the residuals should not have any significant components for lags greater than zero.

**Forecasting Errors on Holdback Series** (Available only if a holdback set is specified.) A plot of the forecasting errors on the observations in the holdback set. The autocorrelation and partial autocorrelation reports for these errors are also shown.

**Iteration History** Contains the value of the objective function at each iteration. This can be useful for diagnosing problems with the fitting procedure. Attempting to fit a model that is poorly suited to the data can result in a failure to converge on an optimum value for the likelihood. The Iteration History table contains the following quantities:

- **Iter** The iteration number.
- **Iteration History** The objective function value for each step.
- **Step** The type of iteration step.
- **Obj-Criterion** The norm of the gradient of the objective function.

**ARIMA and Seasonal ARIMA Model Report Options**

Each ARIMA and Seasonal ARIMA model report has a red triangle menu that contains the following options:

- **Show Points** Shows or hides the data points in the forecast graph.
- **Show Prediction Interval** Shows or hides the prediction intervals in the forecast graph.
- **Save Columns** Creates a new data table that contains columns that represent the results of the model.
- **Save Prediction Formula** (Not available if a holdback set is specified.) Saves the data and prediction formula to a new data table.
- **Create SAS Job** Creates SAS code that duplicates the model analysis in SAS.
- **Submit to SAS** Submits SAS code to SAS that duplicates the model analysis. If you are not connected to a SAS server, this option guides you through the connection process.
Residual Statistics  Controls the displays of residual statistics are shown for the model. These displays are described in the section “Time Series Platform Options” on page 331. However, they are applied to the series of residuals.

Remove Fit  Removes the individual model fit from the report.

State Space Smoothing Report

Each State Space Smoothing model is added to the Model Comparison table. If the Report check box for a state space smoothing model in the Model Comparison table is selected, a State Space Smoothing report appears. Each State Space Smoothing report has a unique outline name that identifies the model. The following reports are included:

Model Type  Describes the best fitting model for the series in terms of error, trend, and seasonality.

Model Summary  Contains fit statistics for the model. In the formulas below, \( n \) is the length of the series and \( k \) is the number of fitted parameters in the model.

-2LogLikelihood  Twice the negative log-likelihood function evaluated at the best-fit parameter estimates. Smaller values are better fits. See Fitting Linear Models.

AIC  The Akaike’s Information Criterion (AIC) value, computed as \(-2\log\text{likelihood} + 2k\). Smaller AIC values indicate better fit.

BIC  The Schwarz’s Bayesian Criterion (SBC) value, computed as \(-2\log\text{likelihood} + k\ln(n)\). Smaller SBC values indicate better fit. Schwarz’s Bayesian Criterion is equivalent to the Bayesian Information Criterion (BIC).

Nparm  The number of parameters in the calculation of the information criteria. This number is one more than the number of free parameters in the likelihood function.

Note: Nparm is not the number of parameters in the parameter estimates table.

Sigma  The estimate of the one-step-ahead forecast standard deviation.

RSquare  The R-Square value, computed as follows:

\[
R^2 = 1 - \frac{\text{SSE}}{\text{SST}}
\]

where

\[
\text{SST} = \sum_{i=1}^{n} (y_i - \bar{y})^2
\]
Time Series Analysis

Chapter 18

Reports Predictive and Specialized Modeling

\[ \text{SSE} = \sum_{i=1}^{n} (y_i - \hat{y}_i)^2 \]

\( \hat{y}_i \) are the one-step-ahead forecasts

\( \bar{y} \) is the mean

If the model does not fit the series well, the model error sum of squares, SSE, might be larger than the total sum of squares, SST. As a result, \( R^2 \) can be negative.

RSquare Adj  The adjusted \( R^2 \) value, computed as follows:

\[ 1 - \left[ \frac{(n-1)}{(n-k)} \left(1 - R^2 \right) \right] \]

MAPE  The Mean Absolute Percentage Error value, computed as follows:

\[ \frac{100}{n} \sum_{i=1}^{n} \left| \frac{y_i - \hat{y}_i}{y_i} \right| \]

where

\( \hat{y}_i \) are the one-step-ahead forecasts

MAE  The Mean Absolute Error value, computed as follows:

\[ \frac{1}{n} \sum_{i=1}^{n} \left| y_i - \hat{y}_i \right| \]

where

\( \hat{y}_i \) are the one-step-ahead forecasts

Parameter Estimates  A table that shows the estimate, standard error, and 95% confidence interval for each parameter in the model.

Forecast  A plot that shows both the observed and predicted values for the time series. See “Forecast” on page 351.

One-Step-Ahead Forecasting Errors  A plot of the one-step-ahead forecasting errors over time. For each time point \( t \), the error is calculated as the observed value of the time series at \( t \) minus the one-step-ahead predicted value at \( t \). If a holdback set is specified, the errors are computed only for the training data. The autocorrelation and partial autocorrelation reports for these errors are also shown.
Forecasting Errors on Holdback Series  (Available only if a holdback set is specified.) A plot of the forecasting errors on the observations in the holdback set. The autocorrelation and partial autocorrelation reports for these errors are also shown.

Component States  A report that contains a plot for each state of the model and the corresponding formula for the model. Each plot includes the state estimates of the series and the state forecasts. If a holdback set is specified, the state estimates are for the training portion and the state forecasts are for the holdback portion. If a holdback set is not specified, the state estimates are for the portion up to the last observation of the time series and the state forecasts are for after the last observation of the time series. A model can have up to three states: Level, Trend, and Seasonal.

The Component States red triangle menu has a Save States option. Select this option to save the component states at each time point to a separate data table.

One-Step-Ahead Relative Forecasting Errors for Multiplicative Error Model  (Available only for multiplicative error models.) A plot of the one-step-ahead relative forecasting errors over time. For each time point $t$, the error is calculated as the one-step-ahead-forecasting error at $t$ divided by the one-step-ahead predicted value at $t$.

State Space Smoothing Report Options

Each state space smoothing report has a red triangle menu that contains the following options:

- Show Points  Shows or hides the data points in the forecast graph.
- Show Prediction Interval  Shows or hides the prediction intervals in the forecast graph.
- Save Columns  Creates a new data table that contains columns that represent the results of the model.
- Remove Fit  Removes the individual model fit from the report.

Transfer Function Report

Each transfer function model is added to the Model Comparison table. If the Report check box for a transfer function model in the Model Comparison table is selected, a Transfer Function Model report is produced. If a holdback set is specified, a model plot is also available in the Model Comparison report.

Each Transfer Function Model report contains the following reports:

- Model Summary
- Parameter Estimates
- Residuals
- Forecasting Errors on Holdback Series
• Interactive Forecasting
• Iteration History

The information in the Model Summary, Parameter Estimates, Residuals, Forecasting Errors on Holdback Series, and Iteration History reports is the same as in the ARIMA and Seasonal ARIMA model report. For more information about these reports, see “ARIMA and Seasonal ARIMA Model Report” on page 349. The Parameter Estimates table is followed by the formula of the model, where $B$ is the backshift operator.

**Interactive Forecasting**

The Interactive Forecasting report provides a forecasting graph based on a prediction interval specified in the Transfer Function Specification window. The prediction interval around the prediction is shown in blue. Change the confidence level for this prediction interval by entering a number in the Prediction Interval box above the graph.

You can drag the plus sign in the graph to change the number of forecast periods in the graph. In the forecast periods, you can change the input values using the Import Inputs from Table button or by dragging points in the input graph to different values. The results of your changes are reflected in the forecast periods of the output graph.

**Figure 18.14** Interactive Forecasting Graph
Spectral Density Report

Figure 18.15 Spectral Density Plots and White Noise Test Report

The White Noise Test report contains the following statistics:

**Fisher's Kappa**  Tests the null hypothesis that the values in the series are drawn from a normal distribution with variance 1 against the alternative hypothesis that the series has a periodic component. Kappa is the ratio of the maximum value of the periodogram, \( I(f_i) \), and its average value.

**Prob > Kappa**  The probability of observing a value larger than Kappa if the null hypothesis is true, given by the following equation:

\[
Pr(k > \kappa) = 1 - \sum_{j=0}^{q} (-1)^j \binom{q}{j} [\max(1 - \frac{i \kappa}{q}, 0)]^{q-1}
\]

where

- \( q = N / 2 \) if \( N \) is even, \( q = (N - 1) / 2 \) if \( N \) is odd
- \( \kappa \) is the observed value of Kappa

The null hypothesis is rejected if this probability is less than the significance level \( \alpha \).

**Bartlett's Kolmogorov-Smirnov**  Compares the normalized cumulative periodogram to the cumulative distribution function of the uniform distribution on the interval (0, 1). The test statistic equals the maximum absolute difference of the cumulative periodogram and the uniform CDF. If it exceeds \( a / \sqrt{q} \), then one typically rejects the hypothesis that the series comes from a normal distribution. The values \( a = 1.36 \) and \( a = 1.63 \) correspond to significance levels 5% and 1% respectively.
Additional Examples of the Time Series Platform

- “Example of Creating Time ID Column”
- “Example Using a Holdback Set”

Example of Creating Time ID Column

This example uses the SeriesP.jmp sample data table to show how to perform a time series analysis. You first create a new column that is appropriate for the Time ID.

Create Appropriate Time ID Column

   The SeriesP.jmp data table contains a Year column and a Quarter column to identify the time period during which the responses were observed. However, the Time Series platform requires one column with unique, equally spaced time points to label the X axis. If no Time ID is specified, then the row number is used to identify the time periods. To avoid this and make the report easier to interpret, you construct a Time ID column from Year and Quarter.

2. Select Cols > New Columns. In the Column Name box, type Year.Quarter.
3. Select Best > Date > yyyyQq next to Format.
4. Select Column Properties > Formula.
5. Click the gray triangle next to Date Time and click Informat.
6. Click the gray triangle next to Character.
7. Select Year, click Char, and then click Concat.
8. Type “Q” in the box (including quotation marks) and press Enter.
9. Click Concat.
10. Select Quarter and click Char.
11. Click the <formatName> box, type yyyyQq, and press Enter.
12. Click OK.
   The completed New Column window should appear as in Figure 18.16.
Figure 18.16  New Column

13. Click OK.

Note: This time column also works for X11 analyses.

Time Series Analysis

Now that the data table contains an appropriate Time ID column, proceed with the analysis.

1. Select Analyze > Specialized Modeling > Time Series.
2. Select GDP and click Y, Time Series.
3. Select Year.Quarter and click X, Time ID.
4. Click OK.
Figure 18.17 Time Series Report for SeriesP.jmp

The series shows an increasing trend over time that is fairly linear. In addition, the autocorrelation chart shows that there is strong correlation between points that are close together. The AutoCorr values for points with lags of 1, 2, and 3 are 0.9551, 0.9112, 0.8666, respectively.

5. Click the Time Series GDP red triangle and select **Difference**.
6. Select 1 for the Nonseasonal Differencing Order and click **Estimate**.
The Difference report helps determine an appropriate model to be fit to the original time series. The plot of differences shows that the differenced series no longer has the trend that was observed in the original data. This indicates that lag-1 differencing is an appropriate choice. Also, even after removing the trend, the series shows no sign of seasonality. For these reasons, models to fit the original series should be able to handle linear trends, but do not necessarily need to handle seasonality. Linear exponential smoothing and ARIMA models would be appropriate.

7. Click the Time Series GDP red triangle and select Smoothing Model > Linear Exponential Smoothing.

8. Click Estimate.

9. Click the Time Series GDP red triangle and select ARIMA Model Group. This enables you to fit multiple ARIMA models for a range of values of \((p,d,q)(P,D,Q)\).

10. In the ARIMA box, set the following ranges:
– Fix $d$, the differencing order, at 1 by setting the range from 1 to 1 because the differencing report showed lag-1 differencing was appropriate.
– Set $p$, the autoregressive order, to range from 0 to 1 because the original series showed evidence of autocorrelation.
– Set $q$, the moving average order, to range from 0 to 1.

**Note:** In most cases, it is sufficient to keep $p$ and $q$ small.

– Leave $P$, $D$, and $Q$ set at 0, since the series showed no evidence of seasonality. These settings lead to the fitting of four total models.

**Figure 18.19** ARIMA Model Group Specification

11. Click **Estimate**.

**Figure 18.20** Model Comparison Table

The Model Comparison Table is sorted such that the best fitting model, according to the AIC criterion, is at the top of the list. In this case, the ARIMA(0,1,0) model (denoted I(1) in the report) best fits the original time series. It should also be noted that although the I(1) model is “best,” all of the models have extremely similar values for the fit statistics. They could all be considered appropriate.
Figure 18.21 Model Report for ARIMA(0,1,0)

The model report for I(1) shows the forecast graph. The blue lines indicate the prediction intervals. GDP is predicted to continue increasing at a linear rate.

Example Using a Holdback Set

This example uses a holdback set to evaluate predictions made on monthly data on lead production. Since a holdback set is used, both State Space Smoothing and ARIMA models can be fit and compared to find the best fitting model for the data.

1. Select Help > Sample Data Library and open Time Series/Lead Production.jmp.
2. Select Analyze > Specialized Modeling > Time Series.
4. Select DATE and click X, Time ID.
5. Select Forecast on Holdback.
   Selecting this options means that forecasts are made on the holdback set instead of on future observations.
6. Enter 12 next to Forecast Periods.
This assigns the last 12 observations in the data to the holdback set. Since this is monthly data, this is equivalent to the last year.

7. Click **OK**.
8. Click the Time Series Sales red triangle and select **State Space Smoothing**.
9. Type 12 next to Period.
10. Select Constrain Parameters.
11. Click **OK**.
12. Click the Time Series Sales red triangle and select **ARIMA Model Group**.
13. Set the range for all parameters from 0 to 1. The Specify ARIMA Model window looks like the one in Figure 18.22.

**Figure 18.22** ARIMA Model Group Specifications

14. Click **Estimate**.

**Figure 18.23** Model Comparison
The fit statistics are comparable between the State Space Smoothing models and the ARIMA models because they are evaluated on the holdback set.

15. Select the Graph check box next to the first three models in the Model Comparison report.

**Figure 18.24 Model Comparison Graph**

The evaluation statistics and the forecasting plots show that there is no substantial differences in forecasting performance among the top models. Based on the report, either an ARIMA model or a State Space Smoothing model is appropriate for this data.

**Statistical Details for the Time Series Platform**

- “Statistical Details for Spectral Density”
- “Statistical Details for X-11 Decomposition”
- “Statistical Details for Smoothing Models”
- “Statistical Details for ARIMA Models”
- “Statistical Details for Transfer Functions”

**Statistical Details for Spectral Density**

The least squares estimates of the coefficients of the Fourier series are computed as follows:

\[ a_t = \frac{2}{N} \sum_{i=1}^{N} y_i \cos(2\pi f_i t) \]
Then the \( f_i = i/N \) are combined to form the periodogram \( I(f_i) = (N/2)(a_i^2 + b_i^2) \), which represents the intensity at frequency \( f_i \).

The periodogram is then smoothed and scaled by \( 1/(4\pi) \) to form the spectral density.

**Statistical Details for X-11 Decomposition**

This method adjusts the original time series using either a multiplicative or an additive decomposition. The model is fit using an iterative process to estimate the three X-11 components: trend cycle, seasonal, and irregular. The trend cycle component contains both the long-term trend and the long-term cyclical effects. The irregular component contains the effects of variation unexplained by the trend and seasonal components. For a historical overview of the development of the X-11 method, see SAS/ETS 15.2 User’s Guide (search for “Historical Development of X-11”).

The multiplicative adjustment fits the following model:

\[
O_t = C_t \cdot S_t \cdot I_t
\]

where

- \( O_t \) is the original time series
- \( C_t \) is the trend cycle component
- \( S_t \) is the seasonal component
- \( I_t \) is the irregular component

The adjusted multiplicative trend is \( O_t/S_t \).

The additive adjustment fits the following model:

\[
O_t = C_t + S_t + I_t
\]

The adjusted additive trend is \( O_t - S_t \).

**Statistical Details for Smoothing Models**

Smoothing models are defined as follows:

\[
y_t = \mu_t + \beta_t \cdot t + s(t) + a_t
\]
where

\( \mu_t \) is the time-varying mean term
\( \beta_t \) is the time-varying slope term
\( s(t) \) is one of the \( s \) time-varying seasonal terms
\( a_t \) are the random shocks

Models without a trend have \( \beta_t = 0 \) and nonseasonal models have \( s(t) = 0 \). The estimators for these time-varying terms are defined as follows:

- \( L_t \) is a smoothed level that estimates \( \mu_t \)
- \( T_t \) is a smoothed trend that estimates \( \beta_t \)
- \( S_{t,j} \) for \( j = 0, 1, ..., s - 1 \) are the estimates of the \( s(t) \)

Each smoothing model defines a set of recursive smoothing equations that describe the evolution of these estimators. The smoothing equations are written in terms of model parameters called smoothing weights:

- \( \alpha \) is the level smoothing weight
- \( \gamma \) is the trend smoothing weight
- \( \phi \) is the trend damping weight
- \( \delta \) is the seasonal smoothing weight

While these parameters enter each model in a different way (or not at all), they have the common property that larger weights give more influence to recent data while smaller weights give less influence to recent data.

### Simple Exponential Smoothing

The model for simple exponential smoothing is \( y_t = \mu_t + a_t \).

The smoothing equation, \( L_t = \alpha y_t + (1 - \alpha)L_{t-1} \), is defined in terms of a single smoothing weight \( \alpha \). This model is equivalent to an ARIMA(0, 1, 1) model where the following is true:

\[
(1 - B)y_t = (1 - \theta B)a_t \quad \text{where} \quad \theta = 1 - \alpha
\]

The moving average form of the model is defined as follows:

\[
y_t = a_t + \sum_{j=1}^{\infty} \alpha a_{t-j}
\]

### Double (Brown) Exponential Smoothing

The model for double exponential smoothing is \( y_t = \mu_t + \beta_t t + a_t \).
The smoothing equations, defined in terms of a single smoothing weight $\alpha$, are defined as follows:

\[
L_t = \alpha y_t + (1 - \alpha)L_{t-1}
\]
\[
T_t = \alpha(L_t - L_{t-1}) + (1 - \alpha)T_{t-1}
\]

This model is equivalent to an ARIMA(0, 1, 1)(0, 1, 1)$_1$ model where the following is true:

\[
(1 - B)^2 y_t = (1 - \theta B)^2 a_t \quad \text{where} \quad \theta_{1,1} = \theta_{2,1} \quad \text{with} \quad \theta = 1 - \alpha
\]

The moving average form of the model is defined as follows:

\[
y_t = a_t + \sum_{j=1}^{\infty} (2\alpha + (j - 1)\alpha^2)a_{t-j}
\]

**Linear (Holt) Exponential Smoothing**

The model for linear exponential smoothing is $y_t = \mu_t + \beta_t \cdot t + a_t$.

The smoothing equations, in terms of smoothing weights $\alpha$ and $\gamma$, are defined as follows:

\[
L_t = \alpha y_t + (1 - \alpha)(L_{t-1} + T_{t-1})
\]
\[
T_t = \gamma(L_t - L_{t-1}) + (1 - \gamma)T_{t-1}
\]

This model is equivalent to an ARIMA(0, 2, 2) model where the following is true:

\[
(1 - B)^2 y_t = (1 - \theta B - \theta_2 B^2)a_t \quad \text{with} \quad \theta = 2 - \alpha - \alpha \gamma \quad \text{and} \quad \theta_2 = \alpha - 1
\]

The moving average form of the model is defined as follows:

\[
y_t = a_t + \sum_{j=1}^{\infty} (\alpha + j\alpha \gamma)a_{t-j}
\]

**Damped-Trend Linear Exponential Smoothing**

The model for damped-trend linear exponential smoothing is $y_t = \mu_t + \beta_t \cdot t + a_t$.

The smoothing equations, in terms of smoothing weights $\alpha$, $\gamma$, and $\phi$, are defined as follows:

\[
L_t = \alpha y_t + (1 - \alpha)(L_{t-1} + \phi T_{t-1})
\]
\[
T_t = \gamma(L_t - L_{t-1}) + (1 - \gamma)\phi T_{t-1}
\]
This model is equivalent to an ARIMA(1, 1, 2) model where the following is true:

\[(1 - \varphi B)(1 - B)y_t = (1 - \theta_1 B - \theta_2 B^2)a_t\]

where

\[\theta_1 = 1 + \varphi - \alpha - \alpha \gamma \varphi\]
\[\theta_2 = (\alpha - 1)\varphi\]

The moving average form of the model is defined as follows:

\[y_t = a_t + \sum_{j=1}^{\infty} \left( \frac{\alpha + \alpha \gamma \varphi (\varphi^j - 1)}{\varphi - 1} \right) a_{t-j}\]

**Seasonal Exponential Smoothing**

The model for seasonal exponential smoothing is \(y_t = \mu_t + s(t) + a_t\).

The smoothing equations in terms of smoothing weights \(\alpha\) and \(\delta\) are defined as follows:

\[L_t = \alpha(y_t - S_{t-s}) + (1 - \alpha)L_{t-1}\]
\[S_t = \delta(y_t - L_{t-s}) + (1 - \delta)S_{t-s}\]

This model is equivalent to a seasonal ARIMA(0, 1, s+1)(0, 1, 0)_s model:

\[(1 - B)(1 - B^s)y_t = (1 - \theta_1 B - \theta_2 B^2 - \theta_3 B^{s+1})a_t\]

where

\[\theta_1 = 1 - \alpha\]
\[\theta_2 = (1 - \delta)(1 - \alpha)\]
\[\theta_3 = (1 - \alpha)(\delta - 1)\]

The moving average form of the model is defined as follows:

\[y_t = a_t + \sum_{j=1}^{\infty} \psi_j a_{t-j}\]

where \(\psi = \begin{cases} 
\alpha & \text{for } j \mod s \neq 0 \\
\alpha + \delta(1 - \alpha) & \text{for } j \mod s = 0 
\end{cases}\)

**Winters Method (Additive)**

The model for the additive version of the Winters method is \(y_t = \mu_t + \beta_t t + s(t) + a_t\).
The smoothing equations in terms of weights $\alpha$, $\gamma$, and $\delta$ are defined as follows:

\[
L_t = \alpha(y_t - S_{t-s}) + (1 - \alpha)(L_{t-1} + T_{t-1})
\]
\[
T_t = \gamma(L_t - L_{t-1}) + (1 - \gamma)T_{t-1}
\]
\[
S_t = \delta(y_t - L_t) + (1 - \delta)S_{t-s}
\]

This model is equivalent to a seasonal ARIMA(0, 1, s+1)(0, 1, 0)s model defined as follows:

\[
(1 - B)(1 - B^2)y_t = \left(1 - \sum_{i=1}^{s+1} \theta_i B^i\right) a_t
\]

The moving average form of the model is defined as follows:

\[
y_t = a_t + \sum_{j=1}^{\infty} \psi_j a_{t-j}
\]

where

\[
\psi = \begin{cases}
\alpha + j\alpha\gamma, & \text{if } j \text{ mod } s \neq 0 \\
\alpha + j\alpha\gamma + \delta(1 - \alpha), & \text{if } j \text{ mod } s = 0
\end{cases}
\]

**Statistical Details for ARIMA Models**

**ARIMA Model**

For a response series $\{y_t\}$, the general form for the ARIMA model is defined as follows:

\[
\phi(B)(w_t - \mu) = \theta(B)a_t
\]

where

- $t$ is the time index
- $B$ is the backshift operator defined as $By_t = y_{t-1}$
- $w_t = (1 - B)^dy_t$ is the response series after differencing
- $\mu$ is the intercept or mean term
- $\phi(B)$ and $\theta(B)$ are the autoregressive operator and the moving average operator, respectively, and are defined as follows:

\[
\phi(B) = 1 - \phi_1B - \phi_2B^2 - \ldots - \phi_pB^p
\]
\[
\theta(B) = 1 - \theta_1B - \theta_2B^2 - \ldots - \theta_qB^q
\]
where

\[ a_t \] are the sequence of random shocks

The \( a_t \) are assumed to be independent and normally distributed with mean zero and constant variance.

The model can be rewritten as follows:

\[ \phi(B)w_t = \delta + \theta(B)a_t \]

The constant estimate \( \delta \) is given by the relation:

\[ \delta = \phi(B)\mu = \mu - \phi_1 \mu - \phi_2 \mu - \ldots - \phi_p \mu \]

### Seasonal ARIMA Model

In the case of Seasonal ARIMA modeling, the differencing, autoregressive, and moving average operators are the product of seasonal and nonseasonal polynomials:

\[ w_t = (1 - B)^d (1 - B^s)^D y_t \]

\[ \phi(B) = (1 - \phi_{1,1}B - \phi_{1,2}B^2 - \ldots - \phi_{1,p}B^p)(1 - \phi_{2,s}B^s - \phi_{2,2s}B^{2s} - \ldots - \phi_{2,p_s}B^{p_s}) \]

\[ \theta(B) = (1 - \theta_{1,1}B - \theta_{1,2}B^2 - \ldots - \theta_{1,q}B^q)(1 - \theta_{2,s}B^s - \theta_{2,2s}B^{2s} - \ldots - \theta_{2,Q_s}B^{Q_s}) \]

where \( s \) is the number of observations per period. The first index on the coefficients is the factor number (1 indicates nonseasonal, 2 indicates seasonal) and the second is the lag of the term.

### Statistical Details for Transfer Functions

A typical transfer function model with \( m \) inputs can be represented as follows:

\[ Y_t - \mu = \frac{\omega_1(B)}{\delta_1(B)}X_{1, t-d1} + \ldots + \frac{\omega_m(B)}{\delta_m(B)}X_{m, m-dm} + \frac{\theta(B)}{\phi(B)}e_t \]

where

\( Y_t \) denotes the output series

\( X_1 \) to \( X_m \) denote \( m \) input series

\( e_t \) represents the noise series

\( X_{1, t-d1} \) indicates the series \( X_1 \) is indexed by \( t \) with a \( d1 \)-step lag

\( \mu \) represents the mean level of the model
\( \phi(B) \) and \( \theta(B) \) represent autoregressive and moving average polynomials from an ARIMA model.

\( \omega_k(B) \) and \( \delta_k(B) \) represent numerator and denominator factors (or polynomials) for individual transfer functions, with \( k \) representing an index for the 1 to \( m \) individual inputs.

Each polynomial in the above model can contain two parts, either nonseasonal, seasonal, or a product of the two as in seasonal ARIMA. When specifying a model, leave the default 0 for any part that you do not want to include in the model.
The Time Series Forecast platform enables you to forecast multiple time series, where the number of series could be very large. The platform provides compact summaries of the multiple time series and provides options for efficiently fitting up to 30 different forecasting models in the exponential smoothing family. The best fitting model is automatically selected.

The Time Series Forecast platform is designed to select a best fitting model automatically from a set of exponential smoothing models. This is in contrast to the Time Series platform which requires manual selection of a best fitting model and uses ARIMA models.

Example of Time Series Forecast

1. Select Help > Sample Data Library and open Time Series/M3C Quarterly.jmp.
2. Select Analyze > Specialized Modeling > Time Series Forecast.
3. Select Y and click Y.
4. Select Series and click Grouping.
5. Select Time and click Time.
6. Click OK.

The initial Time Series Forecast report appears. It contains summaries of the Time and Y variables. There is also a Modeling Specifications report that provides options for fitting forecast models.

Figure 19.2 Initial Report for Time Series Forecast

7. In the Model Specifications report, click the Complete Specifications tab.
8. Click the menu below Model Selection Strategy and select Forecasting Performance.
9. Click Run.
This fits a set of recommended models to the data. The best model for each level of the grouping variable is chosen and reported in the Model Reports. See “Model Reports” on page 376.

Figure 19.3 Model Reports

The model report for one series, Series N646, is shown. This corresponds to the series name that is selected in the Select Series list. You can use the down arrow key to scan through the model reports for each series. Alternatively, you can click a different name in the list to display the model report for the selected series.
Launch the Time Series Forecast Platform

Launch the Time Series Forecast platform by selection **Analyze > Specialized Modeling > Time Series Forecast**.

**Figure 19.4** The Time Series Forecast Launch Window

For more information about the options in the Select Columns red triangle menu, see *Using JMP*.

The Time Series Forecast platform launch window contains the following options:

- **Y**: Assigns one or more columns as time series variables. Multiple time series can be organized as individual columns in a table or they can be stacked in a single column with one or more grouping variables.

- **Grouping**: Assigns one or more columns as grouping variables. Grouping variables are used to identify individual time series when they are in stacked format.

- **Time**: Assigns a column for the time variable. If the individual time series are organized as individual columns, the timestamps in the Time column must not contain any duplicates.

- **By**: Assigns a column that creates a report consisting of separate analyses for each level of the variable. If more than one By variable is assigned, a separate analysis is produced for each possible combination of the levels of the By variables.

**Data Format**

Multiple time series can be organized as individual columns in a table or they can be stacked in a single column with one or more grouping columns to identify the individual series. You can also have a combination of multiple Y columns and multiple grouping columns.

The platform makes the following assumptions about the data:

- All of the time series are recorded at the same time resolution.
• All of the time series are collected up to the same final observed time point. This final observed time point is defined as the latest time point that occurs in any of the individual time series. A series without data up to the final observed time point is assumed to have missing values. For example, in Figure 19.5, the final observed time point is 5, represented by the solid black line. It is assumed that Series 2 has missing observations at time points 4 and 5 and that Series 4 has a missing observation at time point 5.

• All of the forecasts start at the same time point. This starting time point is the next time point following the final observed time point. For example, in Figure 19.5, the final observed time point is 5, represented by the solid black line. Therefore, all of the forecasts start at time point 6, represented by the dashed black line.

**Figure 19.5** Demonstration of Assumptions
The Time Series Forecast Report

The Time Series Forecast report contains summary tables based on the variables specified in the launch window. A summary table of the time series by group is always provided. If a Time column is specified, the report also contains a summary of the time pattern and a summary table of the time by group. The report also contains a Modeling Specifications report that enables you to fit models to each time series.

- “Analysis of Time Pattern"
- “Group Summary of Time”
- “Group Summary of Y”
- “Modeling Specifications”

Analysis of Time Pattern

If a time column is specified, the Time Series Forecast platform analyzes the entries of the column to determine a pattern. The platform is designed to recognize a variety of time patterns, including daily, business daily, monthly, bi-weekly, quarterly, and so on. The pattern is reported as the Date Resolution. A Suggested Seasonality is also provided based on the time pattern.

Group Summary of Time

If a time column is specified, the report contains summaries of the individual time series. The summaries contain the following information for each time series:

<Grouping Column Name>  (Available only if a Grouping variable is specified.) The level of the grouping variable that defines the individual series when data is provided in the stacked format.

N Rows  The number of observations in the series.

Missing Value  Indicates whether any of the time values are missing values.

Unique Timestamps  Indicates whether the time stamps are unique.

Start  The starting time stamp.

End  The ending time stamp.

Missing Record  Indicates whether there are observations missing from the data table, based on the starting and ending time stamps and the data resolution/pattern.
Group Summary of Y

The report contains a summary table for each Y variable. The summaries contain the following information for each time series:

**Variable**  (Available only if there are multiple Y columns and at least one grouping column.)
The column name of the time series variables.

**Time Series**  (Available only if there are multiple series.) The name of the individual time series. When the data are provided in the stacked format, this is the level of the grouping variable. When the data are provided in the wide format, with multiple columns, this is the column name of the individual series.

**Note:** When the data are provided in the stacked format, the column heading in the table is the name of the Grouping column.

**Min**  The minimum value of Y for the individual series.

**Max**  The maximum value of Y for the individual series.

**Length**  The duration of the series. This is determined based on the starting and ending time stamps and the result of the Analysis of Time Pattern.

**N Obs**  The number of observations. If there are no missing records, this number is the same as the Length.

**N Missing**  The number of missing Y values.

**All Positive**  Indicates whether all of the Y values are positive.

**Comment**  Indicates if there is a problem with the series, such as non-unique time stamps.

Modeling Specifications

The Modeling Specifications report enables you to fit models to the individual time series. A variety of models are considered. Hyndman et al. (2008) defines state space smoothing models based on their error, trend component, and seasonal component:

- The errors can be additive (A) or multiplicative (M).
- The trend component can be none (N), additive (A), additive damped (A_d), multiplicative (M), or multiplicative damped (M_d).
- The seasonal component can be none (N), additive (A), or multiplicative (M).

A specific model can be represented by its ETS (Error, Trend, Seasonal). These are the models used in Time Series Forecasting.
There are two tabs in the Modeling Specifications report. Use the Recommended Specifications tab to fit a set of state space smoothing models that is chosen by the platform. Use the Complete Specifications tab to select the specific state space smoothing models that you want to fit. For each individual time series, the best fitting model from the given set is then used for forecasting.

**Select Models**

Available only in the Complete Specifications tab, shown in “Complete Specifications Tab” on page 381. The Select Models report enables you to specify the state space smoothing models to fit to the individual time series. Use the check boxes to select the error, trend, and seasonality for the models. Click **Select Recommended** to select the check boxes that correspond to the models recommended by the platform. Click **Select All** to select all check boxes or **Deselect All** to deselect all check boxes. Click **Constrain Parameters** to constrain the parameters in such a way that the further an observation is from the present, the less effect it has on the present state of the model. In State Space Smoothing models, a forecast at time $t$, given all previous observations, is the same as the weighted sum of all observations up to time $t$. The weights are a function of the parameters. Therefore, constraining the parameters ensures that the weights for past observations go to zero and that the further an observation is from the present, the faster the weight goes to zero.

**Figure 19.6  Complete Specifications Tab**
Forecast Settings

Enables you to specify the following optional settings:

**NAhead**  Specifies the number of steps ahead to forecast. The number of steps must be nonnegative.

**Period**  Specifies seasonality values to be considered in the model fitting process. By default, the period is set to the suggested seasonality from the Analysis of Time Pattern report. If you want to consider models with different seasonality, specify the additional periods here and separate them with a comma. The period must be greater than zero.

Model Selection Strategy

Enables you to specify how the best model is chosen.

**Information Criteria**  Determines the best model based on the specified information criteria. The available information criteria are AIC and BIC.

*Tip:* Use BIC if the time series is long.

Forecasting Performance  Determines the best model based on a performance selection algorithm that involves a holdback set. First, the time series is partitioned into a training set and a holdback set. The value of NHoldback specifies the number of observations in the holdback set. Then, the algorithm fits all recommended or user-specified models on the data in the training set. Forecasts are made on the holdback set using the individual fitted models. These forecasts are compared to the actual holdback observations and the models are evaluated using the specified metric. The model with the best metric is selected for the final model. Last, the selected final model is fit to the entire time series (training set and holdback set) and the refitted model is used to forecast beyond the last observation of the time series.

**Metric**  Specifies the metric to evaluate the forecasts made by the individual model fits. The available metrics are Root Mean Square Error (RMSE), Mean Square Error (MSE), and Mean Absolute Error (MAE).

**NHoldback**  Specifies the number of observations used in the holdback set.

Other Options

Enables you to specify the following options:

**Preserve Model Selection Criterion**  Saves the model selection criterion for the set of models that is fit to the data. After model fitting, this information is shown in the Information Criterion of All Models for All Series report.
Forecast Interval Level  The prediction interval level for the forecasts. This changes the width of the shaded area in the forecasting plots.

Imputation for Applicable Models  Specifies the imputation method used during the model fitting process.

**Note:** These options change only the data that are used for model fitting. The raw data are not changed.

None  Does not impute missing values.

Last Value  Imputes missing values by using the last value that is available before a sequence of missing observations.

Middle Value  Imputes missing values by averaging the last value that is available before a sequence of missing observations and the first value that is available after a sequence of missing observations.

Linear Interpolation  Imputes missing values by creating a linear interpolation between the last value that is available before a sequence of missing observations and the first value that is available after a sequence of missing observations.

When you click Run, the specified set of models is fit. A progress bar appears that reports the number of active threads, the number of finished and total tasks, and the percentage of finished tasks. Note that a task is defined as the fitting of all specified models for one series and response variable combination. When the fitting process is complete, the Model Reports report is shown. See “Model Reports” on page 384. If you make any changes to the options in the Model Specifications report and click Run again, the Model Reports report is replaced with a new report.

**Time Series Forecast Platform Options**

The Time Series Forecast red triangle menu contains the following options:

**Report Options**  (Effective only after fitting a model.) Contains the following report options:

Set Forecast Interval Level  Enables you to change the forecast interval level. The individual model reports update automatically.

Set NAhead  Enables you to change the number of steps ahead to forecast. The individual model reports update automatically.

Set NHoldout  Enables you to change the duration of the holdout set. The individual model reports update automatically.
Save Results  (Effective only after fitting a model.) Saves the forecasts to a separate data table named Forecasts. The Forecasts data table has the same layout and format as the original data table. If a holdout set is specified by NHoldout, an additional data table that saves the actual values from the holdout data and the forecasts is produced. You can use this table to calculate different types of error estimates.

The following additional save options are shown in the Request Outputs window:

Save Forecast Intervals  Saves the lower and upper prediction intervals as columns in the Forecasts data table.

Save One-Step-Ahead Predictions  Stacks the one-step-ahead predictions and the forecasts and saves them to a separate data table.

Save Original Series  Stacks the original series and the forecasts and saves them to a separate data table.

Save Forecast Results to Original Data Table  Saves the results to new columns in the original data table.

See Using JMP for more information about the following options:

Local Data Filter  Shows or hides the local data filter that enables you to filter the data used in a specific report.

Redo  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

Save Script  Contains options that enable you to save a script that reproduces the report to several destinations.

Save By-Group Script  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.

Model Reports

The Model Reports report contains a Select Series list and one or more individual series modeling reports. The individual reports that are displayed are determined by the Select Series list. Click on the name of a series in this list to show the report for the selected series. If you select more than one series name by using either Ctrl or Shift, an individual model fit report for each of the selected series is shown. If you deselect one or more series from the Select Series list, the reports for the corresponding series are removed.
The Select Series list is linked to the data table. When you select a series in the Select Series list, the observations for the series and response variable combination are also selected in the data table. The Select Series list is also linked to the Group Summary of Y table. If a Time variable is specified, the Select Series list is also linked to the Group Summary of Time table. When you select a series in the Select Series list, the corresponding entries are also selected in the tables.

Each individual model report contains the following information:

**Model Type**  Describes the best fitting model for the series in terms of error, trend, and seasonality.

**Model Report**  A group of reports based on the model that is fit to the series.

**Series and Forecasts**  (Available only when Information Criteria is specified as the model selection strategy.) A plot of the original series and forecasts. During the time period of the original series, the one-step-ahead predictions are shown. Beyond the time period of the original series, the forecasts are shown. The shaded region represents the forecasting interval.

**Note:** All of the forecasts start at the time point that immediately follows the last time point across all individual series. See “Data Format” on page 377.

**Training, Holdback, and Forecasts**  (Available only when Forecast Performance is specified as the model selection strategy.) A plot of the training series, holdback series, and the forecasted series. A shaded vertical region represents the holdback series. Since this is the model refit on the entire time series, the one-step-ahead predictions are shown during the time period of the entire original series. During the time period past the last observation, the forecasts are shown. The shaded region represents the forecasting interval.

**Model Summary**  Provides the -2Loglikelihood, the AIC, the number of parameters, and the sigma value. The sigma value is the estimate of the one-step-ahead forecast standard deviation. If Forecast Performance is specified as the model selection strategy, the root mean square error (RMSE) for the holdback set is also shown. See *Fitting Linear Models*.

**Parameter Estimates**  Provides the parameter estimates for the model. The parameters correspond to the parameters in the best fitting model, which is described in the Model Type report.

**One-Step-Ahead Forecasting Errors**  A plot of the one-step-ahead forecasting errors over time. For each time point $t$, the error is calculated as $e(t) = y(t) - \mu(t)$.

**One-Step-Ahead Relative Forecasting Errors for Multiplicative Error Model**  (Available only for multiplicative error models.) A plot of the one-step-ahead relative forecasting errors over time. For each time point $t$, the error is calculated as $e(t) = [y(t) - \mu(t)]/\mu(t)$.
The Matched Pairs platform compares the means between two or more correlated variables and assesses the differences. For example, you might compare a blood pressure measurement taken on the same subject before a treatment and again after the treatment. A statistical method called the paired t test takes the correlated responses into account.

The platform produces a graph of the paired differences by the paired means, and the paired $t$ test results for all three alternative hypotheses. Additional features provide for more than two matched responses and for a grouping column to test across samples, in a simple version of repeated measures analysis.

Overview of the Matched Pairs Platform

The Matched Pairs platform compares row-by-row differences between two response columns using a paired \( t \) test. Often, the two columns represent measurements on the same subject before and after some treatment. Alternatively, the measurements could represent data taken on the same subject with two different instruments.

If you have paired data arranged in two data table columns, then you are ready to use the Matched Pairs platform. However, if all of your measurements are in a single column, then perform one of the following tasks:

- Use the \textbf{Split} option in the \textbf{Tables} menu to split the column of measurements into two columns. Then you can use the Matched Pairs platform.

- For two response columns, create a third column that calculates the difference between the two responses. Then test that the mean of the difference column is zero with the \textbf{Distribution} platform.

- For the two responses stored in a single column, you can do a two-way analysis of variance. One factor (the ID variable) identifies the two responses and the other factor identifies the subject. Use the \textbf{Fit Y by X} Oneway platform with a blocking variable (the subject column), or use the \textbf{Fit Model} platform to do a two-way ANOVA. The test on the ID factor is equivalent to the paired \( t \) test.

\textbf{Note:} If the data are paired, do not do a regular independent \( t \) test. Do not stack the data into one column and use the \textbf{Fit Y by X One-way ANOVA} on the ID without specifying a block variable. To do this has the effect of ignoring the correlation between the responses. This causes the test to overestimate the effect if responses are negatively correlated, or to underestimate the effect if responses are positively correlated.

Example of Comparing Matched Pairs

This example uses the \textit{Therm.jmp} sample data table. The data contains temperature measurements on 20 people. Temperature is measured using two types of thermometers: oral and tympanic (ear). You want to determine whether the two types of thermometers produce equal temperature readings. Note that the differences in temperature between the different people are not important. The matched pairs analysis is testing the differences between the thermometers.

1. Select \textbf{Help > Sample Data Library} and open \textit{Therm.jmp}.
2. Select \textbf{Analyze > Specialized Modeling > Matched Pairs}.
3. Select Oral and Tympanic and click \textbf{Y, Paired Response}. 
4. Click **OK**.

The report window appears.

**Figure 20.2** The Matched Pairs Report Window

The results show that, on average, the tympanic thermometer measures 1.12 degrees higher than the oral thermometer. The small $p$-value ($\text{Prob} > |t|$) indicates that this difference is statistically significant, and not due to chance.

Note that this matched pairs analysis does not indicate which thermometer is correct (if either), but indicates only that there is a difference between the thermometers.
Launch the Matched Pairs Platform

Launch the Matched Pairs platform by selecting **Analyze > Specialized Modeling > Matched Pairs**.

**Figure 20.3** The Matched Pairs Launch Window

For more information about the options in the Select Columns red triangle menu, see *Using JMP*.

**Y, Paired Response**  Provide the two response columns. For information about analyzing more than two responses, see “Multiple Y Columns” on page 391.

**X, Grouping**  Provide a grouping variable to compare the differences across groups. See “Across Groups” on page 393.

**Weight**  Identifies one column whose numeric values assign a weight to each row in the analysis.

**Freq**  Identifies one column whose numeric values assign a frequency to each row in the analysis.

**By**  Performs a separate matched pairs analysis for each level of the By variable.

**Multiple Y Columns**

You can have more than two responses. If the number of responses is odd, all possible pairs are analyzed. The following table shows an example for three responses.

<table>
<thead>
<tr>
<th>Y1 by Y2</th>
<th>Y1 by Y3</th>
</tr>
</thead>
</table>

If the number of responses is even, the Matched Pairs platform asks whether you want to do all possible pairs. If you do not do all possible pairs, adjacent responses are analyzed as a pair. The following table shows the arrangement of analyses for four responses.

<table>
<thead>
<tr>
<th></th>
<th>Y1 by Y2</th>
<th>Y3 by Y4</th>
</tr>
</thead>
<tbody>
<tr>
<td>Y2 by Y3</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

**The Matched Pairs Report**

Follow the instructions in “Example of Comparing Matched Pairs” on page 389 to produce the report window shown in Figure 20.4.

The Matched Pairs report shows a Tukey mean-difference plot, summary statistics, and the results of the paired $t$ test. See “Difference Plot and Report” on page 393. If you specified an $X$, **Grouping** variable, the report also includes the Across Groups report. See “Across Groups” on page 393.

**Figure 20.4  Example of Matched Pairs Report**
Note: The red triangle menu provides additional options that can add reports to the initial report window. See “Matched Pairs Platform Options” on page 394.

Difference Plot and Report

The Difference plot shows differences by means. In the Difference plot, note the following:

- The mean difference is shown as the horizontal line, with the 95% confidence interval above and below shown as dotted lines. If the confidence region includes zero, then the means are not significantly different at the 0.05 level. In this example, the difference is significant.
- If you add a reference frame, the mean of pairs is shown by the vertical line. For more information about a reference frame, see “Matched Pairs Platform Options” on page 394.

The Difference report shows the mean of each response, the difference of the means, and a confidence interval for the difference. The Difference report also shows the results of the paired $t$ test.

Across Groups

Note: The Across Groups report appears only if you have specified an X, Grouping variable.

The Across Groups analysis corresponds to a simple repeated measures analysis. (You can get the same test results using the Manova personality of the Fit Model platform.)

Mean Difference Shows the mean of the difference across rows in each group between the two paired columns. In other words, this is the within-subject by across-subject interaction, or split-plot by whole-plot interaction.

Mean Mean Shows the mean of the mean across rows in each group across the two paired columns. In other words, this is the across-subject or whole-plot effect.

Test Across Groups Two $F$ tests determine whether the across-groups values are different:

- Mean Difference Tests that the change across the pair of responses is different in different groups.
- Mean Mean Tests that the average response for a subject is different in different groups

Related Information

- “Example Comparing Matched Pairs across Groups” on page 395
Matched Pairs Platform Options

The Matched Pairs red triangle menu contains the following options:

**Plot Dif by Mean**  Shows or hides the plot of the paired differences by paired means. For a detailed description of this plot, see “Difference Plot and Report” on page 393.

**Plot Dif by Row**  Shows or hides the plot of paired differences by row number.

**Reference Frame**  Shows or hides the reference frame on the Plot Dif by Mean plot. A rectangle showing where a plot of Y2 by Y1 would be located inside the plot, tilted and possibly squished. A vertical red line is shown representing the mean of means. The reference frame is shown initially when the range of the differences is greater than half the range of the data.

**Wilcoxon Signed Rank**  Shows or hides the Wilcoxon signed rank test. The Wilcoxon signed rank test is applied to the paired differences. It is a nonparametric test that compares the sizes of the positive differences to the sizes of the negative differences. The test uses the Pratt method to address zero differences. The test also assumes that the distribution of differences is symmetric. See *Basic Analysis*. See also Lehman (2006), Conover (1999, p. 350), and Cureton (1967).

**Sign Test**  Shows or hides the sign test. This is a nonparametric version of the paired \( t \) test that uses only the sign (positive or negative) of the difference for the test.

**Set \( \alpha \) Level**  Changes the alpha level used in the analyses. Affects the confidence intervals in the report and on the plot.

See *Using JMP* for more information about the following options:

**Local Data Filter**  Shows or hides the local data filter that enables you to filter the data used in a specific report.

**Redo**  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

**Save Script**  Contains options that enable you to save a script that reproduces the report to several destinations.

**Save By-Group Script**  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.
Example Comparing Matched Pairs across Groups

This example uses the Dogs.jmp sample data table. This example shows you how to produce both a Matched Pairs Across Groups report and the corresponding MANOVA report using Fit Model.

1. Select Help > Sample Data Library and open Dogs.jmp.
2. Select Analyze > Specialized Modeling > Matched Pairs.
3. Select LogHist0 and LogHist1 and click Y, Paired Response.
4. Select drug and click X, Grouping.
5. Click OK.

The report on the left in Figure 20.5 appears.

Now produce the Fit Model report using the same data table.

1. Select Analyze > Fit Model.
2. Select LogHist0 and LogHist1 and click Y.
3. Select drug and click Add.
4. Select the Manova personality.
5. Click Run Model.
7. Click OK.
**Figure 20.5** Examples of Matched Pairs across Groups and Fit Model MANOVA with Repeated Measures

The F Ratio for the Mean Difference in the Across Groups report corresponds to the F Ratio for Time*drug under the Within Subjects report. The F Ratio for the Mean Mean in the Across Groups report corresponds to the F Ratio for drug under Between Subjects in the Manova Fit report.

---

**Statistical Details for the Matched Pairs Platform**

- “Graphics for Matched Pairs”
- “Correlation of Responses”
Graphics for Matched Pairs

The primary graph in the platform is a Tukey mean-difference (Cleveland 1994, p. 130). This graph plots the difference of the two responses on the vertical axis against the mean of the two responses on the horizontal axis. This graph is the same as a scatterplot of the two original variables, but turned 45 degrees. A 45 degree rotation and rescaling turns the original coordinates into a difference and a mean.

Figure 20.6 Example of Transforming to Difference by Mean, Rotated by 45 Degrees

Before rotation, the axes represent $y_1$ and $y_2$.

$$\begin{bmatrix} 1 & 1 \\ -1 & 1 \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = \begin{bmatrix} y_2 + y_1 \\ y_2 - y_1 \end{bmatrix}$$

After rotation, the axes represent a sum and difference.

region where $y_1 < y_2$

region where $y_1 = y_2$

region where $y_1 > y_2$

rescaled to mean of responses

mean difference and 95% CI

line where $y_1 = y_2$
Correlation of Responses

In most cases where the pair of measurements is taken from the same individual at different times, they are positively correlated. However, if they represent competing responses, the correlation can be negative.

Figure 20.7 shows how the positive correlation of the two responses becomes the small variance on the difference (the vertical axis). If the correlation is negative, the ellipse is oriented in the other direction and the variance of the rotated graph is large on the vertical axis.

Figure 20.7 Examples of Positive Correlation Before and After Rotation
Modeling Utilities is a collection of utilities that are designed to assist in the data cleaning and pre-processing stages of data analysis. Each utility has exploratory tools to give you a more thorough understanding of your data. With Modeling Utilities, you can do the following:

- Explore outliers in both the univariate and multivariate cases.
- Explore and impute missing values in your data.
- Explore and find unusual features or patterns in your data.

**Figure 21.1** Multivariate k-Nearest Neighbor Outlier Example

Explore Outliers Utility

The Explore Outliers tool provides four different options to identify, explore, and manage outliers. Exploring and understanding outliers in your data is an important part of analysis. Outliers in data can be due to mistakes in data collection or reporting, measurement systems failure, the inclusion of error or missing value codes in the data set, or simply an unusual value. The presence of outliers can distort estimates and bias results toward those outliers.

Outliers also inflate the sample variance. Sometimes retaining outliers in data is necessary, however, and removing them could underestimate the sample variance and bias the data in the opposite direction.

Whether you remove or retain outliers, it is a good practice to locate them. There are many ways to visually inspect for outliers. For example, box plots, histograms, and scatter plots can easily display these extreme values. See Discovering JMP.

The Explore Outliers tool provides the following options:

Univariate
There are two options for exploring outliers in your univariate data.

- **Quantile Range Outliers**  Uses the quantile distribution of each column to identify outliers as extreme values. This tool is useful for discovering missing value or error codes within the data. This is the recommended method to begin exploring outliers in your data. See “Quantile Range Outliers” on page 406.

- **Robust Fit Outliers**  Finds robust estimates of the center and spread of each column and identifies outliers as those data points that are far from those values. See “Robust Fit Outliers” on page 409.

Multivariate
There are two options for exploring outliers in your multivariate data.

- **Robust PCA Outliers**  Decomposes data into a low-rank matrix and residuals and uses the residuals to detect outliers. See “Robust PCA Outliers” on page 411.

- **K Nearest Neighbor Outliers**  Identifies outliers as values that are far from their k-nearest neighbors. See “K Nearest Neighbor Outliers” on page 414.

Example of the Explore Outliers Utility

Use the Explore Outliers utility to identify outliers that can then be examined using the Distribution platform. The Probe.jmp sample data table contains 387 characteristics (the Responses column group) measured on 5800 semiconductor wafers. The Lot ID and Wafer Number columns uniquely identify the wafer. You are interested in identifying outliers within a select group of columns of the data set.

1. Select Help > Sample Data Library and open the Probe.jmp sample data table.
2. Select **Analyze > Screening > Explore Outliers**.

3. Click the triangle next to **Responses(387/0)** to show all of the columns in the group.

4. Select columns **VDP_M1** through **VDP_SICR** and click **Y, Columns**. There should be 14 columns selected.

**Figure 21.2 Explore Outliers Launch Window**

5. Click **OK**.

6. Click **Quantile Range Outliers**.

   The Quantile Range Outliers report shows each column and lists the number and identity of the outliers found.

7. In the Quantile Range Outliers report, select **Show only columns with outliers**. This limits the list of columns to only those that contain outliers.

   Note that several columns contain outlier values of 9999. Many industries use nines as a missing value code.

8. In the Nines report, select each column.

9. Click **Add Highest Nines to Missing Value Codes**.

   A JMP Alert indicates that you should use the **Save As** command to preserve your original data.

10. Click **OK**.

11. In the Quantile Range Outliers report, click **Rescan**.

12. Select **Restrict search to integers**.
In continuous data, integer values are often error codes or other coded data values. Notice that no additional error codes are included in this set of columns.

13. Deselect **Restrict search to integers**.

**Examine the Data**

1. Select all of the remaining columns in the Quantile Range Outliers report.
2. Click **Select Rows**.
3. Select **Analyze > Distribution**.
4. Assign the selected columns to the **Y, Columns** role. Because you selected these column names in the Quantile Range Outliers report, they are already selected in the Distribution launch window.
5. Click **OK**.

**Figure 21.3** Distribution of Columns with Outliers Selected

In columns **VDP_M1** and **VDP_PEMIT**, notice that some of the selected outliers are somewhat close to the majority of data. For the rest of the columns, the selected outliers appear distant from the majority of data. Investigate the data points and exclude them from your analyses.
Refine Excluded Outliers

1. In the Quantile Range Outliers report, hold Ctrl and deselect columns VDP_M1 and VDP_PEMIT.
2. With the remaining columns selected in the report, click **Exclude Rows**.
3. Change Q to 20.
4. Click **Rescan**.
5. Select columns VDP_M1 and VDP_PEMIT in the report.
6. Click **Select Rows**.

Reexamine the Data

1. Examine the Distributions report again. Notice the selected outliers are now separate enough from the majority of the data to select and exclude them from your analyses.
2. In the Quantile Range Outliers report, click **Exclude Rows**.
3. In the Distributions report, click the Distributions red triangle and select **Redo > Redo Analysis**.

Figure 21.4 Distributions of Columns with Outliers Excluded

The displays of the distributions of the data are now more informative without the outliers.
Launch the Explore Outliers Utility

To launch Explore Outliers, select Analyze > Screening > Explore Outliers.

**Note:** The Explore Outliers commands analyze only columns with a Continuous modeling type. Other columns can be entered in the launch window but are ignored.

**Figure 21.5** Explore Outliers Utility Launch Window

For more information about the options in the Select Columns red triangle menu, see Using JMP.

**Y, Columns** Specifies the columns that you want to analyze.

**Validation** Specifies a validation column that is used for Robust PCA Outliers.

**Label** Specifies a column that replaces row numbers in multivariate analysis reports with labels.

**By** A column or columns whose levels define separate analyses. For each level of the specified column, the corresponding rows are analyzed using the other variables that you have specified. The results are presented in separate reports. If more than one By variable is assigned, a separate report is produced for each possible combination of the levels of the By variables.

After you click **OK**, the Explore Outliers report appears. You are presented with the following four outlier analysis commands:

- “Quantile Range Outliers” on page 406
- “Robust Fit Outliers” on page 409
- “Robust PCA Outliers” on page 411
- “K Nearest Neighbor Outliers” on page 414
**Tip:** To run an outlier analysis across all levels of a **By** variable, press Ctrl and click the desired outlier analysis command button.

### Quantile Range Outliers

The Quantile Range Outliers method of outlier detection uses the quantile distribution of the values in a column to locate extreme values. Quantiles are useful for detecting outliers because there is no distributional assumption associated with them. Data are simply sorted from smallest to largest. For example, the 20th quantile is the value at which 20% of values are smaller. Extreme values are found using a multiplier of the interquantile range, the distance between two specified quantiles. For more information about how quantiles are computed, see *Basic Analysis*.

The Quantile Range Outliers utility is also useful for identifying missing value codes stored within the data. As noted earlier, in some industries, missing values are entered as nines (such as 999 or 9999). This utility finds any nines greater than the upper quartile as suspected missing value codes. The utility then enables you to add those missing value codes as a column property in the data table.

### Quantile Range Outliers Options

The Quantile Range Outliers panel enables you to specify how outliers are to be identified and how you want to manage them.

![Quantile Range Outliers Window](image)

An outlier is considered any value more than $Q$ times the interquantile range from the lower and upper quantiles. You can adjust the value of $Q$ and the size of the interquantile range.

**Tail Quantile**  The probability for the lower quantile that is used to calculate the interquantile range. The probability of the upper quantile is considered $1 - \text{Tail Quantile}$. For example, a Tail Quantile value of 0.1 means that the interquantile range is between the 0.1 and 0.9 quantiles of the data. The default value is 0.1.
Predictive and Specialized Modeling Explore Outliers Utility

Q The multiplier that determines the outlier threshold. Values that fall beyond Q times the interquantile range past the Tail Quantile or 1 - Tail Quantile values are identified as outliers. Large values of Q provide a more conservative set of outliers than small values. The default is 3.

Restrict search to integers Restricts outlier values to only integer values. This setting limits the search for outliers in order to find industry-specific missing value codes and error codes.

Show only columns with outliers Limits the list of columns in the report to those that contain outliers.

After the report is displayed using your specifications, there are many ways to act on these extreme values. You can select the outliers in a column by selecting the specified column in the Quantile Range Outliers report.

Tip: If no columns are selected in the report and you click one of the following buttons, a JMP Alert appears that enables you to select all of the columns.

Select Rows Selects the rows of outliers in the selected columns in the data table.

Exclude Rows Turns on the exclude row state for outliers in the selected columns in the Quantile Range Outliers Report. Click Rescan to update the Quantile Range Outliers report.

Color Cells Colors the cells of the selected outliers in the data table.

Color Rows Colors the rows containing outliers for the selected columns in the data table.

Add to Missing Value Codes Adds the selected outliers to the missing value codes column property. Use this option to identify known missing value or error codes within the data. Missing value and error codes are often integers and are sometimes a series of nines. Click Rescan to update the Quantile Range Outliers report.

Note: Add to Missing Value Codes is not available with Quantile Range Outliers if a By variable is specified in the launch window.

Change to Missing Changes the outlier value to a missing value in the data table. Use caution when changing values to missing. Change values to missing only if the data are known to be invalid or inaccurate. Click Rescan to update the Quantile Range Outliers report.

Note: If the selected outlier has been added to the missing value codes, the outlier is not changed to a missing value.
**Formula Columns**  Creates a new formula column for each column that is specified in the launch window. Each new column contains the original column’s value if the value is within the outlier limits and is set to missing otherwise. The new columns are prefixed or suffixed by a user specified name to distinguish them from the original columns. By default, the suffix is set to “Culled”.

**Formula Script**  Creates a script that is added to the data table. When the script is run, it creates a new formula column for each column that is specified in the launch window. Each new column contains the original column’s value if the value is within the outlier limits and is set to missing otherwise. The new columns are prefixed or suffixed by a user specified name to distinguish them from the original columns. By default, the suffix is set to “Culled”.

**Rescan**  Rescans the data after outlier actions have been taken.

**Note:** Press Ctrl and click Rescan to rescan across all command groups.

**Close**  Closes the Quantile Range Outliers panel.

**Note:** Press Ctrl and click Close to close all command windows.

**Quantile Range Outliers Report**

The Quantile Range Outliers report lists all columns with the outliers found using the specified options. The report shows values for the upper and lower quantiles along with their low and high thresholds. Values outside of these threshold limits are considered outliers. The number of outliers in each column is indicated. The values of each outlier are listed in the last column of the report. Outliers that occur more than once in a column are listed with their count in parentheses. To remove columns without outliers from the report, select Show only columns with outliers.

There are several things to look for when reading this report.

- **Error codes.** For some continuous data, suspiciously high integer values are likely to be error codes. For example, if your upper and lower quantile values are all less than 0.5, outliers such as 1049 or -777 are likely to be error codes.

- **Zeros.** Sometimes zeros can indicate missing values. If the majority of your data is reasonably large and you notice zeros as outliers, they are likely to be due to missing data.
Nines Report

The Nines report within the Quantile Range Outliers window shows a list of columns that contain probable missing value codes. These missing value codes are a series of nines (usually 9999) and are the highest number that is all nines and also higher than the upper quantile. If the count is high, it is likely that these outliers are actually missing value codes. If the count is very low, you should explore further to determine whether the value is an outlier or a missing value code. The Nines Report includes the upper quantile value.

This report is displayed only when probable missing value codes are identified.

**Add Highest Nines to Missing Value Codes**  Adds the selected outlier values to the missing value codes column property. You must click **Rescan** to update the Quantile Range Outliers report.

*Note:* Add Highest Nines to Missing Value Codes is not available with Quantile Range Outliers if a By variable is specified in the launch window.

**Change Highest Nines to Missing**  Replaces the selected outlier values with missing values in the data table.

*Note:* The first time you use choose an action (such as **Change to Missing** or **Exclude Rows**) to change your data, the alert window warns you to use the **Save As** command to save your data table as a new file to preserve a copy of your original data. When this window appears, click **OK**. If you decide to save your new data file, you will automatically be prompted to save the file with a new name.

Robust Fit Outliers

Robust estimates of parameters are less sensitive to outliers than non-robust estimates. Robust Fit Outliers provides several types of robust estimates of the center and spread of your data to determine thresholds for identifying outliers.

**Figure 21.7**  Robust Fit Outliers Window
**Robust Fit Outliers Options**

Given a robust estimate of the center and spread, outliers are defined as those values that are $K$ times the robust spread from the robust center. The Robust Fit Outliers window provides several options for calculating the robust estimates and multiplier $K$ as well as provides tools to manage the outliers found.

**Huber** Uses Huber M-Estimation to estimate center and spread. This option is the default. See Huber and Ronchetti (2009).

**Cauchy** Assumes a Cauchy distribution to calculate estimates for the center and spread. Cauchy estimates have a high breakdown point and are typically more robust than Huber estimates. However, if your data are separated into clusters, the Cauchy distribution tends to consider only the half of the data that makes closer clusters, ignoring the rest.

**Quartile** Uses the interquartile range (IQR) to estimate the spread. The estimate for the center is the median. The estimate for spread is the IQR divided by 1.34898. Dividing the IQR by this factor makes the spread correspond to one standard deviation if the data are normally distributed.

$K$ The multiplier that determines outliers as $K$ times the spread away from the center. Large values of $K$ provide a more conservative set of outliers than small values. The default is 4.

**Show only columns with outliers** Limits the list of columns in the report to those that contain outliers.

Once the report is displayed using your specifications, there are many ways to explore these extreme values. You can select the outliers in a row by selecting the specified row in the Robust Estimates and Outliers report.

**Tip:** If no columns are selected in the report and you click one of the following buttons, a JMP Alert appears that enables you to select all of the columns.

**Select Rows** Selects the rows containing outliers for the selected columns in the data table.

**Exclude Rows** Sets the Exclude Row state for outliers in the selected columns in the data table. Click **Rescan** to update the Robust Estimates and Outliers report.

**Color Cells** Colors the cells of the selected outliers in the data table.

**Color Rows** Colors the rows containing outliers for the selected columns in the data table.

**Add to Missing Value Codes** Adds the selected outliers to the missing value codes column property for the selected columns. Use this option to identify known missing value or error codes within the data. Click **Rescan** to update the Robust Estimates and Outliers report.
**Note:** Add to Missing Value Codes is not available with Robust Fit Outliers if a By variable is specified in the launch window.

**Change to Missing**  Changes the outlier value to a missing value in the data table. Click **Rescan** to update the Robust Estimates and Outliers report.

**Formula Columns**  Creates a new formula column for each column that is specified in the launch window. Each new column contains the original column’s value if the value is within the outlier limits and is set to missing otherwise. The new columns are prefixed or suffixed by a user specified name to distinguish them from the original columns. By default, the suffix is set to “Culled”.

**Formula Script**  Creates a script that is added to the data table. When the script is run, it creates a new formula column for each column that is specified in the launch window. Each new column contains the original column’s value if the value is within the outlier limits and is set to missing otherwise. The new columns are prefixed or suffixed by a user specified name to distinguish them from the original columns. By default, the suffix is set to “Culled”.

**Rescan**  Rescans the data after outlier actions have been taken.

**Note:** Press Ctrl and click **Rescan** to rescan across all command groups.

**Close**  Closes the Robust Fit Outliers panel.

**Note:** Press Ctrl and click **Close** to close all command windows.

**Robust PCA Outliers**

You can use the Robust PCA Outliers utility to quickly identify outlier cells in correlated multivariate data. This method is useful because many other multivariate approaches identify only the outlier rows. Before the method is applied to the data, the columns are first centered (optional) and scaled. The scaling factor is defined as follows:

\[
\text{max}[Q(.75) - Q(.50), Q(.50) - Q(.25)] / \text{normalQuantile}(0.75)
\]

where

\[ Q(p) \] is the \( p \)th quantile

**Note:** If \( Q(75) \) or \( Q(25) \) are equal to the median, then more extreme quantiles are used until there is a non-zero range.
After the data are centered and scaled, the Robust PCA Outliers utility performs a sequence of singular value decompositions and thresholding steps to decompose the data matrix. The data are decomposed into a low-rank matrix and a sparse matrix of residuals. The thresholding is done so that the residuals are either very large or outliers or very close to zero for non-outliers. The algorithm determines a matrix rank appropriate to capture the systematic variation without the outliers or small noise. Outliers that are not in the low-rank space are detected based on their residuals. See Candes et al (2009) and Lin et al (2013). If there are missing values, they are initially replaced with zeros after the centering and scaling steps. Then, after each singular value decomposition (SVD) iteration, the missing values are updated by their predicted values from the SVD.

### Robust PCA Outliers Report

When you select Robust PCA Outliers from the list of commands, you must specify a value for Lambda and select if the data should be centered. If you Shift+Click the Robust PCA Outliers button, the following options are also available:

- **Lambda**  
  Specifies a value that determines the sparsity of the matrix of residuals. For larger values of Lambda, the matrix of residuals is more sparse. For a data table with \( n \) training rows and \( p \) columns, the default value of Lambda is defined as follows:

  \[
  \lambda = \frac{2}{\sqrt{\max(n, p)}}
  \]

- **Max Iterations**  
  Specifies the maximum number of SVD iterations.

- **Converge Criterion**  
  Determines when to stop the algorithm.

- **Outlier Threshold**  
  Specifies the outlier threshold that determines which outliers are shown in the Cell Large Residuals table. An observation is shown if the scaled residuals is larger than the following:

  \[
  \min[0.99 \times \max(\text{abs(residuals)}), \text{Outlier Threshold}] 
  \]

  By default, the Outlier Threshold is 2.

- **Center**  
  Determines if the data are centered before the Robust PCA Outlier algorithm is performed.

  **Note:** If the number of rows is less than or equal to 10, the data are not centered.

- **Scale**  
  Determines if the data are scaled before the Robust PCA Outlier algorithm is performed.

  **Note:** If the number of rows is less than or equal to 10, the data are not scaled.
The Robust PCA Outliers report contains a table with information about the method. This table includes the rank of the low-rank matrix, the number of SVD iterations, the convergence criterion, the value of Lambda, and the number of imputed missing values. The report also contains the following tables and reports:

**Cell Large Residuals**  A table that shows the largest outlier cells. The number of cells shown is determined by the Outlier Threshold. The table contains the column name and row number of the cell, the residual value, and the scaled residual value.

*Tip:* To color specific outlier cells in the data table, select rows in the Cell Large Residuals table and click **Colorize**.

**Row Root Mean Square**  A table that shows the root mean square value for each row in the data table. The root mean square is calculated using the scaled residuals.

*Tip:* If you select a row in the Row Root Mean Square table, the corresponding row is selected in the data table.

**Column Root Mean Square**  A table that shows the root mean square value for each column specified in the launch window. The root mean square is calculated using the scaled residuals.

*Tip:* If you select a row in the Column Root Mean Square table and click **Select Columns**, the corresponding column is selected in the data table.

**Snapshot**  A graphical representation of the outlier cells in the data table. The outlier cells are colored in red.

**Residuals**  The matrix of residuals from the matrix decomposition. A cell is colored if the absolute value of the scaled residual is greater than the following:

\[ \min[0.99 \times \max\{|\text{abs(residuals)}\}], \text{Outlier Threshold}] \]

**Low Rank Approximation**  The matrix of scaled residuals from the matrix decomposition.

**Singular Values**  The vector of singular values from the SVD.

**Robust PCA Outliers Options**

There are buttons at the bottom of the Robust PCA Outliers report that provide options to save different parts of the report.

**Close**  Closes the Robust PCA Outliers report.

**Save Large Outliers**  Saves the information in the Cell Large Residuals table to a new data table.
Save Cleaned  Opens a window that provides several techniques to clean the outliers based on thresholds and save new columns to the data table.

Trim  Trims outlier cells if the corresponding absolute scaled residual is greater than the specified threshold. By default, the threshold is 10. Select Color ▢ to color the outlier cells red. The trimmed cells are set to the value of the unscaled threshold.

Impute  Sets outlier cells to the value of the low rank approximation if the corresponding absolute scaled residual is greater than the specified threshold. By default, the threshold is 100. Select Color ▢ to color these cells green.

Make Missing  Sets outlier cells to missing if the corresponding absolute scaled residual is greater than the specified threshold. By default, the threshold is 1000. Select Color ▢ to color these cells blue.

Color imputed from missing ■ If selected, colors cells that originally had missing values and were imputed.

Save Residuals  Saves the residuals to new columns in the original data table.

Save Scaled Residuals  Saves the scaled residuals to new columns in the original data table.

Save Low Rank Approx  Saves the low-rank approximation to new columns in the original data table.

K Nearest Neighbor Outliers

Use K Nearest Neighbor Outliers to identify an outlier based on distance to its nearest neighbor. For each value of $k$, the K Nearest Neighbor Outliers utility displays a plot of the Euclidean distance from each point to its $k$th nearest neighbor. You specify the largest value of $k$, denoted as $K$. Plots are provided for $k = 1, 2, 3, 5, ..., K$, using the Fibonacci sequence to avoid displaying too many plots.

Before the nearest neighbors are calculated, the columns are centered and scaled. The scaling factor is as follows:

$$\text{max} \left[ Q(.75) - Q(.50), Q(.50) - Q(.25) \right] / \text{normalQuantile}(0.75)$$

where

$Q(p)$ is the $p^{th}$ quantile

**Note:** If $Q(75)$ or $Q(25)$ are equal to the median, then more extreme quantiles are used until there is a non-zero range.
This approach is sensitive to the specified value of $k$. A small value of $k$ can miss identifying points as outliers and a large value of $k$ can falsely classify points as outliers:

- Suppose that the specified $K$ is small, so that you are studying only a few neighbors. If there is a cluster of more than $K$ points that is far from the rest of the points, then the points within the cluster have small distances to their nearest neighbors. You might be unable to detect the cluster of outliers.

- Suppose that the specified $K$ is large, so that you are studying a large number of neighbors. If there are clusters with fewer than $K$ data points, then the points within these clusters can appear to be outliers. You might overlook the fact that the points form a cluster, interpreting the individual cluster members as outliers instead.

### K Nearest Neighbor Outliers Report

When you select K Nearest Neighbor Outliers from the list of commands, you must specify the value of $K$ to use as an upper bound for the farthest neighbor to be considered. You must also specify whether missing values should be imputed. Notice that $K$ is set to 8 and Impute Missing is selected by default.

The report shows plots for select values of $k$ up to the value $K$. The value of $k$ for each plot is displayed in its vertical axis label. It is of the form Distance to Neighbor $k = <a>$, where $a$ is an integer denoting the $a^{th}$ closest neighbor. Each plot shows the distance from the point in the $i^{th}$ row to its $a^{th}$ nearest neighbor. The points that have large distances from their neighbors, across multiple values of $k$, are likely to be outliers.

The buttons above the plots do the following:

- **Exclude Selected Rows** Excludes rows corresponding to selected points from further analysis. The rows are assigned the Excluded row state in the data table. You are asked if you want to rerun or close the K Nearest Neighbors report. Rerunning the analysis identifies new nearest neighbors. The plots are updated and the excluded points are not shown.

- **Scatterplot Matrix** Opens a separate window containing a scatterplot matrix for all columns in the analysis. You can explore potential outliers by selecting them in the K Nearest Neighbors plots and viewing them in the scatterplot matrix.

- **Save NN Distances** Saves the distances from each row to its $n^{th}$ nearest neighbor as new columns in the data table.

- **Close** Closes the K Nearest Neighbors report.
Largest Outliers

The report also includes a Largest Outliers table. This table contains the 20 observations with the largest distances from their $K^{th}$ nearest neighbor. The table has the following columns:

**Row** The row number of the observation.

**Distance** The distance from the observation in the specified row and its $K^{th}$ nearest neighbor. The table is sorted by this column in descending order.

**Nearest Neighbors** Lists the row numbers for the $k$ nearest neighbors. The first row number is the closest nearest neighbor. The last row number is the $K^{th}$ nearest neighbor and the distance between this observation and the specified row is found in the Distance column.

**Col<fn>** Specifies the column name for the corresponding RSM value.

**RSM<fn>** Calculates the root mean squared differences across the $k$ nearest neighbors for each column. The five largest RSM values are displayed in order, where RSM1 is the maximum RSM value. The $p^{th}$ RSM value is calculated as follows:

$$RSM_p = \sqrt{\frac{\sum_{k=1}^{K} (D_{p,i} - D_{p,i_k})^2}{K}}$$

where

$D_p$ is the $p^{th}$ column

$D_{p,i}$ is the value of the $p^{th}$ column for row $i$

$D_{p,i_k}$ is the value of the $p^{th}$ column for the $k^{th}$ nearest neighbor of row $i$

**Note:** The number of Col and RSM columns shown in the Largest Outliers table is the minimum of the number of columns specified in the launch and the number five.

Explore Outliers Utility Options

See *Using JMP* for more information about the following options:

**Local Data Filter** Shows or hides the local data filter that enables you to filter the data used in a specific report.

**Redo** Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.
**Save Script** Contains options that enable you to save a script that reproduces the report to several destinations.

**Save By-Group Script** Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.

### Additional Examples of the Explore Outliers Utility

**Robust PCA Outliers Example**

The Water Treatment.jmp data set contains daily measurement values of 38 sensors in an urban waste water treatment plant. You are interested in exploring these data for potential outliers. Potential outliers could include sensor failures, storms, and other situations.

1. Select **Help > Sample Data Library** and open Water Treatment.jmp.
2. Select **Analyze > Screening > Explore Outliers**.
3. Select the Sensor Measurements column group and click **Y, Columns**.
4. Click **OK**.
5. Shift+Click **Robust PCA Outliers**.
6. Enter 10 next to Outlier Threshold.
   Use the default values for the other options.
7. Click **OK**.
The Cell Large Residuals table shows the cells that have a scaled residual greater than 10 or less than -10. There are several cells with large scaled residuals from the SED-S column. If you look at the Column Root Mean Square table, it shows that the SED-S column does in fact have the largest scaled Root Mean Square value. The row with the largest scaled Root Mean Square value is row 60.

8. Click **Save Cleaned** at the bottom of the report.

This option enables you to adjust cells with large outliers by trimming the values, imputing new values, or setting the cells to missing. The Save Cleaned Columns report provides these options.

9. Select **Impute**. Trim is already selected by default.

10. Click **OK**.

There are 38 new Cleaned columns added to the Water Treatment.jmp data table. Since you know row 60 had the largest scaled Root Mean Square value, scroll to this row to view some of the cells that were trimmed and imputed. You can now use the cleaned columns in any type of analysis.
The presence of missing values in a data set can affect the conclusions made using the data. If, for example, several healthy participants dropped out of a longitudinal study and their data continued on as missing, the results of the study can be biased toward those unhealthy individuals who remained. Missing data values must not only be identified, they must also be understood before further analysis can be conducted.

The Explore Missing Values utility provides several ways to identify and understand the missing values in your data. It also provides methods for conducting multivariate normal imputation for missing values. These imputation methods assume that data are missing at random, which means that any differences between missing and non-missing data cannot be explained by the values of the other variables in the study. If you suspect that missing values are not missing at random, then consider using the Informative Missing procedure, which is available in a number of platforms. See Fitting Linear Models.

**Caution:** Be careful when analyzing data after imputing missing values, as the results have the potential to be biased.
Example of the Explore Missing Values Utility

The Arrhythmia.jmp sample data table contains information from 452 patient electrocardiograms (ECGs). The data was originally collected to classify different patterns of ECGs as cardiac arrhythmia. However, there are missing values in this data table. You are primarily interested in exploring these missing values and imputing them when necessary. Since you can conduct missing value imputation only for columns that have a continuous modeling type, you conduct your analysis in two stages.

Examine Missing Values

1. Select Help > Sample Data Library and open Arrhythmia.jmp.
2. Select Analyze > Screening > Explore Missing Values.
3. Select all columns (280 in all) and click Y, Columns.
4. Click OK. Select the Show only columns with missing check box.

Figure 21.10 Missing Value Report

The Missing Columns report shown in Figure 21.10 indicates that only five columns have missing data. Out of a total of 452 rows, Column J has 376 missing values. Because it is largely missing, imputed values might not result in a meaningful analysis. For such data, you could explore a model using the Informative Missing option for Column J in a platform that supports the Informative Missing option.

Note that the two Imputation options, Multivariate Imputation and Multivariate SVD Imputation, are not shown. A message indicates that imputation is disabled because some columns included in the analysis were categorical. The data table contains several columns that are numeric, but have a nominal modeling type. These cannot be used for imputation.
Impute Missing Values

The five columns that have missing values are continuous. You proceed to impute values for the four columns other than Column J using multivariate imputation for the continuous columns in your data table. By doing so, you tacitly assume that the probabilities that values are missing depend only on the values of the continuous variables and not on the values of excluded nominal variables. To conduct this new analysis, you need to launch the Explore Missing Values utility again.

1. Select Analyze > Screening > Explore Missing Values.
2. In the launch window, click the red triangle next to 280 Columns.
   Use the columns filter menu to view only the columns with a Continuous modeling type in the Select Columns list.
3. Select Modeling Type > Uncheck All.
   This removes all columns from the Select Columns list.
4. Select Modeling Type > Continuous.
   The Select Columns list now contains only the 207 columns that are Continuous.
5. Select all 207 columns. Then Ctrl-click the J column (to deselect it) and click Y, Columns.
6. Click OK.
7. Click Multivariate Normal Imputation.
   A window appears and asks whether you want to use a Shrinkage estimator for covariances.
8. Click Yes Shrinkage.
   A JMP Alert appears, informing you that you should use the Save As command to preserve your original data.
9. Click OK.

Figure 21.11 Imputation Report

The Imputation Report indicates how many missing values were imputed and the specific imputation details. No missing data remain in the four columns that had missing values.
Launch the Explore Missing Values Utility

Launch the Explore Missing Values modeling utility by selecting Analyze > Screening > Explore Missing Values. Enter the columns of interest into the Y, Columns list. You can also specify a By variable.

Note: You can enter only columns with a Numeric modeling type in the Explore Missing Values utility.

The Missing Value Report

Figure 21.12 Missing Value Report for Continuous Variables in Arrhythmia.jmp.

After you click OK in the launch window, the report opens to show a Commands outline and a Missing Columns report. The commands are the following:

- “Missing Value Report” on page 423
- “Missing Value Clustering” on page 423
- “Missing Value Snapshot” on page 423
- “Multivariate Normal Imputation” on page 424 (Not available if you entered a Numeric column with a Nominal or Ordinal modeling type in the launch window.)
- “Multivariate SVD Imputation” on page 424 (Not available if you entered a Numeric column with a Nominal or Ordinal modeling type in the launch window.)
- “Automated Data Imputation” on page 426 (Not available if you entered a Numeric column with a Nominal or Ordinal modeling type in the launch window.)

Tip: To run a missing value command across all levels of a By variable, press Ctrl and click the desired command button.
Missing Value Report

The Missing Value Report opens the Missing Columns report, which lists the name of each column and the number of missing values in that column.

**Show only columns with missing**  Removes columns from the list that do not have missing values.

**Close**  Closes the Missing Columns report.

**Select Rows**  Selects the rows in the data table that contain missing values for the column(s) that you select in the Missing Columns report.

**Exclude Rows**  Applies the excluded row state for rows in the data table that contain missing values for the column(s) that you select in the Missing Columns report.

**Color Cells**  Colors the cells in the data table that contain missing values for the column(s) that you select in the Missing Columns report.

**Color Rows**  Colors the rows in the data table that contain missing values for the column(s) that you select in the Missing Columns report.

Missing Value Clustering

Missing Value Clustering provides a hierarchical clustering analysis of the missing data.

- The dendrogram to the right of the plot shows clusters of missing data pattern rows. These are the rows that you would obtain by using Tables > Missing Data Pattern.
- The dendrogram beneath the plot shows clusters of variables.

Use this report to determine whether certain groups of columns tend to have similar patterns of missing values.

The rows of the plot are defined by the missing data patterns; there is a row for each pattern. The columns correspond to the variables. Each red cell indicates a group of missing values for the column listed beneath the plot. Hover over a cell to see the list of values represented. Click in the plot to select missing data pattern rows. Vertical bars are displayed to indicate the selected patterns.

Missing Value Snapshot

The Missing Value Snapshot shows a cell plot for the missing values. The columns represent the variables. Black cells indicate a missing value. This plot is especially useful in understanding missingness for longitudinal data, where subjects can withdraw from a study before the end of the data collection period.
**Multivariate Normal Imputation**

The Multivariate Normal Imputation utility imputes missing values based on the multivariate normal distribution. The procedure requires that all variables have a Continuous modeling type. The algorithm uses least squares imputation. The covariance matrix is constructed using pairwise covariances. The diagonal entries (variances) are computed using all nonmissing values for each variable. The off-diagonal entries for any two variables are computed using all observations that are nonmissing for both variables. In cases where the covariance matrix is singular, the algorithm uses minimum norm least squares imputation based on the Moore-Penrose pseudo-inverse.

Multivariate Normal Imputation allows the option to use a shrinkage estimator for the covariances. The use of shrinkage estimators is a way of improving the estimation of the covariance matrix. For more information about shrinkage estimators, see Schäfer and Strimmer (2005).

**Note:** If a validation column is specified, the covariance matrices are computed using observations from the Training set.

**Multivariate Normal Imputation Report**

The imputation report explains the results of the multivariate imputation process. Results include the following:

- Method of imputation (either least squares or minimum-norm least squares)
- How many values were replaced
- Shrinkage estimator on/off
- Factor by which the off-diagonals were scaled
- How many rows and columns were affected
- How many different missing value patterns there were

Once the imputation is complete, the cells corresponding to imputed values in the data table are colored in light blue. If the Missing Columns report is open, it is updated to show no missing values.

Click **Undo** to undo the imputation and replace the imputed data with missing values.

**Multivariate SVD Imputation**

The Multivariate SVD Imputation utility imputes missing values using the singular value decomposition (SVD). This utility is useful for data with hundreds or thousands of variables. Because SVD calculations do not require calculation of a covariance matrix, the SVD method is recommended for wide problems that contain large numbers of variables. The procedure requires that all variables have a Continuous modeling type.
The singular value decomposition represents a matrix of observations $X$ as $X = UDV'$, where $U$ and $V$ are orthogonal matrices and $D$ is a diagonal matrix.

The SVD algorithm used by default in the Multivariate SVD Imputation utility is the sparse Lanczos method, also known as the *implicitly restarted Lanczos bidiagonalization method* (IRLBA). See Baglama and Reichel (2005). The algorithm does the following:

1. Each missing value is replaced with its column’s mean.
2. An SVD decomposition is performed on the matrix of observations, $X$.
3. Each cell that had a missing value is replaced by the corresponding element of the $UDV'$ matrix obtained from the SVD decomposition.
4. Steps 2 and 3 are repeated until the SVD converges to the matrix $X$.

**Imputation Method Window**

When you click Multivariate SVD Imputation, the Imputation Method window shows the recommended settings.

**Number of Singular Vectors** Number of singular vectors that are computed and used in the imputation.

*Note:* It is important not to specify too many singular vectors, otherwise the SVD and the imputations do not change from iteration to iteration.

**Maximum Iterations** The number of iterations used in imputing the missing values.

**Show Iteration Log** Opens a Details report that shows the number of iterations and gives details about the criteria.

For large problems, a progress bar shows how many dimensions the SVD has completed. You can stop the imputation and use that number of dimensions at any time.

**Multivariate SVD Imputation Report**

The imputation report explains the results of the multiple imputation process.

- Method of imputation
- How many values were replaced
- How many rows and columns were affected

Once the imputation is complete, the Missing Columns report is automatically shown indicating no missing values in the columns that were imputed. Imputed values are displayed in light blue.

Click **Undo** to undo the imputation and replace the imputed data with missing values.
Automated Data Imputation

The Automated Data Imputation (ADI) utility imputes missing values using a low-rank matrix approximation method, also known as matrix completion. Once trained, the ADI model is capable of performing missing data imputations for streaming data through scoring formulas. Streaming data are added rows of observations that become available over time and were not used for tuning or validating the imputed model. This utility is flexible, robust, and automated to select the best dimension for the low-rank approximation. These features enable ADI to work well for many different types of data sets.

A low-rank approximation of a matrix is of the form \( X = UDV' \) and can be viewed as an extension of singular value decomposition (SVD). ADI uses the Soft-Impute method as the imputation model and is designed such that the data determines the rank of the low-rank approximation.

The ADI algorithm performs the following steps:

1. The data are partitioned into training and validation sets.
2. Each set is centered and scaled using the observed values from the training set.
3. For each partitioned data set, additional missing values are added within each column and are referred to as induced missing (IM) values.
4. The imputation model is fit on the training data set along a solution path of tuning parameters. The IM values are used to determine the best value for the tuning parameter.
5. Additional rank reduction is performed using the training data set by de-biasing the results from the chosen imputation model in step 4.
6. Final rank reduction is performed to calibrate the model for streaming data and to prevent overfitting. This is done by fitting the imputation model on the validation set, using the rank determined in step 5 as an upper bound.
Automated Data Imputation Controls

The ADI utility contains options for saving the imputed values and advanced controls.

Figure 21.13  ADI Controls

Options for Saving Imputed Values  The following three options for saving the imputed values for the ADI method are available:

Create New Data Table  Creates a new data table that has the same dimensions as the original data table. In the new data table, the columns selected in the launch window contain the imputed values.

Save Scoring Formula to Current Data Table  Saves a column group, named Imputed_, to the current data table that contains the imputed columns specified in the launch window. A hidden column, ADI Impute Column, is also added to the current data table that contains the imputed vectors and the scoring formula used in the data imputation. The column formulas automatically update if any additional rows are added to the data table, enabling missing data imputation for streaming data. This is the default option.

Impute Values in Place  Imputes the missing values in the current data table. The imputed values are displayed in light blue.

Advanced Controls  Contains the following advanced controls, which default to recommended settings based on the data:

Dimension Upper Bound  Determines the maximum rank allowed in the low-rank approximation. This is determined by the dimension of the matrix formed by the chosen columns.

Maximum Iterations  Determines the number of values that are iterated over to determine the tuning parameter for the imputation model. The default is 10.
Proportion of Observations to Induce as Missing  Determines the proportion of IM values that are added to the training and validation sets. The default proportion for each set is 0.2.

Proportion of Rows to Use for Validation  Determines the proportion of rows to use in the training and validation sets. The default proportion for the validation set is 0.3.

Set Random Seed  Determines the random seed for ADI. Use this option to obtain reproducible results.

Explore Missing Values Utility Options

ADI Loading Matrix  (Available only for the ADI utility.) Shows or hides a report that contains the columns that correspond to the factor loading for each component.

See Using JMP for more information about the following options:

Redo  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

Save Script  Contains options that enable you to save a script that reproduces the report to several destinations.

Save By-Group Script  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.
Explore Patterns Utility

Data can be messy, so it is sometimes hard to determine the validity of your data by visual inspection alone. The Explore Patterns utility is a tool for detecting unusual or unexpected patterns in your data. Although some patterns occur by chance or some innocent mechanism, they might indicate data that has been falsified or tampered with. This utility is most useful when the values are precise so that matches and patterns are less likely to happen by coincidence. The Explore Patterns utility is also designed to handle large data tables efficiently.

The Explore Patterns utility looks for duplicate values and duplicate sequences of values. These types of patterns can indicate data tampering strategies such as pasting the same value many times, pasting the same value across a range of cells, or copying a range of data and pasting it somewhere else. The utility also analyzes properties of the formatted values to determine whether the data are actual measurements or might have been generated by a random number generator. There are also options to examine distribution properties and detect linear relationships between columns across groups of rows.

**Note:** The Explore Patterns utility ignores excluded rows, but the results are not necessarily equivalent to if you had deleted the row. For runs of rows, such as the Longest Runs and Longest Duplicated Sequences options, an excluded row stops the run.

Example of the Explore Patterns Utility

The Nicardipine Lab Patterns.jmp sample data table is adapted from a study of the drug Nicardipine. The data table contains 27 columns of numeric laboratory results. Use the Explore Patterns Utility to determine whether there are any unexpected patterns in the laboratory results.

1. Select **Help > Sample Data Library** and open the Nicardipine Lab Patterns.jmp sample data table.
2. Select **Analyze > Screening > Explore Patterns**.
3. Select the Laboratory Results column group and click **Y, Columns**.
4. Click **OK**.
5. Click the gray disclosure icon next to Univariate Summary to open the Univariate Summary report.
The Univariate Summary report summarizes the longest runs and longest duplicate sequences found across all of the columns. Each table is sorted by Rarity, a calculation of how likely the run or sequence is to occur by chance. The column with the highest rarity score for longest runs is Creatinine, whereas the column with the highest rarity score for longest duplicate sequences is Activated PTT. You will further examine these columns in the Univariate Patterns Report.

6. In the Univariate Patterns report, the report for the first column, Activated PTT, is shown initially. Press Ctrl and select Creatinine from the Select Columns list.
As you select column names from the Select Columns list, the corresponding column reports are shown. The Activated PTT report shows that this column contains several three count runs and four count sequences. The Creatinine report shows that although it is the column with the highest rarity score for Longest Runs, there is only one run in the column. This column also has one eight count sequence.
Launch the Explore Patterns Utility

Launch the Explore Patterns utility by selecting **Analyze > Screening > Explore Patterns**.

**Figure 21.16** Explore Patterns Utility Launch Window

For more information about the options in the Select Columns red triangle menu, see *Using JMP*.

**Y, Columns** Assigns the columns to analyze. The variables must be numeric and continuous.

**By** Assigns one or more columns whose levels define separate analyses. For each level of the specified column, the corresponding rows are analyzed using the other variables that you have specified. The results are presented in separate reports. If more than one By variable is assigned, a separate report is produced for each possible combination of the levels of the By variables.

**Minimum Run Size** Specifies the minimum number of values in a row for a sequence to be reported as a run.

**Minimum Longest Duplicate Size** Specifies the minimum length of a sequence for it to be reported as a duplicate sequence within a column.

**Minimum Cross Column Duplicate Run Size** Specifies the minimum length of a sequence for it to be reported as a duplicate sequence across columns.

**Minimum Rows for Linear Relationship** Specifies the minimum number of rows used for detecting linear relationships between columns across groups of rows.

**Note:** The minimum number of rows must be greater than or equal to three.
Include Missing  Specifies that missing values be included in pattern detection.

Explore Patterns Report

The initial Explore Patterns report contains a Control Panel, Univariate Summary report, and Univariate Patterns report. Many of the tables in these reports contain rows that can be selected. If a row is selected and you right-click the first column, a menu appears that enables you to select or colorize the related rows and columns in the data table.

Control Panel

The control panel contains options that enable you to select which reports appear in the report window. These are the same options that are in the Explore Patterns red triangle menu. See “Explore Patterns Utility Options” on page 434. There is also a section of the control panel to specify report settings. These are the same settings that are found in the launch window. See “Launch the Explore Patterns Utility” on page 432. If you change the settings in the control panel, the reports are automatically updated.

Univariate Summary

The Univariate Summary report combines results from several patterns reports across columns. By default, there are summary tables for Longest Runs and Longest Duplicate Sequences. Longest Runs and Longest Duplicate Sequences with rarity ≥ 2 are shown in the tables.

If the Fraction Length option is selected a Fraction Length summary table is also shown. This table shows the proportion of values in each column that have a fraction length greater than or equal to 15. Columns that do not contain any values that have fraction lengths greater than or equal to 15 are not shown in the Fraction Length summary table.

If at least one of the Y columns has a Spec Limit column property and the Distribution wrt Spec Limits option is selected, a Spec Limits Distrib summary table is also shown. This table shows the columns that have a statistically significant number of observations outside of the specification limits.

For more information about the Univariate Summary report contents, see “Explore Patterns Utility Options” on page 434.
Univariate Patterns

The Univariate Patterns report contains a Select Columns list and one or more column-specific patterns reports. The column-specific reports that are displayed are determined by the Select Columns list. To examine each column’s report, select the first column and then successively use the down arrow key to advance to the next column. Alternatively, you can click a column name in this list to display the patterns report for the selected column. If you select more than one column name by using either Ctrl or Shift, a patterns report for each of the selected columns is displayed. If you deselect one or more columns from the Select Columns list, the reports for the corresponding columns are removed.

Each individual patterns report displays a summary table that contains the number of rows, number of missing observations, and number of unique values for the given column. By default, there are also tables for Most Duplicated Values, Longest Runs, and Longest Duplicate Sequences. If the Formatted Widths, Fraction Lengths, or Leading and Trailing Digits options are selected from either the control panel or the Explore Patterns red triangle menu, a corresponding table is added to each individual patterns report.

If you right-click on a row in any of the tables in the Univariate Patterns report, a menu of right-click options appears.

Select Rows and Column  Selects the column and rows in the original data table that correspond to the selected row in a specific table in the Univariate Patterns report. For example, if you right-click the second row of the Leading Digits table for a specific column, the rows in that column that have a leading digit of 2 are selected in the original data table.

Colorize Cells  Colors the cells in the original data table that correspond to the selected row in a specific table in the Univariate Patterns report. The rows of the colored cells are also selected.

There are red triangle options for the column-specific patterns report. See “Univariate Patterns Report Options” on page 438.

Explore Patterns Utility Options

The control panel and Explore Patterns red triangle menu contain options for summary and pattern tables.

Most Duplicated Values  Shows or hides a table of the values that appear most frequently in the data. Shows up to ten numbers for each column.

Longest Runs  Shows or hides a table of the longest run of the same value. The table contains the following information:

Starting Row  The row number that corresponds to the start of the run.
Count  The length of the run.

Value  The value of the entries in the run.

Rarity  A measurement of how rare it would be for the run to occur by chance. A high rarity indicates that it is not likely that the run occurred by chance. See “Rarity in Longest Runs” on page 440.

**Longest Duplicated Sequences**  Shows or hides a table of the longest sequence of values that appears more than once in the same column. Sequences of repeated values are also considered. If a sequence is duplicated more than once, each instance appears in the table. The table contains the following information:

Starting Row I  The row number that corresponds to the start of the first sequence.

Starting Row J  The row number that corresponds to the start of the duplicate sequence.

Count  The length of the sequence.

Rarity  A measurement of how rare it would be for the duplicate sequence to occur by chance. A high rarity indicates that it is not likely that the duplicate sequence occurred by chance. See “Rarity in Longest Sequences” on page 441.

First few values  The first few values of the duplicate sequence. Shows up to three values for each sequence.

**Formatted Widths**  Shows or hides a table of overall widths and decimal widths of the formatted values. The table contains the following information:

Width  The width size.

Overall Count  The number of observations in the column whose overall width equals the specified width.

Decimal Count  The number of observations in the column whose decimal width equals the specified width.

**Fraction Length**  Shows or hides a table of the continued fraction lengths for the values. A continued fraction is a representation of a number as a sequence of continually divided terms. The fraction length can indicate how rational a number is. Lengths of 15 or more indicate that the number is an irrational number, such as from a root function, a function involving an irrational number, or from a random number generator (Benford, 1938).

Note: In Explore Patterns, the maximum fraction length is 15. Numbers with fraction lengths of 15 or more are all reported as 15.

Length  The length of the continued fraction.
**Count**  The number of observations in the column whose continued fraction length equals the specified continued fraction length.

**Leading and Trailing Digits**  Shows or hides a table of counts for each leading and trailing digit, 1 through 9. For the leading digits, there are also columns for the expected rate and the minimum and maximum values that contain the corresponding leading digit. The expected rate is based on Benford’s Law, which states that the frequency that a number has a first digit that is equal to \( a \) is 

\[
F_a = \log_{10}(a+1/a)
\]

This law applies to data that have a large range of numbers that all have four or more digits.

**Spec Limit Matches**  (Available when at least one of the columns has a Spec Limit column property.) Shows or hides a table of values that are exactly the lower specification limit, upper specification limit, or target value. If there are no exact matches, the report is not shown.

**Distribution wrt Spec Limits**  (Available only when at least one of the columns has a Spec Limit column property.) Shows or hides a table of observed versus expected observations that are outside of the specification limits. The Chi-Square and PValue columns appear only if the number of observed observations is significantly higher than the number of expected observations.

**Duplicates Across Columns**  Shows or hides the Duplicates Across Columns report. The report contains a table of sequences of values that appear in the same rows across more than one column. There is a note at the top of the report that states the minimum length of a sequence for it to be considered a duplicate. This number is specified in the launch window or control panel as Minimum Cross Column Duplicate Run Size. There is also a Colorize option at the top of the report. See “Colorize Duplicates Across Columns” on page 436.

**Colorize Duplicates Across Columns**  (Available only after Duplicates Across Columns has been selected.) Colors cells in the data table to correspond to the duplicate matches found in the Duplicates Across Columns report. The rows that contain the duplicates are also selected.

**Linear Relationships**  Shows or hides the Linear relationships between variables report. The report contains a table of exact linear relationships across columns over a specified number of sequential rows. An exact linear relationship is defined as a linear relationship that has an \( R^2 \) value greater than or equal to 0.999999. There is a note at the top of the report that states the minimum number of rows considered. This number is specified in the launch window or control panel as Minimum Rows for Linear Relationships. There is also a Colorize option at the top of the report. See “Colorize Linear Relationships” on page 436.

**Colorize Linear Relationships**  (Available only after Linear Relationships has been selected.) Colors cells in the data table to correspond to the linear relationships found in the Linear
relationships between variables table. The rows that contain the linear relationships are also selected.

**Save Columns** Contains the following save options:

- **Save Table of Runs** Saves the longest runs for all columns to a new data table. The data table contains the same columns as the Longest Runs table in the Univariate Patterns report and is sorted by Starting Row.

- **Save Table of Duplicate Sequences** Saves the longest duplicate sequences for all columns to a new data table. The data table contains the same columns as the Longest Duplicate Sequences table in the Univariate Patterns report and is sorted by Starting Row I.

- **Save Duplicates Across Columns** Saves the Duplicates Across Columns table to a new data table.

- **Save Linear Relationships** Saves the Linear relationships between values table to a new data table.

**Ordering Columns** Contains options for ordering. When you change the ordering, the column list in the Univariate Patterns report is reordered. The top column is automatically selected and the report for only that column is displayed.

- **Order by Runs Rarity** Orders the column list by the rarity values of the longest runs. Higher rarity values are at the top.

- **Order by Sequence Rarity** Orders the column list by the rarity values of the long duplicate sequences. Higher rarity values are at the top.

- **Order by Column Name** Orders the column list in alphabetical order by column name.

- **Original Order** Orders the column list in the original order in which the columns were specified in the launch window.

**Clear Cell Colors** Clears the cell colors for columns selected in the data table or for all columns if no columns are selected in the data table.

See *Using JMP* for more information about the following options:

- **Redo** Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

- **Save Script** Contains options that enable you to save a script that reproduces the report to several destinations.
Save By-Group Script  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.

Univariate Patterns Report Options

Each Univariate Patterns red triangle menu contains the following options:

Select Most Duplicated  Selects the observations in the data table that correspond to the values in the Most Duplicated Values table.

Select Longest Runs  Selects the observations in the data table that correspond to the values in the Longest Runs table.

Select Longest Duplicate Sequences  Selects the observations in the data table that correspond to the values in the Longest Duplicate Sequences table.

Select by Formatted Width  Selects the observations in the data table that correspond to the values in the Formatted Widths table that have the user-specified overall width.

Select by Decimal Width  Selects the observations in the data table that correspond to the values in the Formatted Widths that have the user-specified decimal width.

Select by Fraction Length  Selects the observations in the data table that correspond to the values in the Fraction Length table that have the user-specified fraction length.

Select by Leading Digit  Selects the observations in the data table that correspond to the values in the Leading and Trailing Digits table that have the user-specified leading digit.

Additional Example of the Explore Patterns Utility

The Water Treatment.jmp data table contains data from an urban waste water treatment plant. The columns are daily measurements of different sensors in the plant. Use the Explore Patterns Utility to determine whether there are any unexpected patterns in the sensor measurements.

1. Select Help > Sample Data Library and open the Water Treatment.jmp sample data table.
2. Select Analyze > Screening > Explore Patterns.
3. Select the Sensor Measurements column group and click Y, Columns.
4. Click OK.
5. In the Control Panel, under Across Columns, click the box next to Duplicates Across Columns.
Figure 21.17 Duplicates Across Columns Report

The Duplicates Across Columns report shows a long list of duplicate columns. However, the minimum run size is 2 and there are many small runs in the list. You want to focus on the larger runs of at least 10.

6. In the Control Panel, under Settings, enter 10 in the box next to Minimum Cross Column Duplicate Run Size.

   **Tip:** Click anywhere outside of the box to automatically update the report.

Figure 21.18 Duplicates Across Columns Report With Runs at Least 10

The updated Duplicates Across Columns report shows that there are two duplicate sets with runs of at least 10. Both sets include the PH-P column.

7. Click **Colorize** in the Duplicates Across Columns Report.
Statistical Details for the Explore Patterns Utility

Rarity in Longest Runs

To calculate the rarity for longest runs, first define the following variables:

- \( n \) = the number of rows in the column
- \( k \) = the number of times a specific value occurs in the column
- \( p = \frac{k}{n} \) = the probability of observing the specific value in the column
- \( m \) = the length of the run
- \( N \) = the number of unique runs

Then, the rarity for longest runs is calculated as follows:

\[
Rarity = -\log_2(1 - (1 - p^{m-1})^N)
\]
Rarity in Longest Sequences

To calculate the rarity for longest sequences, first define the following variables:

\( p \) = the probability of observing the specific sequence one time in the column
\( k \) = the number of times the starting value of the sequence occurs in the column

Then, the rarity for longest sequences is calculated as follows:

\[
Rarity = -\log_2(1 - (1 - p)^k)
\]
The analysis of large-scale data sets, where hundreds or thousands of measurements are taken on a part or an organism, requires innovative approaches. But testing many responses for the effects of factors can be challenging, if not misleading, without appropriate methodology.

Response Screening automates the process of conducting tests across a large number of responses. Your test results and summary statistics are presented in data tables, rather than reports, to enable data exploration. A False-Discovery Rate approach guards against incorrect declarations of significance. Plots of $p$-values are scaled using the LogWorth, making them easily interpretable.

Because large scale data sets are often messy, Response Screening presents methods that address irregularly distributed and missing data. A robust estimate method allows outliers to remain in the data, but reduces the sensitivity of tests to these outliers. Missing data options allow missing values to be included in the analysis. These features enable you to analyze your data without first conducting an extensive analysis of data quality.

When you have many observations, even differences that are of no practical interest can be statistically significant. Response Screening presents tests of practical difference, where you specify the difference that you are interested in detecting. On the other hand, you might want to know whether differences do not exceed a given magnitude, that is, if the means are equivalent. For this purpose, Response Screening presents equivalence tests.

Overview of the Response Screening Platform

Response Screening automates the process of conducting tests across a large number of responses. It tests each response that you specify against each factor that you specify. Response screening addresses two main issues connected with large-scale data. These are the need to conduct many tests, and the requirement to deal effectively with outliers and missing values.

Response screening is available as a platform and as a Fit Model personality. In both cases, it performs tests analogous to those found in the Fit Y by X platform, as shown in Table 22.1. As a personality, it performs tests of the response against the individual model effects.

To facilitate and support the multiple inferences that are required, Response Screening provides these features:

**Data Tables**

Results are shown in data tables, as well as in a report, to enable you to explore, sort, search, and plot your results. Statistics that facilitate plot interpretation are provided, such as the LogWorth of $p$-values.

**False Discovery Rates**

Because you are conducting a large number of tests, you need to control the overall rate of declaring tests significant. Response screening controls the *false discovery rate*. The False Discovery Rate (FDR) is the expected proportion of significant tests that are incorrectly declared significant (Benjamini and Hochberg 1995; Westfall et al. 2011).

**Tests of Practical Significance**

When you have many observations, even small effects that are of no practical consequence can result in statistical significance. To address this issue, you can define an effect size that you consider to be of *practical significance*. You then conduct tests of practical significance, thereby only detecting effects large enough to be of pragmatic interest.

**Equivalence Tests**

When you are studying many factors, you are often interested in those that have essentially equivalent effects on the response. In this case, you can specify an effect size that defines practical equivalence and then conduct equivalence tests.

To address issues that arise when dealing with messy data, Response Screening provides features to deal with outliers and missing data. These features enable you to analyze your data directly, without expending effort to address data quality issues:

**Robust Estimation**

Outliers in your data increase estimates of standard error, causing tests to be insensitive to real effects. Select the Robust option to conduct Huber M-estimation. Outliers remain in the data, but the sensitivity of tests to these outliers is reduced.

**Missing Value Options**

The platform contains an option to treat missing values on categorical predictors in an informative fashion.

The Response Screening platform generates a report and a data table: the Response Screening report and the PValues table. The Response Screening personality generates a report and two data tables: the Fit Response Screening report, the PValues table, and the Y Fits table.

The JSL command `Summarize Y by X` performs the same function as the Response Screening platform but without creating a platform window. See the JSL Syntax Reference.

**Example of Response Screening**

The Probe.jmp sample data table contains 387 characteristics (the Responses column group) measured on 5800 wafers. The Lot ID and Wafer Number columns uniquely identify the wafer. You are interested in which of the characteristics show different values across a process change (Process).

1. Select Help > Sample Data Library and open Probe.jmp.
2. Select Analyze > Screening > Response Screening.
3. Select the Responses column group and click Y, Response.
4. Select Process and click X.
5. Enter 100 in the MaxLogWorth box.
   A logworth (-\log_{10}(p\text{-value})) of 100 or larger corresponds to an extremely small \( p \)-value. Setting a value for the MaxLogWorth helps control the scale of plots as it limits the reported logworth value.
6. Click OK.

The report shows a table of \( p \)-value results and the FDR PValue Plot, and also contains two other plot reports.
The FDR PValue Plot shows two types of \( p \)-values, FDR PValue and PValue, for each of the 387 tests. These are plotted against Rank Fraction. PValue is the usual \( p \)-value for the test of a \( Y \) against \( \text{Process} \). The FDR PValue is a \( p \)-value that is adjusted to guarantee a given false discover rate (FDR), here 0.05. The FDR PValues are plotted in blue and the PValues are plotted in red. The Rank Fraction ranks the FDR \( p \)-values from smallest to largest, in order of decreasing significance.

Both the horizontal blue line and the sloped red line on the plot are thresholds for FDR significance. Tests with FDR \( p \)-values that fall below the blue line are significant at the 0.05 level when adjusted for the false discovery rate. Tests with ordinary \( p \)-values that fall below the red line are significant at the 0.05 level. In this way, the plot enables you to read FDR significance from either set of \( p \)-values.

**Figure 22.2** Response Screening Report for 387 Tests against Process
The FDR PValue Plot shows that more than 60% of the tests are significant. A handful of tests are significant using the unadjusted $p$-value, but not significant using the FDR $p$-value. These tests correspond to the red points that are above the red line, but below the blue line.

To identify the characteristics that are significantly different across Process, you can drag a rectangle around the appropriate points in the plot. This selects the rows corresponding to these points in the Result table, where the names of the characteristics are given in the first column.

The Result table contains 387 rows, one for each response measure in the Responses group. The response is given in the first column, called Y. Each response is tested against the effect in the X column, namely, Process.

The remaining columns give information about the test of Y against X. Here the test is a Oneway Analysis of Variance. In addition to other information, the table gives the test’s $p$-value, LogWorth, FDR (False Discovery Rate) $p$-value, and FDR LogWorth. Use this table to sort by the various statistics, select rows, or plot quantities of interest.

Notice that LogWorth and FDR LogWorth values that correspond to $p$-values of 1e-100 or less are reported as 100, because you set MaxLogWorth to 100 in the launch window. Also, cells corresponding to FDR LogWorth values greater than two are colored with an intensity gradient.

See “The Response Screening Report” on page 451 for more information about the report and PValues table.
Launch the Response Screening Platform

Launch the Response Screening platform by selecting Analyze > Screening > Response Screening.

Figure 22.3 Response Screening Launch Window

For more information about the options in the Select Columns red triangle menu, see Using JMP.

Launch Window Roles

Y, Response  Identifies the response columns containing the measurements to be analyzed.

X  Identifies the columns against which you want to test the responses.

Grouping  For each level of the specified column, analyzes the corresponding rows separately, but presents the results in a single table and report.

Weight  Identifies a column whose values assign a weight to each row. These values are used as weights in the analysis. See Fitting Linear Models.
Freq  Identifies a column whose values assign a frequency to each row. These values enable you to account for pre-summarized data. See Fitting Linear Models.

By  For each level of the specified column, analyzes the corresponding Ys and Xs and presents the results in separate tables and reports.

Launch Window Options

PValues Table on Launch  Creates a data table for the p-values and individual model fit statistics.

Robust  For continuous responses, uses Huber M-estimates (Huber and Ronchetti 2009) in fitting regression and ANOVA models. This robust method down weights outliers to reduce the sensitivity of tests to outliers. If there are no outliers, these estimates are close to the least squares estimates. Note that this option increases processing time. See Basic Analysis for more information about Huber M-estimation. For an example, see “Example of Robust Fit” on page 470.

Cauchy  Assumes that the errors have a Cauchy distribution. A Cauchy distribution has fatter tails than the normal distribution, resulting in a reduced emphasis on outliers. This option can be useful if you have a large proportion of outliers in your data. However, if your data are close to normal with only a few outliers, this option can lead to incorrect inferences. The Cauchy option estimates parameters using maximum likelihood and a Cauchy link function.

Poisson Y  Fits each Y response as a count having a Poisson distribution. The test is performed only for categorical X. This option is appropriate when your responses are counts.

Missing is category  For any categorical X variable, treats missing values on X as a category.

Paired X and Y  Performs tests only for Y columns paired with X columns according to their order in the Y, Response and X lists. The first Y is paired with the first X, the second Y with the second X, and so on.

Practical Difference Portion  The fraction of the specification range, or of an estimated six standard deviation range, that represents a difference that you consider pragmatically meaningful. If Spec Limits is not set as a column property, a range of six standard deviations is estimated for the response. The standard deviation estimate is computed from the interquartile range (IQR), as \( \hat{\sigma} = \frac{(IQR)}{(1.3489795)} \).

If no Practical Difference Proportion is specified, its value defaults to 0.10. Tests of practical significance and equivalence tests use this difference to determine the practical difference. See “Compare Means Data Table” on page 459.

MaxLogWorth  Use to control the scale of plots involving LogWorth values (-log10 of p-values). LogWorth values that exceed MaxLogWorth are plotted as MaxLogWorth to
prevent extreme scales in LogWorth plots. See “Example of the MaxLogWorth Option” on page 469 for an example.

**Advanced Options** Contains the following options:

- **Kappa** Adds a new column called Kappa to the data table. If Y and X are both categorical and have the same levels, kappa is provided. This is a measure of agreement between Y and X.

- **Corr** The Corr option computes the Pearson product-moment correlation in terms of the indices defined by the value ordering.
  
  If X and Y are both binary, the Pearson product-moment calculation gives Spearman’s rho and Kendall’s Tau-b. Otherwise, a value of Corr that is large in magnitude indicates an association; a Corr value that is small in magnitude does not preclude an association.

- **Force X Categorical** Ignores the modeling type and treats all X columns as categorical.

- **Force X Continuous** Ignores the modeling type and treats all X columns as continuous.

- **Force Y Categorical** Ignores the modeling type and treats all Y columns as categorical.

- **Force Y Continuous** Ignores the modeling type and treats all Y columns as continuous.

- **Unthreaded** Suppresses multithreading used for computational speed.

---

### The Response Screening Report

The Response Screening report consists of a results table and several plots. These plots focus on False Discovery Rate (FDR) statistics. See “The False Discovery Rate” on page 474.

The default plots are the FDR PValue Plot, the FDR LogWorth by Effect Size, and the FDR LogWorth by RSquare. If you select the Robust option on the launch window, Robust versions of each of these reports are also presented. In addition, a Robust LogWorth by FDR LogWorth plot is presented to help assess the impact of using the robust fit.

### Result Table

The Response Screening Result table contains a row for each pair of Y and X variables. The columns of the table contain measures and model fit statistics that are specific to the selected fit and Y and X modeling types.

- **Group** (Appears only if there is a grouping variable.) The level of the grouping column.

- **Y** The specified response columns.
X  The specified factor columns.

Count  The number of rows used for testing, or the corresponding sum of the Freq or Weight variable.

PValue  The p-value for the significance test corresponding to the pair of Y and X variables. For more information about Fit Y by X statistics, see Basic Analysis.

LogWorth  The quantity -log_{10}(p-value). This transformation adjusts p-values to provide an appropriate scale for graphing. A value that exceeds 2 is significant at the 0.01 level (-log_{10}(0.01) = 2).

FDR PValue  The False Discovery Rate p-value calculated using the Benjamini-Hochberg technique. This technique adjusts the p-values to control the false discovery rate for multiple tests. If there is no Group variable, the set of multiple tests includes all tests displayed in the table. If there is a Group variable, the set of multiple tests consists of all tests conducted for each level of the Group variable. For more information about the FDR correction, see Benjamini and Hochberg (1995). For more information about the false discovery rate, see “The False Discovery Rate” on page 474.

FDR LogWorth  The quantity -log_{10}(FDR PValue). This is the statistic to use for plotting and assessing significance. Note that small p-values result in high FDR LogWorth values. Cells corresponding to FDR LogWorth values greater than two (p-values less than 0.01) are colored with an intensity gradient.

Effect Size  Indicates the extent to which response values differ across the levels or values of X. Effect sizes are scale invariant.

– When Y is continuous, the effect size is the square root of the average sum of squares from the hypothesis test divided by a robust estimate of the response standard deviation. If the interquartile range (IQR) is nonzero and IQR > range/20, the standard deviation estimate is IQR/1.3489795. Otherwise the sample standard deviation is used.
– When Y is categorical and X is continuous, the effect size is the square root of the average ChiSquare value for the whole model test.
– When Y and X are both categorical, the effect size is the square root of the average Pearson ChiSquare.

Rank Fraction  The rank of the FDR LogWorth expressed as a fraction of the number of tests. If the number of tests is m, the largest FDR LogWorth value has Rank Fraction 1/m, and the smallest has Rank Fraction 1. The Rank Fraction is used in plotting the PValues and FDR PValues in rank order of decreasing significance.

RSquare  (Appears only when Y is continuous.) The coefficient of determination, which measures the proportion of total variation explained by the model.
**Kappa**  (Appears only when Y and X are both categorical and have the same number of levels.) A measure of agreement between Y and X.

**Corr**  (Appears only when Y and X are both categorical.) The Pearson product-moment correlation in terms of the indices defined by the value ordering.

The following columns are added to the Result table when the Robust option is selected in the launch window. The Robust option applies only when Y is continuous, so Robust column cells are empty when Y is categorical.

**Robust PValue**  The $p$-value for the significance test corresponding to the pair of Y and X variables using a robust.

**Robust LogWorth**  The quantity $-\log_{10}(\text{Robust PValue})$.

**Robust FDR PValue**  The False Discovery Rate calculated for the Robust PValues using the Benjamini-Hochberg technique. If there is no Group variable, the multiple test adjustment applies to all tests displayed in the table. If there is a Group variable, the multiple test adjustment applies to all tests conducted for each level of the Group variable.

**Robust FDR LogWorth**  The quantity $-\log_{10}(\text{Robust FDR PValue})$.

**Robust Rank Fraction**  The rank of the Robust FDR LogWorth expressed as a fraction of the number of tests.

**Robust Chisq**  The chi-square value associated with the robust test.

**Robust Sigma**  The robust estimate of the error standard deviation.

**Robust Outlier Portion**  The portion of the values whose distance from the robust mean exceeds three times the Robust Sigma.

---

**FDR PValue Plot**

The FDR PValue Plot report shows a plot of FDR PValues and PValues against the Rank Fraction. The Rank Fraction ranks the PValues in order of decreasing significance. FDR PValues are plotted in blue and PValues in red.

A blue horizontal line shows the 0.05 significance level. Note that you can change this level by double-clicking the vertical axis, removing the current reference line, and adding a new reference line.

A red increasing line provides an FDR threshold for unadjusted $p$-values. A $p$-value falls below the red line precisely when the FDR-adjusted $p$-value falls below the blue line. This enables you to read significance relative to the FDR from either the adjusted or unadjusted $p$-values.
Figure 22.4 shows the FDR PValue Plot for the Probe.jmp sample data table. Note that some tests are significant according to the usual $p$-value but not according to the FDR $p$-value.

**Figure 22.4** FDR PValue Plot

![FDR PValue Plot](image)

**FDR LogWorth by Effect Size**

When you have large effects, the associated $p$-values are often very small. Visualizing these small values graphically can be challenging. When transformed to the LogWorth ($-\log_{10}(p$-value)) scale, highly significant $p$-values have large LogWorths and nonsignificant $p$-values have low LogWorths. A LogWorth of zero corresponds to a nonsignificant $p$-value of 1. Any LogWorth above 2 corresponds to a $p$-value below 0.01.

In the FDR LogWorth by Effect Size plot, the vertical axis is the FDR LogWorth and the horizontal axis is the Effect Size. Generally, larger effects lead to more significant $p$-values and larger LogWorths. However, this relationship is not necessarily strong because significance also depends on the error variance. In fact, large LogWorths can be associated with small effects, and small LogWorths can be associated with large effects, because of the size of the error variance. The FDR LogWorth by Effect Size plot enables you to explore this relationship.

Figure 22.5 shows the FDR LogWorth by Effect size plot for the Probe.jmp sample data table with MaxLogWorth set to 100. Most FDR LogWorth values exceed 2, which indicates that most effects are significant at the 0.01 level. The FDR LogWorth values of 100 correspond to extremely small $p$-values.
Figure 22.5  FDR LogWorth by Effect Size

FDR LogWorth by RSquare

The FDR LogWorth by RSquare plot shows the FDR LogWorth on the vertical axis and RSquare values on the horizontal axis. Larger LogWorth values tend to be associated with larger RSquare values, but this relationship also depends on the number of observations.

The PValues Data Table

If the PValues Tables on Launch option is selected in the launch window, a PValues data table is created when the Response Screening platform is launched. This data table contains the same information as the Result table that is in the Response Screening report. The PValues data table also contains the additional, model specific columns:

- **YMean**  The mean of Y.
- **SSE**  Appears when Y is continuous. The sum of squares for error.
- **DFE**  Appears when Y is continuous. The degrees of freedom for error.
- **MSE**  Appears when Y is continuous. The mean squared error.
- **F Ratio**  Appears when Y is continuous. The F Ratio for the analysis of variance or regression test.
- **Intercept**  Appears when Y and X are both continuous. The intercept of the regression model relating the corresponding pair of Y and X variables.
**Slope**  Appears when Y and X are both continuous. The slope of the regression model relating the corresponding pair of Y and X variables.

**DF**  Appears when Y and X are both categorical. The degrees of freedom for the ChiSquare test.

**LR Chisq**  Appears when Y and X are both categorical. The value of the Likelihood Ratio ChiSquare statistic.

**Robust Elapsed Time**  (Appears only when Robust is specified in the launch window.) Computing time, in seconds, required to create the Robust report.

---

**PValues Data Table Scripts**

Relevant scripts are saved to the PValues data table. All but one of these reproduce plots provided in the report. When you select rows in the PValues table, the Fit Selected script produces the appropriate Fit Y by X analyses.

---

**Response Screening Platform Options**

The Response Screening red triangle menu contains options to customize the display and to compute and save calculated data.

**Results Table**  Shows or hides the table of results.

**Fit Selected Items**  For selected relationships, adds the appropriate Fit Y by X reports to the Response Screening report. You can select relationships by selecting points in the plots, rows in the Result Table, or if opened, rows in the PValue data table.

**Select Columns**  Selects the columns in the original data table that correspond to rows that you select in the Result Table, to points that you select in plots in the Response Screening report window, or if opened, rows in the PValues table. Select the rows or points first, then select Select Columns. The corresponding columns in the data table are selected. You can select columns corresponding to additional rows in the PValues table or points in plots by first selecting them and then selecting Select Columns again. To select columns corresponding to different rows or points, first clear the current column selection in the original data table.

**Select Where**  Opens the Select Where window. You can select specific responses in the Result table that correspond to a particular condition by using the Comparison menu and Value text box. For example, you can select all responses such that Effect Size > 0.80. After you click OK, the responses are selected in the Result table.
Tip: You can also access the Select Where window by right-clicking anywhere in the Result table.

**Save PValues**  Creates the PValues data table. See “The PValues Data Table” on page 455.

**Save Means**  For continuous Ys and categorical Xs, creates a data table with the counts, means, and standard deviations for each level of the categorical variable. If the Robust option is selected, the robust mean is included.

**Save Compare Means**  For continuous Ys and categorical Xs, tests all pairwise comparisons across the levels of the categorical variable. For each comparison, the data table gives the usual t test, a test of practical significance, an equivalence test, and a column that uses color coding to summarize the results. The data table also contains a script that plots Practical LogWorth by Relative Practical Difference. See “Compare Means Data Table” on page 459. For an example, see “Example of Tests of Practical Significance and Equivalence” on page 467.

**Save Std Residuals**  Saves a new group of columns to the original data table and places these in a column group call Residual Group. For each continuous Y and categorical X, a column is constructed containing the residuals divided by their estimated standard deviation. In other words, the column contains standardized residuals. The column is defined by a formula.

If the Robust option is selected, standardized residual columns are constructed using robust fits and robust estimates.

**Save Outlier Indicator**  Saves a new group of columns to the original data table and places these in a column group call Outlier Group. Save Outlier Indicator is most effective when you have selected the Robust option.

For each continuous Y and categorical X, a column that indicates outliers is constructed. An outlier is a point whose distance to the predicted value exceeds three times an estimate of sigma. In other words, an outlier is a point whose standardized residual exceeds three. The column is defined by a formula.

If the Robust option is selected, robust fits and robust estimates are used. An outlier is a point whose distance to the predicted value exceeds three times the robust estimate of sigma.

The Cluster Outliers script is added to the original data table. The script shows outliers on a hierarchical cluster plot of the data.

See *Using JMP* for more information about the following options:

**Local Data Filter**  Shows or hides the local data filter that enables you to filter the data used in a specific report.
Redo  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

Save Script  Contains options that enable you to save a script that reproduces the report to several destinations.

Save By-Group Script  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.

Means Data Table

The Means data table contains a row for each combination of response and X level. For the Probe.jmp sample data table, there are 387 response variables, each tested against Process at two levels. The Means table contains $387 \times 2 = 774$ rows.

Figure 22.6 Means Data Table

The Means data table includes the following columns:

Y  The continuous response variables.

X  The categorical variables.

Level  The level of the categorical X variable.

Count  The count of values in the corresponding Level.

Mean  The mean of the Y variable for the specified Level.
**StdDev**  The standard deviation of the Y variable for the specified Level.

**Robust Mean**  The robust M-estimate of the mean. Appears when you select the Robust option on the launch window.

### Compare Means Data Table

When your data table consists of a large number of rows (large \(n\)), the standard error used in testing can be very small. As a result, tests might be statistically significant, when in fact, the observed difference is too small to be of practical consequence. Tests of practical significance enable you to specify the size of the difference that you consider worth detecting. This difference is called the *practical difference*. Instead of testing that the difference is zero, you test whether the difference exceeds the practical difference. As a result, the tests are more meaningful, and fewer tests need to be scrutinized.

Equivalence tests enable you to determine whether two levels have essentially the same effect, from a practical perspective, on the response. In other words, an equivalence test tests whether the difference is smaller than the practical difference.

The Compare Means data table provides results for both tests of practical difference and tests of practical equivalence. Each row compares a response across two levels of a categorical factor. Results of the pairwise comparisons are color-coded to facilitate interpretation. See “Practical Difference” on page 460 for a description of how the practical difference is specified. See “Example of Tests of Practical Significance and Equivalence” on page 467 for an example.

**Figure 22.7**  Compare Means Data Table
The Compare Means data table contains a script that plots Practical LogWorth by Relative Practical Difference. Relative Practical Difference is defined as the actual difference divided by the practical difference.

**Y** The continuous response variables.

**X** The categorical variables.

**Leveli** The level of the categorical X variable.

**Levelj** The level of the categorical X variable being compared to Leveli.

**Difference** The estimated difference in means across the two levels. If the Robust option is selected, robust estimates of the means are used.

**Std Err Diff** The standard error of the difference in means. This is a robust estimate if the Robust option is selected.

**Plain Dif PValue** The p-value for the usual Student’s t test for a pairwise comparison. This is the robust version of the t test when the Robust option is selected. Tests that are significant at the 0.05 level are highlighted.

**Practical Difference** The difference in means that is considered to be of practical interest. If you assign a Spec Limit property to the Y variable, the practical difference is computed as the difference between the specification limits multiplied by the Practical Difference Proportion. If no Practical Difference Proportion has been specified, the Practical Difference is the difference between the specification limits multiplied by 0.10.

If you do not assign a Spec Limit property to the Y variable, an estimate of its standard deviation is computed from its interquartile range (IQR). This estimate is \( \hat{\sigma} = (IQR)/(1.3489795) \). The Practical Difference is computed as \( 6\hat{\sigma} \) multiplied by the Practical Difference Proportion. If no Practical Difference Proportion has been specified, the Practical Difference is computed as \( 6\hat{\sigma} \) multiplied by 0.10.

**Practical Dif PValue** The p-value for a test of whether the absolute value of the mean difference in Y between Leveli and Levelj is less than or equal to the Practical Difference. A small p-value indicates that the absolute difference exceeds the Practical Difference. This indicates that Leveli and Levelj account for a difference that is of practical consequence.

**Practical Equiv PValue** Uses the Two One-Sided Tests (TOST) method to test for a practical difference between the means (Schuirmann 1987). The Practical Difference specifies a threshold difference for which smaller differences are considered practically equivalent. One-sided t tests are constructed for two null hypotheses: the true difference exceeds the Practical Difference; the true difference is less than the negative of the Practical Difference.
If both tests reject, this indicates that the absolute difference in the means falls within the Practical Difference. Therefore, the groups are considered practically equivalent.

The Practical Equivalence PValue is the largest $p$-value obtained on the one-sided $t$ tests. A small Practical Equiv PValue indicates that the mean response for Level$i$ is equivalent, in a practical sense, to the mean for Level$j$.

**Practical Result** A description of the results of the tests for practical difference and equivalence. Values are color-coded to help identify significant results.

- Different (Pink): Indicates that the absolute difference is significantly greater than the practical difference.
- Equivalent (Green): Indicates that the absolute difference is significantly within the practical difference.
- Inconclusive (Gray): Indicates that neither the test for practical difference nor the test for practical equivalence is significant.

---

**The Response Screening Personality in Fit Model**

If you are interested in univariate tests against linear model effects, you can fit the Response Screening personality in Fit Model. The report and tables produced test all responses against all model effects.

- “Launch Response Screening in Fit Model”
- “The Fit Response Screening Report”
- “Fit Response Screening Options”
- “PValues Data Table”
- “Y Fits Data Table”
Launch Response Screening in Fit Model

Select **Analyze > Fit Model**. Enter your Ys and model effects. Select **Response Screening** from the Personality list.

**Figure 22.8** Response Screening from the Fit Model Window

For more information about the options in the Select Columns red triangle menu, see *Using JMP*.

There are two options for robust estimation:

**Robust Fit (Huber)** Specifies robust (Huber) estimation to down weight outliers for continuous responses. If there are no outliers, these estimates are close to the least squares estimates. Note that this option increases processing time.

**Very Robust Fit (Cauchy)** Specifies very robust (Cauchy) estimation to down weight outliers for continuous responses. Assumes that the errors have a Cauchy distribution. A Cauchy distribution has fatter tails than the normal distribution, resulting in a reduced emphasis on outliers. This option can be useful if you have a large proportion of outliers in your data. However, if your data are close to normal with only a few outliers, this option can lead to incorrect inferences. The Cauchy option estimates parameters using maximum likelihood and a Cauchy link function.

**Tip:** If both robust options are selected, the platform uses only Cauchy estimation.
The **Informative Missing** option provides a coding system for missing values. The Informative Missing coding allows estimation of a predictive model despite the presence of missing values. It is useful in situations where missing data are informative. Select this option from the Model Specification red triangle menu.

**Figure 22.9** Informative Missing Option

For more information about the Fit Model window, see *Fitting Linear Models*.

### The Fit Response Screening Report

The Fit Response Screening report shows two plots:

- The FDR PValue Plot
- The FDR LogWorth by Rank Fraction Plot

The FDR PValue Plot is interpreted in the same way as for the platform itself. See “The Response Screening Report” on page 451.
The FDR LogWorth by Rank Fraction plot shows FDR LogWorth values plotted against the ranks of the $p$-values. The plotted points decrease or remain constant as rank fraction increases. The plot gives an indication of what proportion of tests are significant. An example using the Response Screening personality is given in “Response Screening Personality” on page 473.

**Fit Response Screening Options**

The Fit Response Screening red triangle menu contains options to save the calculated data.

- **Model Dialog** Opens a window containing the model dialog that you have run to obtain the given report.

- **Save Estimates** Opens a data table in which each row corresponds to a response and the columns correspond to the model terms. The entries are the parameter estimates obtained by fitting the specified model. This data table also contains a table variable called Original Data that gives the name of the data table that was used for the analysis. If you specified a By variable, JMP creates an estimates table for each level of the By variable, and the Original Data variable gives the By variable and its level.

- **Save Prediction Formula** Adds columns to the original data table containing prediction equations for all responses.

- **Save Least Squares Means** Opens a data table where each row corresponds to a response and a combination of effect settings. The row contains the least squares mean and standard error for that combination of settings.

See *Using JMP* for more information about the following options:

- **Local Data Filter** Shows or hides the local data filter that enables you to filter the data used in a specific report.

- **Redo** Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

- **Save Script** Contains options that enable you to save a script that reproduces the report to several destinations.

- **Save By-Group Script** Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.
PValues Data Table

The PValues data table contains a row for each pair consisting of a Y variable and a model Effect. The columns in the table include the following. If you select the Robust Fit option on the launch window, the models are fit using Huber M-estimation.

**Y**  The specified response columns.

**Effect**  The specified model effects.

**FRatio**  The test statistic for a test of the Effect. This is the value found in the Effect Tests report in Least Squares Fit.

**PValue**  The $p$-value for the significance test corresponding to the FRatio. See *Fitting Linear Models* for more information about Effect Tests.

**LogWorth**  The quantity $-\log_{10}(p$-value$)$. This transformation adjusts $p$-values to provide an appropriate scale for graphing. A value that exceeds 2 is significant at the 0.01 level (because $-\log_{10}(0.01) = 2$).

**FDR PValue**  The False Discovery Rate $p$-value calculated using the Benjamini-Hochberg technique. This technique adjusts the $p$-values to control the false discovery rate for multiple tests. For more information about the FDR correction, see Benjamini and Hochberg (1995). For more information about the false discovery rate, see “The False Discovery Rate” on page 474 or Westfall et al. (2011).

**FDR LogWorth**  The quantity $-\log_{10}(\text{FDR PValue})$. This is the best statistic for plotting and assessing significance. Note that small $p$-values result in high FDR LogWorth values.

**Rank Fraction**  The rank of the FDR LogWorth expressed as a fraction of the number of tests. If the number of tests is $m$, the largest FDR LogWorth value has Rank Fraction $1/m$, and the smallest has Rank Fraction 1. Equivalently, the Rank Fraction ranks the $p$-values in increasing order, as a fraction of the number of tests. The Rank Fraction is used in plotting the PValues and FDR PValues in rank order of decreasing significance.

**Test DF**  The degrees of freedom for the effect test.

The PValues data table also contains a table variable called Original Data that gives the name of the data table that was used for the analysis. If you specified a By variable, JMP creates a PValues table for each level of the By variable, and the Original Data variable gives the By variable and its level.
Y Fits Data Table

The Y Fits data table contains a row for Y variable. For each Y, the columns in the table summarize information about the model fit. If you select the Robust Fit option on the launch window, the models are fit using Huber M-estimation.

Y    The specified response columns.
RSquare  The multiple correlation coefficient.
RMSE  The Root Mean Square Error.
Count  The number of observations (or sum of the Weight variable).
Overall FRatio  The test statistic for model fit from the Analysis of Variance report in Least Squares Fit.
Overall PValue  The p-value for the overall test of model significance.
Overall LogWorth  The LogWorth of the p-value for the overall test of model significance.
Overall FDR PValue  The overall p-value adjusted for the false discovery rate. (See “The Response Screening Report” on page 451.)
Overall FDR LogWorth  The LogWorth of the Overall FDR PValue.
Overall Rank Fraction  The rank of the Overall FDR LogWorth expressed as a fraction of the number of tests. If the number of tests is m, the largest Overall FDR LogWorth value has Rank Fraction 1/m, and the smallest has Rank Fraction 1.
<Effect> PValue  These columns contain p-values for tests of each model effect. These columns are arranged in a group called PValue in the columns panel.
<Effect> LogWorth  These columns contain LogWorths for the p-values for tests of each model effect. These columns are arranged in a group called LogWorth in the columns panel.
<Effect> FDR LogWorth  These columns contain FDR LogWorths for tests of each model effect. These columns are arranged in a group called FDR LogWorth in the columns panel.

The Y Fits data table also contains a table variable called Original Data that gives the name of the data table that was used for the analysis. If you specified a By variable, JMP creates a Y Fits table for each level of the By variable, and the Original Data variable gives the By variable and its level.
Additional Examples of Response Screening

- “Example of Tests of Practical Significance and Equivalence”
- “Example of the MaxLogWorth Option”
- “Example of Robust Fit”
- “Response Screening Personality”

Example of Tests of Practical Significance and Equivalence

This example tests for practical differences using the Probe.jmp sample data table.

1. Select Help > Sample Data Library and open Probe.jmp.
2. Select Analyze > Screening > Response Screening.
   The Response Screening Launch window appears.
3. Select the Responses column group and click Y, Response.
4. Select Process and click X.
5. Type 0.15 in the Practical Difference Portion box.
6. Click OK.
7. Click the Response Screening red triangle and select Save Compare Means.
   Figure 22.10 shows a portion of the data table. For each response in Y, the corresponding row gives information about tests of the New and the Old levels of Process.

Figure 22.10 Compare Means Table, Partial View
Because specification limits are not saved as column properties in `Probe.jmp`, JMP calculates a value of the practical difference for each response. The practical difference of 0.15 that you specified is multiplied by an estimate of the 6σ range of the response. This value is used in testing for practical difference and equivalence. It is shown in the **Practical Difference** column.

The Plain Difference column shows responses whose $p$-values indicate significance. The **Practical Diff PValue** and **Practical Equiv PValue** columns give the $p$-values for tests of practical difference and practical equivalence. Note that many columns show *statistically* significant differences, but do not show *practically* significant differences.

8. Display the Compare Means data table and select **Analyze > Distribution**.
9. Select **Practical Result** and click **Y, Columns**.
10. Click **OK**.

Figure 22.11 shows the distribution of results for practical significance. Only 37 tests are different, as determined by testing for the specified practical difference. For 5 of the responses, the tests were inconclusive. You cannot tell whether the responses result in a practical difference across **Process**.

**Figure 22.11** Distribution of Practical Significance Results

![Practical Result Distribution](image)

The 37 responses can be selected for further study by clicking on the corresponding bar in the plot.
Example of the MaxLogWorth Option

Use the Response Screening MaxLogWorth option to control the LogWorth scale from being distorted by very large values. When data sets have a large number of observations, $p$-values can be very small. LogWorth values provide a useful way to study $p$-values graphically in these cases. In some data sets the $p$-values are so small that the LogWorth scale is distorted by very large values.

1. Select Help > Sample Data Library and open Probe.jmp.
2. Select Analyze > Screening > Response Screening.
3. In the Response Screening Launch window, select the Responses column group and click Y, Response.
4. Select Process and click X.
5. Select the Robust check box.
6. Click OK.

The analysis is numerically intensive and might take some time to complete.

7. In the Response Screening report, open the Robust FDR LogWorth by Effect Size report.

The detail in the plot is difficult to see, because of the huge Robust FDR LogWorth value of about 58,000. To ensure that your graphs show sufficient detail, you can set a maximum value of the LogWorth.

Figure 22.12 Robust FDR LogWorth vs. Effect Size, MaxLogWorth Not Set
8. Repeat step 1 through step 5.
9. Type 1000 in the MaxLogWorth box at the bottom of the launch window.
10. Click **OK**.
    The analysis might take some time to complete.
11. In the Response Screening report, open the Robust FDR LogWorth by Effect Size report.
    Now the detail in the plot is apparent.

**Figure 22.13** Robust FDR LogWorth vs. Effect Size, MaxLogWorth = 1000

---

**Example of Robust Fit**

1. Select **Help > Sample Data Library** and open Drosophila Aging.jmp.
2. Select **Analyze > Screening > Response Screening**.
3. Select all of the continuous columns and click **Y, Response**.
4. Select line and click **X**.
5. Check **Robust**.
6. Click **OK**.
Figure 22.14 Robust FDR PValue Plot for Drosophila Data

Note that a number of tests are significant using the unadjusted robust p-values, as indicated by the red points that are less than 0.05. However, only two tests are significant according to the robust FDR p-values. These two points are more easily identified in a plot that shows FDR LogWorths.

7. Click the Robust FDR LogWorth by Effect Size disclosure icon.
8. Drag a rectangle around the point with a Robust FDR LogWorth value that exceeds 1.5.
9. In the graph, right click and select Row Label.

Figure 22.15 Robust LogWorth by Effect Size for Drosophila Data
Points above the red line at 2 have significance levels below 0.01 (-log_{10}(0.01) = 2). A horizontal line at about 1.3 corresponds to a 0.05 significance level.

10. Click the Robust LogWorth by LogWorth disclosure icon.

*Figure 22.16* Robust LogWorth by LogWorth for Drosophila Data

If the robust test for a response were identical to the usual test, its corresponding point would fall on the diagonal line in Figure 22.16. The circled point in the plot does not fall near the line, because it has a Robust LogWorth value that exceeds its LogWorth value.

11. Drag a rectangle around this point in the plot.

12. Find the row for this point in the Result table.

   Note that the response, log2in_CG8237 has PValue 0.9568 and Robust PValue 0.0176.

13. Click the Response Screening red triangle and select **Fit Selected Items**.

   A Fit Selected Items report is displayed containing a Oneway Analysis for the response log2in_CG8237. The plot shows two outliers for the ORE line (Figure 22.17). These outliers indicate why the robust test and the usual test give disparate results. The outliers inflate the error variance for the non-robust test, which makes it more difficult to see a significant effect. In contrast, the robust fit down-weights these outliers, thereby reducing their contribution to the error variance.
Response Screening Personality

The Response Screening personality in Fit Model enables you to study tests of multiple responses against linear model effects.

2. Select Analyze > Fit Model.
3. Select all the continuous columns and click Y.
4. Select channel and click Add.
5. Select sex, line, and age and select Macros > Full Factorial.
6. Select Response Screening from the Personality list.
7. Click Run.

The Fit Response Screening report appears. Two data tables are also presented: Y Fits summarizes the overall model tests, and PValues tests the individual effects in the model for each Y.

To get a general idea of which effects are important, do the following:

8. Run the FDR LogWorth by Rank Fraction script in the PValues data table.
9. Select Rows > Data Filter.
10. In the Data Filter window, select Effect and click Add.
11. In the Data Filter, click through the list of the model effects while you view the selected points in the FDR LogWorth by Rank Fraction plot.
Keep in mind that values of LogWorth that exceed 2 are significant at the 0.01 level. The Data Filter helps you see that, with the exception of sex and channel, the model effects are rarely significant at the 0.01 level. Figure 22.18 shows a reference line at 2. The points for tests of the line*age interaction effect are selected. None of these are significant at the 0.01 level.

Figure 22.18  FDR LogWorth vs Rank Fraction Plot with line*age Tests Selected

Statistical Details for the Response Screening Platform

The False Discovery Rate

All of the Response Screening plots involve p-values for tests conducted using the FDR technique described in Benjamini and Hochberg (1995). See also Westfall et al. (2011). This method assumes that the p-values are independent and uniformly distributed.

JMP uses the following procedure to control the false discovery rate at level $\alpha$:

1. Conduct the $m$ hypothesis tests of interest to obtain p-values $p_1, p_2, \ldots, p_m$.
2. Rank the p-values from smallest to largest. Denote these by $p(1) \leq p(2) \leq \ldots \leq p(m)$. 
3. Find the largest \( p \)-value for which \( p(i) \leq \frac{i}{m} \alpha \). Suppose this first \( p \)-value is the \( k \)th largest, \( p(k) \).

4. Reject the \( k \) hypotheses associated with \( p \)-values less than or equal to \( p(k) \).

This procedure ensures that the false discovery rate does not exceed \( \alpha \).

The \( p \)-values adjusted for the false discovery rate, denoted \( p(i), FDR \), are computed as follows:

\[
p(i, FDR) = \begin{cases} 
p(m) & \text{for } i = m \\
\min \left[ p(i+1, FDR), \frac{m}{i} p(i) \right] & \text{for } i = m - 1, \ldots, 1
\end{cases}
\]

If a hypothesis has an FDR-adjusted \( p \)-value that falls below \( \alpha \), then it is rejected by the procedure.
Use the Process Screening platform for exploring a large number of processes across time. The platform calculates process stability and process capability metrics. The platform creates control charts and detects large process shifts. The platform is intended to expedite the evaluation of a very large number of processes by enabling you to quickly focus on the processes that are unstable, not capable of meeting specification limits, or subject to shifts in the mean.

Based on your initial results, you can choose to explore specific processes graphically or in greater analytical depth. You can easily access the Control Chart Builder and Process Capability platforms. You can save detailed results for all of your processes or for specific processes.

Overview of the Process Screening Platform

The Process Screening platform facilitates the task of assessing data from a large number of processes for stability and capability. The results are largely based on control chart calculations to determine when a process is out of control. The Process Screening platform enables you to do the following:

- Specify a constant subgroup size or use a variable containing subgroup identifiers for control chart calculations using subgroups.
- Use grouping variables. For each combination of values of the group variables, an analysis is provided for each process variable.
- Use medians to make your centerline and sigma calculations robust to outliers.
- Obtain information about the location of large shifts in the mean of your processes.

You can customize the Summary report to show specific control chart tests, including tests for changes in process mean and spread. The report also provides capability information when you supply specification limits. The Process Performance Graph gives you a visual representation of the performance of your processes in terms of stability and capability. The Shift Graph shows locations of upshifts and downshifts.

Tip: For information about adding specification limits, see Using JMP.

Process Screening makes it easy to select specific processes for further analysis. The platform provides small run charts for these processes - the size of the plots makes it easy for you to view a substantial number at a time. You can also link to Control Chart Builder and the Process Capability platform for analyses of select processes.

You can save data tables containing results in various forms, either for your entire set of processes or only for select processes.

Example of Process Screening

The Semiconductor Capability.jmp sample data table contains 128 columns of process measurements. Each column contains 1,455 measurements. You are interested in identifying unstable processes. Also, each column contains a Spec Limits column property. If a process is stable, it is appropriate to calculate its process capability. You proceed to assess both stability and capability for this data table.

1. Select Help > Sample Data Library and open Semiconductor Capability.jmp.
2. Select Analyze > Screening > Process Screening.
3. Select the Processes column group and click Process Variables.
Notice that the Control Chart Type is set to Indiv and MR.

4. Click OK.

**Figure 23.2** Partial View of Initial Report

The Process Screening window appears, showing a table of results for each process. The table is sorted by Stability Index. This is a measure of the stability of a process, where a stable process has a stability index near 1. Higher values of the stability index indicate a less stable process. (The sorting is indicated by the caret beside Stability Index in the report.) You want to take a closer look at processes with a stability index value greater than or equal to 1.03.

5. In the report window, select processes PMS1 through IVP9.

Each of these first 11 processes has a value of 1.03 or larger in the Stability Index column.

6. Right-click the selected processes and select **Quick Graph for Selected Items**.

**Figure 23.3** Quick Graphs for Highest Alarm Rate Processes

You decide to take a closer look at IVP8 (row 3, column 1 in the Graphs of Selected Items).
7. Select the second process in the Summary table, which corresponds to IVP8.
8. Right-click the selected process and select Control Charts for Selected Items.

**Figure 23.4** Control Chart Builder Report for IVP8

A Control Chart Builder report appears. Because IVP8 has a Spec Limits column property, the report also includes a capability analysis.
Launch the Process Screening Platform

Launch the Process Screening platform by selecting Analyze > Screening > Process Screening.

**Figure 23.5** Process Screening Launch Window

For more information about the options in the Select Columns red triangle menu, see Using JMP.

**Launch Window Roles**

**Process Variables**  The columns of process data containing the measurements to be analyzed. The columns must have a Numeric data type. If a process variable has a Control Limits column property, the Process Screening platform uses those limits to calculate the Specified Sigma.

*Note:* The platform does not support control limits that are specified in a Control Limits column property for dispersion (R) charts.

**Grouping**  Columns assigned as grouping variables. Each process variable is analyzed at each combination of levels of the grouping variables. The results are presented in a single report.
**Subgroup** A column whose values assign a subgroup identifier to each row. The process data are sorted by the Subgroup variable before calculations are performed.

**Time** A numeric column whose values are used for the time order for the data. Use the Time role for data that are time-stamped. The time stamp is used for the time axis in quick graphs and shift graphs. The process data are sorted by the Time variable before calculations are performed.

**By** A column whose levels define separate analyses. For each level of the specified column, the corresponding rows are analyzed using the other variables that you have specified. The results are presented in separate tables and reports. If more than one By variable is assigned, a separate analysis is produced for each possible combination of the levels of the By variables.

**Launch Window Options**

**Control Chart Type** Select one of five control chart types: Indiv and MR (Individual Measurement and Moving Range); XBar and R; XBar and S; XBar, MR, and R; or XBar, MR, and S. The XBar, MR, and R control chart and the XBar, MR, and S control chart are also referred to as three way control charts. For more information about statistical details, see *Quality and Process Methods*.

*Note:* The three way control charts are available only when the subgroup sizes are bigger than 1. If a three way control chart is selected and the subgroup sizes are 1, an error message appears.

*Note:* If the subgroup size for a process is 1, the chart automatically switches to an Indiv and MR chart.

**Subgroup Sample Size** Specifies a constant sample size for subgroups. The minimum subgroup size is 2. A subgroup size of 5 is the default. The Subgroup Sample Size specification is ignored for Indiv and MR charts or when a subgroup variable is specified.

**KSigma** Specifies the sigma multiplier. KSigma is the value that is multiplied by sigma in the calculation of control limits. By default, KSigma is 3.

**Use Limits Table** Enables you to import historical control limits and specification limits from a data table. When you select this option and click OK in the launch window, a Choose limits table window appears. Once you choose a limits table and click OK, a Limits Specification window appears. Assign columns in your limits table to appropriate roles and click OK. See “Limits Table” on page 485.
**Note:** If you do not select this option, limits are obtained from the Control Limit and Specification Limit column properties for the Process Variables. If you do not select this option and the Process Variables do not have control limit column properties, the control limits are calculated from the data.

**Use Medians instead of Means** Estimates the center line using the median of the observations. Sigma is estimated using scaling factors obtained using Monte Carlo simulation. The table of factors is given in “Statistical Details for the Process Screening Platform” on page 501. The calculation depends on the type of chart selected:

- For XBar and R chart or Indiv and MR chart calculations, sigma is estimated using the scaled median of the ranges.
- For XBar and S chart calculations, sigma is estimated using the scaled median of the standard deviations.
- For unequal subgroup sizes, the scaling factor corresponds to the average subgroup size rounded to the nearest integer.

When one or more outliers influence the location of the center line, many subgroups can appear out of control. Using the median alleviates this problem.

**Note:** When Use Medians instead of Means is selected, the results obtained from the Control Charts for Selected Items or the Process Capability for Selected Items red triangle menu options do not match the Process Screening results.

**Advanced Options** Contains the following options:

**Shift Threshold** Specify a value that controls the sensitivity of the Shift Graph. Shift Threshold is set to three by default. After outlier removal, the Shift Graph shows a plot of the time occurrence of all process shifts that exceed the number of within-sigma units specified by the Shift Threshold. See “Shift Graph” on page 494.

**Outlier Threshold** Specify a value that controls the sensitivity of outlier removal for detection of large recent shifts and for the Shift Graph. Outlier Threshold is set to five by default. If the number of within sigma units from an observation to both of its neighboring observations exceeds the specified Outlier Threshold, that observation is replaced with a value that is one within-sigma unit away from its closest neighboring observation. See “Shift Magnitudes and Positions” on page 491.

**Shift Lambda** Enables you to change the exponentially weighted moving average (EWMA) weight used in the Shift Graph. See “Shift Magnitudes and Positions” on page 491.

**Drift Beta** The weight used in the exponentially weighted moving average (EWMA) for drift detection. Drift Beta is set to 0.05 by default.
Minimum Process Length  The minimum number of data values that a process must have in order to be included in the analysis. By default, this value is set to 3.

Limits Table

A Limits Table contains a row for each process defined by the Process Variables and Grouping variables in your table of process data. When you use a Limits Table, the Limits Specifications window enables you to specify variables with the roles listed below. You do not need to specify variables for all of these roles. All of these roles are optional.

Figure 23.6  Limits Specifications Window

Columns in the Limits Table that have appropriate names or names that match the role buttons are auto-filled. For example, any column called “Process”, “Column”, or “Parameter” is auto-filled into the Process Variables list.

If you have control limits but do not have columns for Center or Sigma, then you can use the Derived Sigma options.

Process Variables  A column that contains values corresponding to the column names in your table of process data.
**Grouping**  One or more columns that contain the values of the grouping variables for your table of process data.

**Center**  A column containing values for the center line for each process. This is usually the historical process mean.

**Sigma**  A column containing values for the within standard deviation for each process. This is usually the historical standard deviation.

**Derived Sigma**  Calculates sigma based on the given control limits and subgroup size. The derived sigma is calculated as follows:

\[ \text{Sigma} = d \times \frac{\text{UCL} - \text{LCL}}{6} \]

where \( d \) is the square root of the subgroup size.

**LCL**  A column containing the lower control limits for each process.

**UCL**  A column containing the upper control limits for each process.

**Subgroup Size**  A column containing the subgroup size for each process.

**LSL**  A column containing lower specification limits for each process.

**USL**  A column containing upper specification limits for each process.

**Target**  A column containing a target value for each process.

**Importance**  A column containing an importance value for each process. The Importance column provides a mechanism to sort processes in the order that you prefer.

---

**The Process Screening Report**

The Process Screening report opens with a Summary table that contains results about process stability. There is a label above the summary table that shows the type of control chart on which the results are based. The sample size or subgroup variable is also shown above the summary table for every chart type except for Indiv and MR. The summary table also contains capability results if you have provided specification limits. The processes and groups are initially sorted in decreasing order by Stability Index. If Importance values are specified by the user, the processes and groups are sorted in decreasing order by Stability Index within Importance. The columns for Stability Index, Ppk, Cpk, Cp, and Target Index are colored as green, yellow, and red to indicate adequate, marginal, and poor stability or capability, respectively. This color coding scheme matches the Process Performance graph color coding scheme.
Tip: To sort the report by a column, click the column name. A caret appears to the right of the column name. The direction of the caret indicates whether the sorting is descending or ascending. To change the order of the sorting, click the column name again.

The control chart calculations in the Summary table include Nelson tests and a Range Limit Exceeded test. These tests assume the following about the control chart limits:

- The center line for the XBar or X control charts is given by the mean of all measurements. If you use the Medians instead of Means option, the center line is given by the median of the observations.
- Control limits are placed at $K$ sigma units from the center line. Use the KSigma option in the launch window to specify $K$. By default, KSigma is 3.
- Sigma is estimated using the conventions that correspond to the control chart type that you specified or, if you use Medians instead of Means, as described in “Use Medians instead of Means” on page 484.

Tip: The eight Nelson tests in the Process Screening platform follow the test settings in the Control Chart Builder platform preferences. You can customize the tests at File > Preferences > Platforms > Control Chart Builder.

The Summary table can contain the following information:

**Column**  The columns that you entered as Process. There is a row for each distinct combination of Process and Grouping columns. This column is suppressed if there is only one process column.

Tip: To access options that operate on selected items, right-click the **Column** column.

**Grouping Columns**  There is a report column for each column in the data table that you entered as Grouping. The levels of the Grouping columns are listed so that there is a unique row in the report table for each distinct combination of Process name and Grouping columns values.

**Importance**  (Appears only when there are importance values specified by the user, as inputs from a limits table.) The user-specified importance value for the processes.

**Variability**  Contains the following columns:

- **Stability Index**  A measure of stability of the process. A stable process has a stability index near one. Higher values indicate less stability. The stability index is defined as follows:

  $\frac{(\text{Overall Sigma} / \text{Within Sigma})}{\text{(Overall Sigma / Within Sigma)}}$

  If a three way control chart is selected in the launch, the stability index is defined as follows:
Stability Ratio  A measure of stability of the process. A stable process has a stability ratio near one. Higher values indicate less stability. The stability ratio is defined as follows:

\[(\text{Overall Sigma} / \text{Within Sigma})^2\]

If a three way control chart is selected in the launch, the stability ratio is defined as follows:

\[(\text{Overall Sigma} / \text{Between-and-Within Sigma})^2\]

Within Sigma  An estimate of the standard deviation based on within subgroup variation. The estimate is based on the control chart type that you specified, and is a short-term measure of variation. See Quality and Process Methods for statistical details. If you select Medians instead of Means, Within Sigma is computed as described in “Use Medians instead of Means” on page 484.

Overall Sigma  The usual estimate of standard deviation based on all observations.

Between Sigma  (Appears only when three way control chart is selected in the launch window.) An estimate of the standard deviation based on the variation between subgroups. See Quality and Process Methods for statistical details.

Between-and-Within Sigma  (Appears only when three way control chart is selected in the launch window.) An estimate of the standard deviation based on the variation between subgroups and the variation within subgroups. The Between-and-Within Sigma estimate is defined as follows:

\[\text{Between-and-Within Sigma} = \sqrt{\text{Within Sigma}^2 + \text{Between Sigma}^2}\]

Specified Sigma  The standard deviation specified by a sigma control limit in the Limits Specification dialog or an estimate of the standard deviation derived from the control limits and subgroup size. See “Derived Sigma” on page 486. The control limits and subgroup size can be specified using a limits table or a Control Limits column property.

Summary  Contains the following columns:

Centerline  (Appears if you do one of the following: select Use Medians instead of Means in the launch window, import a Center value using a limits table, or import control limits to derive sigma.) The value listed under Centerline is used in control chart calculations as the center line.

- If you select Use Medians instead of Means in the launch window, the overall median of the observations is displayed.
- If you import a Center value from a limits table, that value is displayed.
- If you import control limits, the value displayed is calculated as \((\text{UCL} + \text{LCL})/2\).
Mean  The average of all observations.
Count  The number of observations.
Subgroups  The number of subgroups.

Control Chart Alarms  Contains information about the subgroups that result in alarms for a variety of tests, including each of the 8 Western Electric rules. The standard deviation estimate is the Within Sigma value. By default, only the Alarm Rate, Test 1, and Latest Alarm columns are shown in the Summary table.

Alarm Rate  The number of subgroups that resulted in alarms for any of the tests selected under the Choose Test option (Any Alarm) divided by the number of non-missing subgroups (Subgroups).

Any Alarm  (Appears only when more than one Test column is shown.) The number of subgroups that trigger alarms for any of the tests selected under the Choose Test option. These are the eight Nelson tests and the test for Range Limit Exceeded.

Tip: The eight Nelson tests in the Process Screening platform follow the test settings in the Control Chart Builder platform preferences. You can customize the tests at File > Preferences > Platforms > Control Chart Builder.

Test 1  One point is more than three standard deviations from the center line. The subgroup associated with that point triggers the alarm.
Test 2  Nine or more consecutive points are on the same side of the center line. The subgroup associated with the ninth point triggers the alarm.
Test 3  Six or more consecutive points are continually increasing or decreasing. The subgroup associated with the sixth point triggers the alarm.
Test 4  Fourteen consecutive points alternate in direction: increasing and then decreasing or decreasing and then increasing. The subgroup associated with the 14th point triggers the alarm.
Test 5  Two out of three consecutive points on the same side of the center line are more than two standard deviations from the center line. The subgroup associated with the second point that exceeds two standard deviations triggers the alarm.
Test 6  Four out of five consecutive points on the same side of the center line are more than one standard deviation from the center line. The subgroup associated with the fourth point that exceeds one standard deviation triggers the alarm.
Test 7  Fifteen consecutive points, on either side of the center line, are all within one standard deviation of the center line. The subgroup associated with the 15th point triggers the alarm.
**Test 8**  Eight consecutive points, on either side of the center line, all fall beyond one standard deviation of the center line. The subgroup associated with the eighth point triggers the alarm.

**Range Limit Exceeded**  The number of subgroups that exceed the upper control limit on the R, S, or MR chart calculation.

**Moving Range Limit Exceeded**  The number of subgroups that exceed the moving range limit on the three way control chart calculation.

**Latest Alarm**  The position of the subgroup, counting from the last subgroup, that signaled the most recent alarm for any of the Nelson or Range Limit Exceeded tests.

**Capability**  (Appears only when there are Spec Limits specified for some processes.) Contains the following options:

**Ppk**  Capability index based on Overall Sigma and assuming a normal distribution. See *Quality and Process Methods* for statistical details. On by default.

**Cpk**  Capability index based on Within Sigma or Between-and-Within Sigma and assuming a normal distribution. See *Quality and Process Methods* for statistical details. On by default.

**Cp**  The potential capability if target and drift issues are resolved. See *Quality and Process Methods* for details.

**Target Index**  The number of short-term standard deviations that the process average differs from the target value. This measures the ability of the process to hit the target value. The Target Index is calculated as $3(Cp - Cpk)$. A target index is considered poor if above 1, marginal if between 0.5 and 1, and adequate if less than 0.5. See White et al. (2018).

**Out of Spec Count**  The number of observations that fall outside the specification limits. On by default.

**Out of Spec Rate**  The proportion of observations that fall outside the specification limits. On by default.

**Expected Out of Spec Rate**  The expected proportion of observations that fall outside of the specification limits. The Expected Out of Spec Rate assumes a stable and normally distributed process and uses overall sigma.

**Latest Out of Spec**  The number of observations, counting from the last observation to the most recent observation that falls outside the specification limits. On by default.

**(Mean-Tgt)/SpecRange**  The spec centered mean. This is the same as the Mean Shift Standardized to Spec in Process Capability. See *Quality and Process Methods* for statistical details.
**StdDev/SpecRange**  The spec scaled standard deviation. This is the same as the Std Deviation Standardized to Spec in Process Capability. See *Quality and Process Methods* for statistical details.

**LSL**  The lower specification limits.

**USL**  The upper specification limits.

**Target**  The target value.

**Shift Magnitudes and Positions**  (Shown only if you have selected a Shift Detection option from the Process Screening red triangle menu.) Shift detection is performed to identify shifts that exceed one within-sigma unit. The algorithm uses outlier-correction and an EWMA smoothing approach for the individual observations. This is the algorithm:

- Outliers are removed so that single outliers do not indicate shifts. The value specified as Outlier Threshold (five by default) on the launch window controls the sensitivity of outlier removal. If the number of within-sigma units from an observation to both of its neighboring observations exceeds the specified Outlier Threshold, that observation is replaced with a value that is one within-sigma unit away from its closest neighboring observation.

- An EWMA fit is constructed for the subgroup means in forward time order and another EWMA fit is constructed for the subgroup means in reverse time order. The EWMA fits have lambda equal to 0.3.

- The largest positive and negative differences between successive EWMA values that exceed one within-sigma unit are identified.

- The absolute values of these differences, divided by the within estimate of sigma, are the values reported as Largest Upshift and Largest Downshift.

- The locations of the first subgroups involved in these largest shifts define the Upshift Position and Downshift Position.

**Largest Upshift**  The magnitude of the largest upward shift that exceeds one within-sigma unit, reported in within-sigma units.

**Upshift Position or Upshift <Time Variable>**  The position of the subgroup having the largest Upshift. If you specify a Time variable, the column in the Summary table is named Upshift <Time Variable> and the position of the shift is given in terms of the Time variable.

**Largest Downshift**  The magnitude of the largest downward shift that exceeds one within-sigma unit, reported in within-sigma units.
**Downshift Position or Downshift <Time Variable>**  The position of the subgroup having the largest Downshift. If you specify a Time variable, the column in the Summary table is named Downshift <Time Variable> and the position of the shift is given in terms of the Time variable.

**Drift Magnitudes and Positions**  (Shown only if you have selected the Drift Summaries option from the Process Screening red triangle menu.) Drift detection is performed to detect smaller, more gradual changes in processes. The algorithm is identical to the one used in shift detection, except that drift detection uses a Holt Double-Exponential Smoother instead of an EWMA. This is the algorithm:

- Outliers are removed through the same process that is used in shift detection. See “Shift Magnitudes and Positions” on page 491.
- The drift detection algorithm fits a Holt Double-Exponential Smoothing model for the subgroup means in forward time order and fits another Holt Double-Exponential Smoothing model for the subgroup means in reverse time order. The two smoothing model fits each have two smoothing constants: $\alpha$ for the level and $\beta$ for the slope. The $\beta$ smoothing constant is set at 0.05 and the $\alpha$ smoothing constant is estimated to minimize the error.
- The means of the positive drift values, negative drift values, and absolute drift values are reported as Mean Up Drift, Mean Down Drift, and Mean Abs Drift, respectively.

**Mean Up Drift**  The sum of the positive drift values divided by the count.

**Mean Down Drift**  The sum of the negative drift values divided by the count.

**Mean Abs Drift**  The sum of the absolute value of all drift values divided by the count.

---

**Process Screening Platform Options**

The Process Screening red triangle menu contains options to customize the display and to save calculated statistics. The options that operate on selected items are also accessible by right-clicking the **Column** column in the Summary table.

**Summary**  Shows or hides the Summary table. See “The Process Screening Report” on page 486.

**Find and Select**  Enter search strings for columns that you entered as Process Variables or Grouping in the launch window. A panel appears for each column. The corresponding processes are selected in the Summary table.

**Select Where**  Opens the Select Where window. You can select specific processes in the Summary table that correspond to a particular condition by using the Comparison menu.
and Value text box. For example, you can select all processes such that \( Ppk < 1.33 \). After you click OK, the processes are selected in the Summary table.

**Tip:** You can also access the Select Where window by right-clicking anywhere in the Summary table.

**Show Summary Columns** Enables you to choose some of the summary columns that are shown in the Summary table.

**Quick Graph for Selected Items** Plots small graphs of the processes that you select in the Summary table in a Graphs of Selected Items report. The report makes it possible to view and compare many processes at once. The plots are ordered according to their order of entry on the launch window. Each quick graph also has lines for the spec limits. There is a solid blue line for the target value and dotted blue lines for the LSL and USL values. To remove the quick graphs, click the Graphs of Selected Items red triangle and select Remove.

**Tip:** To change the layout of the quick graphs, click the Graphs of Selected Items red triangle and select Number of Plots Across.

**Control Charts for Selected Items** Opens a Control Chart Builder report window for the processes that you selected in the Summary table. The control chart corresponds to your selections in the Process Screening launch window.

**Note:** Only the tests selected in Process Screening are sent to Control Chart Builder. Tests that have been turned off are not sent.

**Process Capability for Selected Items** Opens a Process Capability report window showing Individual Detail Reports for the processes that you select in the Summary table. If you select a process for which specification limits are not specified, a Spec Limits window appears. In this window, you can specify specification limits by selecting a data table or entering values directly.

The Process Capability analysis assumes normal distributions and uses within sigma values that correspond to your Control Chart Type selection in the Process Screening launch window:

- Moving range for Indiv and MR
- Average of ranges for XBar and R
- Average of unbiased standard deviations for XBar and S
**Note:** If you specify sigma using a sigma control limit or the Derived Sigma option in the Limits Specifications window, this value is not used in Process Capability. This is because the Process Screening and Process Capability platforms use these control limits differently.

**Color Selected Items**  Applies a color of your choosing to the values in the selected rows of the Summary table.

**Remove Selected Items**  Removes the rows selected in the Summary table and reruns the analysis without those processes.

**Show Tests**  Shows or hides test results for Nelson tests that are selected under the Choose Tests option in the Process Screening report’s summary table.

**Choose Tests**  Enables you to choose the tests that you want to include in the calculation of Alarm Rate and Any Alarm.

**Tip:** To select multiple tests, press Alt and click the Process Screening red triangle to open a menu of all platform options.

**Shift Detection**  Provides options for detecting shifts after outlier removal. See “Shift Magnitudes and Positions” on page 491.

**Largest Upshift**  Adds columns for Largest Upshift and Upshift Position to the Summary table. The largest upward shift in the series that exceeds one within-sigma unit is identified. See “Shift Magnitudes and Positions” on page 491.

**Largest Downshift**  Adds columns for Largest Downshift and Downshift Position to the Summary table. The largest downward shift in the series that exceeds one within-sigma unit is identified. See “Shift Magnitudes and Positions” on page 491.

**Shift Graph**  (Available only when some processes have shifts that exceed the Shift Threshold.) Shows a plot of the time occurrence of all process shifts that exceed the number of within-sigma units specified by the Shift Threshold (three by default). You can also change the Shift Threshold by using the slider bar on the Shift Graph. Hover over the diamond to see the value. Green markers indicate upshifts and red markers indicate downshifts. The markers are located at the local peaks of the shifts.

To identify the processes that correspond to one or more shift occurrences, select the points and click Select Process. The corresponding processes are selected in the Summary table. Processes that have no shifts exceeding the Shift Threshold number of within-sigma units are not plotted.
**Note:** The Shift Graph does not show the positions of Largest Upshift and Largest Downshift values that appear in the Summary table if the shifts are less than the specified Shift Threshold number of within-sigma units in magnitude. See “Additional Example of Process Screening” on page 499.

**Show Shifts in Quick Graphs**  (Available only when a Quick Graph has been added to the report window.) Shows the location of the shifts in the Quick Graphs using green and red vertical lines.

**Drift Summaries**  Adds columns for Mean Up Drift, Mean Down Drift, and Mean Abs Drift to the Summary Table. See “Drift Magnitudes and Positions” on page 492.

**Drift Graph Selected**  Displays a drift graph for each process that you select in the Summary Table. Drift graphs enable you to detect smaller, more gradual changes in the selected processes. The values plotted are the slope estimates from a Holt Double-Exponential Smoothing model. See “Drift Magnitudes and Positions” on page 492. Each drift graph displays the within-sigma value and the estimates for the two smoothing parameters in the Holt Double-Exponential Smoothing model.

**Process Performance Graph**  (Available only when specification limits are defined for at least one process variable.) Shows a four-quadrant graph that assesses the performance of processes in terms of stability and capability. See “Process Performance Graph” on page 498.

**Process Performance Graph Boundaries**  (Available only once the Process Performance Graph is in the report window.) Opens a window where you can set values for the Process Performance Graph’s stability index and Ppk capability boundaries.

**Tip:** You can set preferences for your desired boundaries for Stability Index and Ppk Capability in File > Preferences > Platforms > Process Screening.

**Goal Plot**  (Available only when specification limits are defined for at least one process variable.) The Goal Plot shows, for each variable, the spec-normalized mean shift on the X axis, and the spec-normalized standard deviation on the Y axis. If you define importance values for the processes, the goal plot points are sized by importance. It is useful for getting a quick, summary view of how the variables are conforming to specification limits. See *Quality and Process Methods* for more information about goal plots and their features.

**Tip:** Hover over a point in the Goal Plot to view the Quick Graph for that process. Click the Quick Graph to add it to the report window.

The Goal Plot red triangle menu contains the following options:

**Show Within Sigma Points**  Shows or hides the points calculated using the within sigma estimate.
Show Within or Between-and-Within Sigma Points  (Available only when three way control chart is selected in the launch window.) Shows or hides the points calculated using the between-and-within sigma estimate.

Show Overall Sigma Points  Shows or hides the points calculated using the overall sigma estimate.

Shade Levels  Shows or hides the Ppk level shading. This is turned on by default. The shaded areas depend on the relationship between $p$ and Ppk, with $p$ representing the value shown in the box beneath Ppk. By default, $p = 1.33$.

- Points in the red area have $Ppk < p$.
- Points in the yellow area have $p < Ppk < 2p$.
- Points in the green area have $2p < Ppk$.

Label Within Sigma Points  Shows or hides labels for points calculated using the within sigma estimate.

Label Within or Between-and-Within Sigma Points  (Available only when a three way control chart is selected in the launch window.) Shows or hides labels for points calculated using the between-and-within sigma estimate.

Label Overall Sigma Points  Shows or hides labels for points calculated using the overall sigma estimate.

Defect Rate Contour  Shows or hides a contour representing a specified defect rate.

Show Capability  (Available only when specification limits are defined for at least one process variable.) Displays a submenu that enables you to show or hide the Capabilities in the Summary table.

Note: Spec Centered Mean and Spec Scaled Std Dev are displayed in the Summary table as (Mean-Tgt)/SpecRange and StdDev/SpecRange. The Spec Limits option displays the LSL, USL, and Target columns in the Summary table.

The following option is also available in the submenu:

Color Out of Spec Values  Colors the cells in the data table that correspond to values that are out of spec. The cell is colored blue if the value is above the USL and red if the value is below the LSL.

Tip: To remove colors in specific cells, select all cells of interest. Right-click in one of the cells and select Clear Color. To remove colors in all cells, deselect Color Out of Spec Values.

Save Summary Table  Saves all of the information that can appear in the Summary table to a Process Summary data table. The Process Summary data table also contains specification
limit details, if these are specified for at least one process. As in the summary table, the columns for Stability Index, Ppk, Cpk, Cp, and Target Index are colored as green, yellow, and red to indicate adequate, marginal, and poor stability or capability, respectively.

**Save Summary Table with Graphs**  Creates the Process Summary data table with an additional column titled Graph. The Graph column contains a quick graph for each process in the Process Summary table.

**Save Details Table**  Saves detailed information about control chart calculations to a Process Details data table. For each combination of process and grouping variables, the table contains a row for each subgroup showing:

- The values of the subgroup sample statistics.
- The control limits.
- The subgroup size.
- A list of indicators for which, if any, alarms were triggered. Alarms for the Nelson tests are indicated with the numbers for the tests. An alarm for the Range Limit Exceeded test is indicated with an R.
- The Drift

**Save Selected Details**  For the selected rows in the Summary table, saves a Process Details table with the information that is saved when you select Save Details Table.

See *Using JMP* for more information about the following options:

**Local Data Filter**  Shows or hides the local data filter that enables you to filter the data used in a specific report.

**Redo**  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

**Save Script**  Contains options that enable you to save a script that reproduces the report to several destinations.

**Save By-Group Script**  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.
Process Performance Graph

The Process Performance Graph is a four-quadrant plot of capability versus stability. Each process for which specification limits are provided is represented by a marker. The marker type depends on if the process violates guidelines for the Target Index and Cp values. A left-pointing triangle indicates the process is below target, a circle indicates the process is on target, and a right-pointing triangle indicates the process is above target. An open marker indicates that the variation of the process is adequate and a filled marker indicates that the variation of the process could be reduced. A complete description of the marker combinations is provided in Table 23.1. Additionally, if you define importance values for the processes, the markers on the Process Performance Graph are sized by importance.

<table>

</tbody>
</table>

On the graph, the horizontal coordinate represents the stability index of the process and the vertical coordinates represent the capability of the process, given as Ppk. The graph is divided into four quadrants based on the following default boundaries:
- A stability index that exceeds 1.25 indicates that the process is unstable.
- A Ppk that is smaller than 1.33 indicates that the process is not capable.

Additionally, there is a red line on the graph at 1.33 divided by Stability Index that indicates where the Cpk value is 1.33. This line categorizes the processes in the unstable and incapable quadrants in terms of how they might be fixed. Processes below the red line are fixable by special causes; processes above the red line are fixable by reducing variability. Selecting points in the graph selects the corresponding processes in the Summary table.
Chapter 23
Predictive and Specialized Modeling

Process Screening

### Additional Example of Process Screening

This example illustrates the use of a Grouping column and the construction of a Shift Graph using Consumer Prices.jmp.

The consumer price index data table contains monthly data on 17 products. The time periods vary by product. The data are arranged so that all 17 products are listed in a single column called Series. To separate the products, you must treat Series as a Grouping column.

1. Select Help > Sample Data Library and open Consumer Prices.jmp.
2. Select Analyze > Screening > Process Screening.
4. Select Series and click Grouping.
   This ensures that each level of Series is treated as a separate process.
5. Select Date and click Time.
6. Set the Control Chart Type to XBar and R.
7. Set the Subgroup Sample Size to 3.
   Because the data are given monthly, subgroups of size three represent quarters.
8. Click OK.
9. Press Alt and click the red triangle next to Process Screening.
   This opens a window showing the available red triangle options. You can select multiple options at once in this window.
10. Check the following: Largest Upshift, Largest Downshift, and Shift Graph.
11. Click OK.

The columns Largest Upshift, Upshift Date, Largest Downshift, and Downshift Date are added to the Summary table. The shifts are the largest shifts exceeding one within-sigma unit. The position of each shift is given in terms of the Time variable, Date. See “Shift Magnitudes and Positions” on page 491.

A Shift Graph also appears. The Shift Graph shows all shifts that exceed the number of Shift Threshold within-sigma units, which is set to three by default. See “Shift Graph” on page 494. Green points correspond to upshifts and red points correspond to downshifts. Notice that Gasoline, All has values for both Largest Upshift and Largest Downshift in the Summary table. The Largest Downshift value, 1.8296, is less than three. Because the Shift
Graph shows shifts of only three or more within-sigma units, the Largest Downshift value for Gasoline, All is not plotted on the Shift Graph.

Also notice that Tomatoes is not included on the Shift Graph. For Tomatoes, no shifts of three or more within-sigma units were found.

12. Double-click the horizontal axis of the Shift Graph to open the X Axis Settings window.
13. In the Tick/Bin Increment panel, set # Minor Ticks to 1.
15. Click OK.

**Figure 23.7** Shift Graph

Most series show primarily upshifts. Price Coffee, however, has several alternating downshifts and upshifts. To better understand this series, obtain a control chart.

16. Select any point to the right of Price Coffee in the Shift Graph and click Select Process.
   
   This action selects the row of the Summary table corresponding to Coffee.
17. Right-click the selected process in the Summary table and select Control Charts for Selected Items.
Figure 23.8 Control Chart for Coffee

The control chart shows the upshifts and downshifts that are identified in the Shift Graph. The Summary table indicates that the largest upshift (25.399 within-sigma units) occurs for the subgroup that includes September 1994. In the control chart in Figure 23.8, this is the subgroup in position 59. The Summary table also indicates that the largest downshift (9.1674 within-sigma units) occurs for the subgroup that includes March 1981. This is the subgroup in position 5 in the control chart.

Because shifts are calculated using EWMA-smoothed series and an outlier-correction algorithm, the shift positions might not precisely correspond to the subgroups that seem to start the shifts on a Shewhart control chart.

Statistical Details for the Process Screening Platform

Scaling Factors for Using Medians to Estimate Sigma

When you select Use Medians instead of Means, sigma is estimated using a scaled median range or median standard deviation. The table below gives the scaling factors, which were obtained using Monte Carlo simulation.
For subgroups of size $n$ drawn from a normal distribution, the following are true:

- The theoretical median of the ranges is approximately $d_2_{\text{Median}} \times \sigma$, where $d_2_{\text{Median}}$ is the value corresponding to $n$.
- The theoretical median of the standard deviations is approximately $c_4_{\text{Median}} \times \sigma$, where $c_4_{\text{Median}}$ is the value corresponding to $n$.

The analysis of large data sets, where hundreds to thousands of measurements on a part, process, or sample are taken requires innovative approaches. The Predictor Screening platform provides a method of screening many predictors for their ability to predict an outcome. For example, predictor screening can be used to help identify biomarkers from thousands tested in samples from patients with and without a condition to predict the condition.

Predictor screening differs from response screening. Response screening tests factors one at a time as a predictor of the response. Predictor screening uses bootstrap forest partitioning to evaluate the contribution of predictors on the response. The partition models are built on multiple predictors. Predictor screening can identify predictors that might be weak alone but strong when used in combination with other predictors. See the “Response Screening” chapter on page 443.

Overview of the Predictor Screening Platform

Predictor screening is useful for the identification of significant predictors from a large number of candidates. Suppose you had hundreds of Xs and needed to determine which of those were most significant as predictors of an outcome.

The predictor screening platform uses a bootstrap forest to identify potential predictors of your response. For each response, a bootstrap forest model using 100 decision trees is built. The column contributions to the bootstrap forest model for each predictor are ranked. Because the bootstrap forest method involves a random component, column contributions can differ when you rerun the report. For more information about decision trees, see the “Partition Models” chapter on page 51.

Example of Predictor Screening

The Bands Data.jmp data table contains measurements from machinery in the rotogravure printing business. The data set contains 539 records and 38 variables. The response Y is the column Banding? and its values are “BAND” and “NOBAND”. You are interested in understanding what properties are most likely to contribute to the response.

1. Select Help > Sample Data Library and open Bands Data.jmp.
2. Select Analyze > Screening > Predictor Screening.
4. Select the grouped columns grain screened to chrome content and click X.
5. Click OK.

**Note:** Because this analysis is based on the Bootstrap Forest method that has a random selection component, your results can differ slightly from those in Figure 24.2. See “Bootstrap Forest” on page 89.

The columns are sorted and ranked in order of contribution in the bootstrap forest model. Predictors with the highest contributions are strong candidate predictors for the response of interest.

**Tip:** Click on a column heading to change how the columns are sorted in the table.
Launch the Predictor Screening Platform

Launch the Predictor Screening platform by selecting Analyze > Screening > Predictor Screening.

Figure 24.3 Predictor Screening Launch Window

For more information about the options in the Select Columns red triangle menu, see Using JMP.

Y, Response  The response columns.

X  Predictor columns.

By  A column or columns whose levels define separate analyses. For each level of the specified column, the corresponding rows are analyzed using the other variables that you have specified. The results are presented in separate reports. If more than one By variable is assigned, a separate report is produced for each possible combination of the levels of the By variables.

Number of Trees  The number of decision trees in the bootstrap forest model.

Set Random Seed  Sets the seed for the starting values used in the fitting procedures. Set Random Seed is useful if you want to reproduce an analysis. If you set a random seed and save the script, the seed is automatically saved in the script.
The Predictor Screening Report

The report (Figure 24.2) shows the list of predictors with their respective contributions and rank. Predictors with the highest contributions are likely to be important in predicting Y.

The Contribution column shows the contribution of each predictor to the bootstrap forest model. The Portion column in the report shows the percent contribution of each variable.

You can select the important predictors in the Predictor Screening report. Selecting the important predictors selects the corresponding columns in the data table, enabling you to easily enter these columns into the launch windows for modeling platforms. The Copy Selected button enables you to copy the selected columns to the clipboard so that you can paste them into a model as well. In this way, the Predictor Screening enhances the modeling process.

Predictor Screening Platform Options

See *Using JMP* for more information about the following options:

**Local Data Filter**  Shows or hides the local data filter that enables you to filter the data used in a specific report.

**Redo**  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

**Save Script**  Contains options that enable you to save a script that reproduces the report to several destinations.

**Save By-Group Script**  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.
Chapter 25

Association Analysis

Perform Market Basket Analysis

The Association Analysis platform is available only in JMP Pro.

Association analysis enables you to identify items that have an affinity for each other. It is frequently used to analyze transactional data (also called market baskets) to identify items that often appear together in transactions. For example, grocery stores and online merchants use association analysis to strategically organize and recommend products that tend to be purchased together.

Association analysis is also used for identifying dependent or associated events. For example, you can identify car parts that seem to fail around the same time. In this application, car inspections are treated as the market baskets and you analyze the associations among groups of faulty parts found in each inspection.

Overview of the Association Analysis Platform

The Association Analysis platform identifies connections among groups of items in an independent event or transaction. In association analysis, an item is the basic object of interest. For example, an item could be a product, a web page, or a service. An item set is a list of one or more items.

The relationship between two item sets is defined by an association rule. An association rule consists of a condition item set and a consequent item set. Antecedents are the individual items in the condition item set. Association analysis identifies association rules, which predict that a consequent item set will be in a transaction, given that the condition item set is already in the transaction. Some association rules are stronger, and therefore more useful, than others. The following three performance measures describe the strength of an association rule:

- **Support** is the proportion of transactions in which an item set appears. A high value for support indicates that the item set occurs frequently.

- **Confidence** is the proportion of transactions that contain the consequent item set, given that the condition item set is in the transaction. Confidence measures the strength of implication, or the predictive power, of an association rule. Note that confidence in association analysis is not related to the concept of confidence intervals.

- **Lift** is the ratio of an association rule’s confidence to its expected confidence, assuming that the condition and consequent item sets appear in transactions independently. Lift measures how much the consequent item set depends on the presence of the condition item set. The minimum value for lift is 0.
  - A lift ratio less than 1 indicates that the condition and consequent repel each other, because they occur together less frequently than one would expect by chance alone.
  - A lift ratio close to 1 indicates that the consequent occurs at the same rate in transactions that contain the condition as one would expect from chance alone.
  - A lift ratio greater than 1 indicates that the consequent item set has an affinity for the condition item set. The consequent item set occurs more often with the condition item set than one would expect by chance alone.

For more information about these performance measures, see “Association Analysis Performance Measures” on page 527.

The Association Analysis platform also enables you to perform singular value decomposition. Singular value decomposition (SVD) groups similar transactions and also groups similar items using a matrix reducing methodology that is different from what is used in association analysis. Use the SVD methodology to gain insights that complement what you learn from association analysis.

For more information about association analysis, see Hastie et al. (2009) and Shmueli et al. (2010). For more information about singular value decomposition, see Jolliffe (2002).
Example of the Association Analysis Platform

This example uses the Grocery Purchases.jmp sample data table, which contains transactional data reported by a grocery store. The data table lists the items purchased by 1001 customers, each assigned a unique customer ID. You want to explore the associations among items in order to identify patterns in consumer behavior.

1. Select Help > Sample Data Library and open Grocery Purchases.jmp.
2. Select Analyze > Screening > Association Analysis.
3. Select Product and click Item.
4. Select Customer ID and click ID.
5. Click OK.

By default, the Rules report is sorted in decreasing order by Confidence. However, association rules with extremely high confidence also tend to have a higher number of items in the condition set. Since you want to view association rules with smaller condition sets, sort the report by Confidence, but in increasing order.

The Select Columns window appears.

7. Select Confidence and then check the Ascending option.
8. Click OK.

Figure 25.2  Association Analysis Report

9. Scroll down the report to where the Confidence values are 58%.
There is an entry in the Rules report table that indicates that 58% of customers who bought an avocado also bought an artichoke. The value of Lift is 1.908, indicating that there is a likely dependency. You want to verify that avocados and artichokes occur in a significant portion of transactions.

10. Click the disclosure icon next to Frequent Item Sets.

<tr>
<td>{artichokes}</td>
<td>25%</td>
<td>2</td>
</tr>
</tbody>
</table>

The Frequent Item Sets report shows that 36% of customers purchased avocados. The Rules report in Figure 25.2 shows that 58% of these customers also bought artichokes. Because of the large proportion of customers who follow this behavior, the grocery store management might use this information to strategically locate avocados and artichokes.

You also decide to look at the association rules with the highest lift.

11. Right-click in the Rules report table and select **Sort By Column**.

The Select Columns window appears.

12. Select Lift and click **OK**.

The Rules table is sorted by decreasing values of lift. Notice that the second association rule has a lift of 5.642 and 83% confidence. You want to verify that both the condition set, \{chicken, ice cream\}, and the consequent item set, \{Coke, sardines\}, have adequate support.

13. Right-click in the Frequent Item Sets report and select **Sort By Column**.

The Select Columns window appears.

14. Select Item Set and then check the Ascending option.

15. Click **OK**.
The Frequent Item Sets table is sorted alphabetically by item set. Scroll through the list to see that the condition item set, \{chicken, ice cream\}, has 14% support. The consequent item set, \{Coke, sardines\}, has 15% support. This association rule has high lift, but represents fewer transactions than the first association rule that you examined.

Launch the Association Analysis Platform

Launch the Association Analysis platform by selecting **Analyze > Screening > Association Analysis**.

**Figure 25.4** Association Analysis Launch Window

For more information about the options in the Select Columns red triangle menu, see *Using JMP*.

**Item**  The categorical column or columns that contain the item data to be analyzed. If the column has the Multiple Response modeling type, each of the multiple responses in each row is treated as an item. If multiple columns are specified, each column in each row is treated as an item.

**ID**  The column that identifies the transaction to which an item belongs. The ID role is required, unless the Item role is filled by a column with the Multiple Response modeling type or the Item role is filled by multiple columns.

**Note:** If an ID role is specified, all rows with the same ID are combined into one transaction.

**Freq**  The column that identifies a frequency for the transactions in the Item column. For example, if a transaction has a frequency of 3, that is treated as three identical transactions that contain the items in the Item column.

**Note:** The Freq role is ignored if the Item role is filled by a column that does not have the Multiple Response modeling type.
By  Produces a separate report for each level of the By variable. If more than one By variable is assigned, a separate report is produced for each possible combination of the levels of the By variables.

Minimum Support  Specifies a minimum value for the proportion of occurrences of an item set. This value must be between 0 and 1. Only item sets with support equal to or exceeding this value are considered in the analysis.

Minimum Confidence  Specifies a minimum value for the proportion of occurrences that a consequent item set occurs within transactions that contain the conditional item set. This value must be between 0 and 1. Only association rules with confidence equal to or exceeding this value appear in the report.

Minimum Lift  Specifies a minimum dependency ratio. Lift values must be 0 or greater. Only association rules with lift equal to or exceeding this value appear in the report.

Maximum Antecedents  Specifies the maximum number of items in the condition item set. Association rules with more than this number of items in the condition set are not considered in the analysis.

Maximum Rule Size  Specifies the maximum number of items that appear in the union of the condition and consequent item sets. Association rules with more than this combined number of items are not considered in the analysis. The default value is 4.

Note: You can use the minimum support, maximum antecedent, and maximum rule size options in the launch window to reduce computational time for large data sets. For more information about these measures, see “Statistical Details for the Association Analysis Platform” on page 527.

Data Format

There are three data formats that are accepted in the Association Analysis platform:

- You can specify a single item response in each row in the Item role and identify which items are included in each transaction using the ID role. In this format, the Item and ID roles are required and the Freq role is ignored.
- You can specify a Multiple Response modeling type column for the Item role. In this format, the Item role is required, the ID and Freq roles are optional. If an ID role is specified, all rows with the same ID are combined into one transaction. If a Freq role is specified, the frequency applies to the transaction, not the specific items in the transaction.
- You can specify multiple item response columns in the Item role. In this format, the ID and Freq roles are optional. If an ID role is specified, all rows with the same ID are combined into one transaction. If a Freq role is specified, the frequency applies to the transaction, not the specific items in the transaction.
The Association Analysis Report

By default, the Association Analysis report contains the following reports:

- “Frequent Item Sets” on page 518
- “Rules” on page 518

Tip: To order the contents of a table in a report by any of its columns, right-click in the table and select **Sort by Column**.

**Frequent Item Sets**

The Frequent Item Sets report lists item sets in decreasing order of support. The listed item sets meet the Minimum Support value that you specified in the launch window. Each item set is considered as a conditional and as a consequent item set to form association rules. The table contains the following columns:

- **Item Set**: The item sets that are considered as conditional or consequent sets for the association rules.
- **Support**: The proportion of transactions in which all of the items in the Item Set occur.
- **N Items**: The number of items in the Item Set.

**Rules**

The Rules report shows a table of association rules that are sorted in decreasing order of confidences. Only association rules that meet the Minimum Support, Minimum Confidence, Minimum Lift, Maximum Antecedents, and Maximum Rule Size requirements that you specified in the launch window appear in this report.

The Rules report table contains the following columns:

- **Rule**: The association rules formed by combining Condition and Consequent item sets.
  - **Condition**: The item set that is thought to influence the presence of a Consequent item set within transactions.
  - **Consequent**: The item set whose presence is thought to be influenced by the presence of a Condition item set.
- **Confidence**: The proportion of transactions that contain the Consequent item set, given that the condition item set is in the transaction. Confidence measures the strength of implication, or the predictive power, of an association rule.
**Lift**  The ratio of an association rule’s confidence to its expected confidence, assuming that the condition and consequent item sets appear in transactions independently. Lift measures how much the Consequent item set depends on the presence of the Condition item set. The minimum value for lift is 0.

- A lift ratio less than 1 indicates that the Condition and Consequent item sets repel each other, because they occur together less frequently than one would expect by chance alone.
- A lift ratio close to 1 indicates that the Consequent item set occurs at the same rate in transactions that contain the Condition item set as one would expect from chance alone.
- A lift ratio greater than 1 indicates that the Consequent item set has an affinity for the Condition item set. The Consequent item set occurs more often with the Condition item set than one would expect by chance alone.

**Association Analysis Platform Options**

The Association Analysis red triangle menu contains the following options:

**Transaction Listing**  Shows or hides a table listing each Transaction ID value and the items included in that transaction. The table is sorted by the Transaction ID column.

**Frequent Item Sets**  Shows or hides a list of item sets whose support exceeds the Minimum Support value specified in the launch window. See “Frequent Item Sets” on page 518.

**Rules**  Shows or hides a table of association rules that meet the Minimum Support, Minimum Confidence, Minimum Lift, Maximum Antecedents, and Maximum Rule Size requirements specified in the launch window. See “Rules” on page 518.

**SVD**  Shows or hides a report of a partial singular value decomposition (SVD) of the incidence matrix for the items. This decomposition reduces the incidence matrix into a user-specified number of dimensions for analysis. The SVD report also contains options to visualize the singular vectors, cluster transactions and items, save out singular vectors, and perform a rotated SVD analysis. See “Singular Value Decomposition” on page 520.

See Using JMP for more information about the following options:

**Local Data Filter**  Shows or hides the local data filter that enables you to filter the data used in a specific report.

**Redo**  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.
**Singular Value Decomposition**

Singular value decomposition (SVD) complements association analysis by providing another method to identify items that have an affinity for each other. Singular value decomposition of the transaction item matrix reduces the matrix to a manageable number of dimensions, thereby enabling you to group similar transactions and similar items. The SVD analysis is equivalent to performing principal components analysis (PCA) on a correlation matrix.

The transaction item matrix is a matrix for which each row corresponds to a transaction and each column corresponds to an item. The entries of the matrix are zeros and ones. If an item occurs in a transaction, the corresponding row and column entry is one. Otherwise, the row and column entry is zero. Because the transaction item matrix usually contains more values of zero than one, it is called a sparse matrix.

The partial singular value decomposition approximates the column-standardized transaction item matrix using three matrices: \( U \), \( S \), and \( V' \). The relationship between these matrices is defined as follows:

\[
\text{Transaction Item Matrix} \approx U \cdot S \cdot V'
\]

Define \( n_{\text{Tran}} \) as the number of transactions (rows) in the transaction item matrix, \( n_{\text{Item}} \) as the number of items (columns) in the transaction item matrix, and \( n_{\text{Vec}} \) as the specified number of singular vectors. Note that \( n_{\text{Vec}} \) must be less than or equal to \( \min(n_{\text{Tran}}, n_{\text{Item}}) \). It follows that \( U \) is an \( n_{\text{Tran}} \) by \( n_{\text{Vec}} \) matrix that contains the left singular vectors of the transaction item matrix. \( S \) is a diagonal matrix of dimension \( n_{\text{Vec}} \). The diagonal entries in \( S \) are the singular values in the transaction item matrix. \( V' \) is an \( n_{\text{Vec}} \) by \( n_{\text{Item}} \) matrix. The rows in \( V' \) (or columns in \( V \)) are the right singular vectors.

The right singular vectors capture connections among different items with similar functions or topic areas. If three items tend to appear in the same transactions, the SVD is likely to produce a singular vector in \( V' \) with large values for those three items. The \( U \) singular vectors represent the transactions projected into this new item space.

The SVD also captures indirect connections. If two items never appear together in the same transaction, but they generally appear in transactions with another third item, the SVD is able to capture some of that connection. If two transactions have no items in common but contain items that are connected in the dimension-reduced space, they map to similar vectors in the SVD plots.
The SVD transforms transaction data into a fixed-dimensional vector space, making it amenable to clustering, classification, and regression techniques. The Save options enable you to export this vector space to be analyzed in other JMP platforms.

The transaction item matrix is centered, scaled, and divided by $n_{Ttran}$ minus 1 before the singular value decomposition is carried out. This analysis is equivalent to a PCA of the correlation matrix of the transaction item matrix. The SVD implementation takes advantage of the sparsity of the transaction item matrix.

**SVD Report**

The SVD option produces two SVD plots and a table of the singular values from the singular value decomposition.

**SVD Plots**

The first plot contains a point for each transaction. For a given transaction, the point that is plotted is defined by the transaction’s values in the first two singular vectors (the first two columns of the $U$ matrix) multiplied by the diagonal singular values matrix ($S$). This plot is equivalent to the Score Plot in the Principal Components platform. Each point in this plot represents a transaction. In the Transaction SVD plot, points that are visibly grouped together indicate transactions with a similar composition.

The second plot contains a point for each item. For a given item, the point that is plotted is defined by the item’s values in the first two singular vectors (the first two rows of the $V'$ matrix) multiplied by the diagonal singular values matrix ($S$). This plot is equivalent to the Loadings Plot in the Principal Components platform. Each point in this plot represents an item. In the Item SVD plot, items that are visibly grouped together indicate items that have similar functions or topic areas.

**Singular Values**

Below the transaction and item SVD plots, a table of the singular values appears. These are the diagonal entries of the $S$ matrix in the singular value decomposition of the transaction item matrix. The Singular Values table also contains a column of corresponding eigenvalues for the equivalent principal components analysis. Like in the Principal Components platform, there are columns for the percent and cumulative percent of variation explained by each eigenvalue (or singular value). You can use the Cum Percent column to decide what percent of variance from the transaction item matrix you want to preserve, and then use the corresponding number of singular vectors.
SVD Report Options

The SVD red triangle menu contains the following options:

**SVD Scatterplot Matrix**  Shows or hides a scatterplot matrix of the item and transaction singular value decomposition vectors. You must select the size of the scatterplot matrix when you select this option. This scatterplot matrix enables you to visualize more than the first two dimensions of the singular value decomposition.

**Topic Analysis, Rotated SVD**  Performs a varimax rotated partial singular value decomposition of the item transaction matrix to produce groups of items called topics. You can select this option multiple times to find different numbers of topics. See “Topic Analysis” on page 523.

**Cluster Items**  Shows or hides a hierarchical clustering analysis of the items in the data. The following options are available to the right of the dendrogram:

- **Set Clusters**  Specifies the number of clusters that are colored in the dendrogram and used in the Save Clusters option. Points in the Item SVD plot are also colored by cluster.

- **Save Clusters**  Saves a data table that contains the items and their cluster assignments. You must set the number of clusters before clicking Save Clusters.

For more information about clustering and dendrograms, see *Multivariate Methods*.

**Cluster Transactions**  Shows or hides a hierarchical clustering analysis of the transactions in the data. The following options are available to the right of the dendrogram:

- **Set Clusters**  Specifies the number of clusters that are colored in the dendrogram and used in the Save Clusters option. Points in the Transaction SVD plot are also colored by cluster.

- **Save Clusters**  Saves a data table that contains the transactions and their cluster assignments. You must set the number of clusters before clicking Save Clusters.

For more information about clustering and dendrograms, see *Multivariate Methods*.

**Save Transaction Singular Vectors**  Saves a user-specified number of singular vectors from the transaction singular value decomposition as columns to a new data table where each row corresponds to a transaction. The first two saved columns represent the points plotted in the transaction SVD plot. See “Singular Value Decomposition” on page 520.

**Save Item Singular Vectors**  Saves a user-specified number of singular vectors from the items singular value decomposition as columns to a new data table where each row corresponds to an item. The first two saved columns represent the points plotted in the item SVD plot. See “Singular Value Decomposition” on page 520.
**Topic Analysis**

The Topic Analysis, Rotated SVD option performs a varimax rotation on the partial singular value decomposition (SVD) of the transaction item matrix. See “Singular Value Decomposition” on page 520. You must specify a number of rotated singular vectors, which corresponds to the number topics that you want to retain from the transaction item matrix. After you specify a number of topics, the Topic Analysis report appears.

Topic analysis is equivalent to a rotated principal component analysis (rotated PCA). The varimax rotation takes a set of singular vectors and rotates them to make them point more directly in the coordinate directions (toward the items). This rotation makes the vectors help explain the composition of the transactions as each rotated vector orients toward a set of items. Negative values indicate a repulsion force. The items with negative values occur in a topic less frequently compared to the items with positive values.

**Topic Analysis Report**

The Topic Analysis report shows the items that have the largest loadings in each topic after rotation. There are additional reports that show the components of the rotated singular value decomposition.

The Top Loadings by Topic report shows a table for each topic. The items in each table are the ones that have the largest loadings in absolute value for each topic. Each table is sorted in descending order by the absolute value of the loading. These tables can be used to determine conceptual themes that correspond to each topic.

The Topic Analysis report also contains the following reports:

- **Topic Loadings** Contains a matrix of the loadings across topics for each item. This matrix is equivalent to the factor loading matrix in a rotated PCA.

- **Word Clouds by Topic** Contains a matrix of word clouds, one for each topic.

- **Topic Scores** Contains a matrix of transaction scores for each topic. Transactions with higher scores in a topic are more likely to be associated with that topic.

- **Topic Scores Plots** Shows the topic scores for all transactions in one-dimensional scatterplots. Negative values indicate transactions that are negatively associated with a topic. Use these plots to explore the distribution of transactions within each topic.

- **Variance Explained by Each Topic** Contains a table of the variance explained by each topic. The table also contains columns for the percent and cumulative percent of the variation explained by each topic.

- **Rotation Matrix** Contains the rotation matrix for the varimax rotation.
**Topic Analysis Report Options**

The Topic Analysis red triangle menu contains the following options:

- **Topic Scatterplot Matrix**  Shows or hides a scatterplot matrix of the rotated singular value decomposition vectors.

- **Display Options**  Contains options to show or hide content that appears in the Topic Analysis report. See “Topic Analysis Report” on page 523.

- **Rename Topics**  Shows a dialog that enables you to add descriptive names for one or more of the topics.

- **Save Transaction Topic Vectors**  Saves a user-specified number of singular vectors from the rotated singular value decomposition as columns to the data table.

- **Save Item Topic Vectors**  Saves the topic vectors as columns to a new Item Topic Scores data table.

- **Remove**  Removes the Topic Analysis report from the SVD report.

---

**Additional Example: SVD Analysis**

In this example, you use singular value decomposition of the transaction item matrix to gain further insight into the Grocery Purchases.jmp sample data.

1. Select Help > Sample Data Library and open Grocery Purchases.jmp.
2. Select Analyze > Screening > Association Analysis.
3. Select Product and click Item.
4. Select Customer ID and click ID.
5. Click OK.
6. Click the Association Analysis red triangle and select SVD.
7. Click OK.
Figure 25.5 SVD Plots

The transaction SVD plot suggests that there might be two or three groups of transactions. In the upper right corner of the item SVD plot, notice that the points that represent Coke and ice cream overlap. The proximity of these two items indicates that there is a strong affinity between them.

8. Click the SVD red triangle and select **Topic Analysis, Rotated SVD**.

9. Type 3 next to Number of topics (rotated singular vectors) and click **OK**.

   The Topic Items and Topic Scores reports appear.

</tbody>
</table>

Three groups, or topics, are created and shown in the Topic Items report. The first items listed in the Topic Item tables represent the primary items for that group. For example, Topic 1 is a group that is identified primarily by transactions that do not contain avocados, but do contain olives.
The topic scores that are assigned to each of the 1001 transactions are plotted in the Topic Scores report. Select groups of points for a topic to see how those transactions relate to other topics. For example, transactions with very high values on Topic 1 tend to have low values on Topics 2 and 3.

10. Open the Singular Values report.

As seen in Figure 25.8, the first two singular values explain only about 30% of the variability in the grocery store data. Additional dimensions might be required to explain a sufficient amount of variability.
Statistical Details for the Association Analysis Platform

- “Frequent Item Set Generation”
- “Association Analysis Performance Measures”

Frequent Item Set Generation

The Association Analysis platform uses the Apriori algorithm to reduce computational time when generating frequent item sets. The Apriori algorithm leverages the fact that an item set’s support is never larger than the support of its subsets. The platform generates larger item sets from combinations of smaller item sets that meet the minimum support level. In addition, the platform does not generate item sets that exceed either the specified maximum number of antecedents or the maximum rule size. These options are useful when working with large data sets, because the total possible number of rules increases exponentially with the number of items. For more information about the Apriori algorithm, see Agrawal and Srikant (1994).

Association Analysis Performance Measures

This section defines the performance measures used in the Association Analysis platform. Denote an association rule with condition item set $X$ and consequent item set $Y$ by $X \Rightarrow Y$. Hahsler (2015) contains a collection of performance measures used in association analysis, including support, confidence, and lift.

Support

Support is the proportion of transactions in which an item set occurs. Support can also be viewed as the probability that a transaction contains an item set.

The support $S$ of a condition item set $X$ is defined as follows:

$$supp(X) = \frac{N_X}{N} = Pr(X)$$

where:

- $N_X$ is the number of transactions that contain the item set $X$
- $N$ is the total number of transactions.

Support for an association rule is defined as follows:

$$supp(X \Rightarrow Y) = supp(X \cup Y) = Pr(X \cap Y)$$
In this case, support is equivalent to the probability that a transaction contains both item sets X and Y.

For both the item set and association rule cases, support ranges from 0% to 100%.

**Confidence**

Confidence is the proportion of transactions that contain the consequent item set, given that the transaction contains the condition item set. Confidence can also be viewed as the conditional probability that a transaction contains the consequent item set, given that the transaction contains the condition item set.

\[
\text{conf}(X \Rightarrow Y) = \frac{\text{supp}(X \cup Y)}{\text{supp}(X)} = \frac{\Pr(X \cap Y)}{\Pr(X)} = \Pr(Y|X)
\]

Confidence ranges from 0% to 100%. An association rule with a confidence of 0% has a consequent item set that does not appear in any transaction with the condition item set. A confidence of 100% indicates that every transaction that contains the condition item set also contains the consequent item set.

**Note:** Confidence in association analysis is not related to the concept of confidence intervals.

**Lift**

Lift measures dependency between X and Y.

\[
lift(X \Rightarrow Y) = \frac{\text{supp}(X \cup Y)}{\text{supp}(X) \times \text{supp}(Y)} = \frac{\Pr(X \cap Y)}{\Pr(X)\Pr(Y)}
\]

The numerator for lift is the proportion of transactions where X and Y occur jointly. The denominator is an estimate of the expected joint occurrence of X and Y, assuming that they occur independently.

Lift ranges from 0 to \(\infty\). A lift value of 1 indicates that X and Y jointly occur in transactions with the frequency that would be expected by chance alone. Increasing lift values suggest that Y occurs more often than expected when X is present.

**Note:** The lift for association rule X \(\Rightarrow\) Y is equal to the lift for association rule Y \(\Rightarrow\) X.
Note: The Process History Explorer platform is new and experimental. It is subject to change in future releases.

In complex manufacturing situations, such as in semiconductor factories, a defective tool or route combination might lead to poor yield or reduced quality. However, there might be hundreds of steps that a unit passes through that involve many different tools. It can be difficult to determine the exact combination of factors that leads to the poor yield.

The Process History Explorer platform organizes all of the production tracking data and enables you to identify factors that seem to be associated with poor yield. You can then perform stepwise regression. You can analyze the time that a unit spends waiting between steps or tools in the process and see how that waiting time is related to yield. You can also analyze the effect on yield of transitions from one tool to another.

Example of Process History Explorer

This example uses two data tables. The first data table contains step-by-step history of 25 wafers in 50 lots that went through a complex manufacturing process. The second data table contains the yield for each wafer in each lot.

1. Select Help > Sample Data Library and open Quality Control > Lot Wafer History.jmp and Quality Control > Lot Wafer Yield.jmp.
2. From the Lot Wafer History.jmp data table, select Analyze > Screening > Process History Explorer.
3. Select Lot and Wafer and click ID.
4. Select Tool and Route and click X, Process.
5. Select Layer and Operation and click Step.
6. Select TimeIn and TimeOut and click Timestamp.
7. Click OK.

A window appears that enables you to select the corresponding yield table.
8. Select Lot Wafer Yield and click OK.

A window appears that enables you to select the yield column.
9. Select Yield and click OK.
10. Click the Process History Explorer red triangle and select Levels with Lowest Yield.
The report contains information about the process, including the number of units, steps, operations, and levels in the X columns. The Levels with Lowest Yields table contains counts and yield information for the 195 levels in the X columns. Notice that the PlanarTool008 tool had the lowest yield and 1,000 units went through that tool.
Launch the Process History Explorer Platform

Launch the Process History Explorer platform by selecting Analyze > Screening > Process History Explorer.

**Figure 26.3** Process History Explorer Launch

For more information about the options in the Select Columns red triangle menu, see *Using JMP*.

**Launch Window Roles**

**ID**  Specifies one or more columns that identify a unit in the process.

*Note:* The ID columns must have corresponding columns in the yield table.

**X, Process**  Specifies one or more columns that identify the components or specific details that make up the steps of the process.

**Step**  Optional columns that specify the steps and sub-steps that a unit goes through. For example, the layer and the type of operation within the layer.

**Timestamp**  Specifies the time of the operation. The time can be specified as a single time point or as a pair of time points that indicate the times that the operation started and ended.

**Order**  Optional column that specifies the order that a batch of units went through the components specified in the X, Process role.
By  Produces a separate report for each level of the By variable. If more than one By variable is assigned, a separate report is produced for each possible combination of the levels of the By variables.

Launch Window Options

Goal is to Minimize Y  Specifies that the goal of the analysis is to minimize the response. By default, the analysis seeks to maximize the response.

Note: The response is specified in a second data table, not in the data table used to launch the platform.

Data Format

The data for Process History Explorer must be specified in two data tables. The first table is used to launch the platform and contains the steps and details of the process. The second table contains the response, or yield, for each level of the ID columns.

The sample data tables Quality Control > Lot Wafer History and Quality Control > Lot Wafer Yield provide an example of how the data are specified in two data tables.

The Process History Explorer Report

The initial Process History Explorer Report provides a summary of the information in the data table(s).

- The number of Units, determined by the ID columns. If there is more than one ID column, this is the number of unique combinations.
- The number of Steps, determined by the Step columns. If there is more than one Step column, this is the number of unique combinations.
- The number of Operations, determined by the Timestamp columns. This is the same as the number of rows in your data table.
- The number of levels, determined by the X, Process columns. If there is more than one X, Process column, this is the sum of the number of levels in each column.
- The number of responses, determined by the Yield columns.

Select options from the Process History Explorer red triangle menu to continue your analysis. See “Process History Explorer Platform Options” on page 535.
Process History Explorer Platform Options

The Process History Explorer red triangle menu contains the following options:

**Levels with Lowest Yield**  Displays a table of summary statistics for the yield for each level of each X, Process variable. The summary statistics provided for each level are the number of operations, and the mean, standard error, and standard deviation of the yield. By default, the table is sorted in ascending order by mean yield.

**Levels with Lowest Yield with Time Filter**  Displays a table of summary statistics for the time intervals of the top 50 levels with the lowest yields. The routine searches for a time interval for each of the top 50 levels in the Levels with Lowest Yield table that minimizes the mean yield within the interval. The interval must contain at least 25% of the operations in that level. The summary statistics provided for each level are the number of operations in the identified interval, the mean yield in the identified interval, the timestamps for the first and last operations in the level (First Time and Last Time), and the timestamps for the first and last operations in the identified interval (RunStart Time and RunEnd Time).

**Stepwise Regression**  Displays a Stepwise Regression window that enables you to specify options for a stepwise regression analysis. You can use stepwise regression to find problems in the process, where a problem is something that causes your yield to decrease. At each step in the regression, a term enters according to which term has the largest negative yield. This helps you identify process steps that most impact the yield. Stepwise Regression provides a table that shows the order in which terms entered the model at each step of the regression.

**Note:** If the Goal is to Minimize Y option is selected in the launch window, Stepwise Regression adjusts to detect terms that cause the yield to increase.

**Goal**  Specifies the criterion used in the stepwise regression model. The Biggest individual difference option identifies the terms that individually cause the yield to change the most. The Biggest total difference option identifies the terms that cause the biggest total difference, which is the difference multiplied by the number of units affected. The Most predictive option produces a traditional stepwise regression model.

**Time Filtering**  Enables you to use the starting time of a component in the stepwise regression model. If you choose the None option, the times are averaged over the entire time period. If you choose the Starting Time option, the component is allowed to fail at a particular starting time. The starting time is the time that maximizes the negative yield affect. If you choose the Starting Time option, the Stepwise Regression report table contains a Start Time column.
**X Transform**  Enables you to use the regular count data or the Log(Count + 1) data for the X, Process variables in the stepwise regression. The Log(Count + 1) option transforms the variables in the regression such that high frequency counts have less of a linear influence in the regression. If you choose the None option, high frequency counts have a linear influence in the regression.

**Number of Regression Steps**  The number of steps in the Stepwise Regression analysis. The default is ten.

**Waiting Time Analysis**  (Available only when two Timestamp variables are specified.) Each unique ID can go through only one level of a step at a time. In addition, each step can process only one ID at a time. Waiting Time Analysis provides a table of waiting time summary statistics for each ID. In this table, waiting time is the amount of time between when an ID is done with one step and when it starts another step. Additional Waiting Time Analysis tables are also provided. These tables contain waiting time summary statistics for each ID within the levels of each Step variable. In these tables, waiting time is the amount of time between when an ID is done with a particular level of a Step variable and when it goes through that same level again. The tables provide the following statistics:

**Waiting Sum**  The sum of the waiting times for the given combination of ID and Step variable levels.

**Waiting Count**  The number of waiting times for the given combination of ID and Step variable levels.

**Waiting Mean**  The mean of the waiting times for the given combination of ID and Step variable levels.
**Waiting Max**  The maximum waiting time for the given combination of ID and Step variable levels.

**Transition Analysis**  Displays a report that helps you identify transitions from one component to another that are problematic for the resulting yield. This report can help you identify alignment and registration issues in the process. For example, some levels of the process column might be out of alignment with respect to other levels of the process column. If there is a transition problem, you would expect that items that repeat a specific level to have better yields than items that go through different levels of the process column.

When you select this option, you must choose one or more X, Process columns and one or more levels in each of those columns to include in the analysis. For each column that you specify for the analysis, a report appears that contains four tables. The first shows yields and counts for transitions from a specific level of the column to another specific level of the column. The second shows yields and counts for transitions away from specific levels of the column. The third shows yields and counts for transitions to specific levels of the column. The fourth shows yields and counts for transitions where the unit repeats a specific level of the column.

**Order Interaction**  (Available only if an Order variable is specified in the launch window.) Displays a report of a one-way analysis of the yield on the Order column. The report contains a table for each X, Process column. In each table, the levels of the process column are listed in descending order of LogWorth of the corresponding analysis of variance model. The tables also contain the \( p \)-values and a heat map for each level of the process column.

**Save Count Table**  Creates a new data table that contains counts of how many units went through each level of the X, Process variables. The count table has a row for each unique unit, determined by the ID values.

**Save Log Count Table**  Creates a new data table that is the same format as the Count table, except with entries of Log(Count + 1).

**Save Waiting Time**  (Available only when two Timestamp variables are specified.) Saves each table in the Waiting Time Analysis report to a separate data table.
This appendix discusses measures of fit and the types of cross validation available in each platform.

Measures of Fit

Entropy RSquare

The Entropy RSquare is computed for the training set and for the validation and test sets if validation is used. For the training set, Entropy RSquare is computed as follows:

- The specified model is fit using the training set.
- Predicted probabilities for each level of the response are obtained, based on the model.
- Using these predicted probabilities, the likelihood is computed for observations in the training set. Call this Likelihood_FullTraining.
- The reduced model (no predictors) is fit using the training set.
- The predicted probabilities for the levels of the response from the reduced model are used to compute the likelihood for observations in the training set. Call this quantity Likelihood_ReducedTraining.
- The Entropy RSquare for the training set is:

\[
\text{Entropy RSquare}_{\text{Training}} = 1 - \frac{\log(\text{Likelihood}_{\text{FullTraining}})}{\log(\text{Likelihood}_{\text{ReducedTraining}})}
\]

The Entropy RSquare for the validation and test sets are computed in a manner analogous to the Entropy RSquare for the training set.

Validation in JMP Modeling

Data can be partitioned into sets before modeling to avoid overfitting and to select a good predictive model. This process uses part of the original data to estimate parameters and uses the rest of the data to tune or evaluate the parameters, or do both. In JMP Pro, you can partition the data into two or three sets in the following ways:

- **Train and Evaluate**  Partitions the data into two sets, called Training and Validation. The training set is used to estimate the model parameters. The validation set is used to independently evaluate the performance of the fitted model.

- **Train and Tune**  Partitions the data into two sets, called Training and Validation. The training set is used to estimate the model parameters. The validation set is used in the model fitting algorithm to tune the model parameters and ultimately choose a model with good predictive ability. There is no independent model evaluation done in this case.
**Train, Tune, and Evaluate** Partitions the data into three sets, called Training, Validation, and Test. The training set is used to estimate the model parameters. The validation set is used in the model fitting algorithm to tune the model parameters and ultimately choose a model with good predictive ability. The test set is then used to independently evaluate the performance of the fitted model.

### Validation Column Role

The Validation Column role is available only in JMP Pro. For JMP, see “Excluded Rows as Validation Holdback” on page 544.

One way to create data partitions is to use the Validation Column role. The Validation Column role uses the column’s values to divide the data into parts. The column is assigned using the Validation role in the platform’s launch window. For information about how to create a validation column, see the “Make Validation Column” chapter on page 201.

**Caution:** The use of a validation column is platform specific. Different platforms use the levels of the validation column differently. See notes in Table A.1.

K-Fold and Holdback Validation

The Validation Column role provides a framework for partitioning data into cross validation sets. In addition, some JMP platforms also support K-Fold and various types of Holdback validation.

K-Fold Cross-Validation Divides the original data into $K$ subsets. In turn, each of the $K$ sets is used to validate the model fit on the rest of the data, fitting a total of $K$ models. The model that produces the best validation statistic is chosen as the final model, and the fold that is not used in the building of that model provides the test set performance statistics.

Note: For some platforms, you must specify K-Fold Cross-Validation in the model control panel. For other platforms, you must specify K-Fold Cross-Validation in the platform launch window. For still other platforms, you must specify K-Fold Cross-Validation through a validation column that contains more than three levels.

Random Validation Holdback (Available as a launch option for specific platforms.) Randomly divides the original data into the training and validation sets. A test set can also be included. You can specify the proportions of the original data to use in each set.

Leave-One-Out Validation Holdback (Available as an option for specific platforms.) Repeatedly fits the model leaving out one observation at a time. Leave-one-out validation is also known as the jackknife procedure.

Excluded Rows as Validation Holdback Uses the excluded rows in the data table as a validation holdback set. For JMP Pro, this option is available by selecting in the platform preferences.

Note: For platforms that support using excluded rows as a validation holdback set, the excluded rows are used only when there is no validation column or validation proportion specified in the launch window.

Get the Most from JMP

Whether you are a first-time or a long-time user, there is always something to learn about JMP.

Visit JMP.com to find the following:

• live and recorded webcasts about how to get started with JMP
• video demos and webcasts of new features and advanced techniques
• details on registering for JMP training
• schedules for seminars being held in your area
• success stories showing how others use JMP
• the JMP user community, resources for users including examples of add-ins and scripts, a forum, blogs, conference information, and so on

Introduction to Multivariate Analysis
Overview of Multivariate Techniques

*Multivariate Methods* describes the following techniques for analyzing several variables simultaneously:

- The Multivariate platform examines multiple variables to see how they relate to each other. See Chapter 3, “Correlations and Multivariate Techniques”.

- The Principal Components platform derives a small number of independent linear combinations (principal components) of a set of measured variables that capture as much of the variability in the original variables as possible. It is a useful exploratory technique and can help you create predictive models. See Chapter 4, “Principal Components”.

- The Discriminant platform looks to find a way to predict a classification (X) variable (nominal or ordinal) based on known continuous responses (Y). It can be regarded as inverse prediction from a multivariate analysis of variance (MANOVA). See Chapter 5, “Discriminant Analysis”.

- The Partial Least Squares platform fits linear models based on factors, namely, linear combinations of the explanatory variables (Xs). PLS exploits the correlations between the Xs and the Ys to reveal underlying latent structures. See Chapter 6, “Partial Least Squares Models”.

- The Multiple Correspondence Analysis (MCA) platform takes multiple categorical variables and seeks to identify associations between levels of those variables. MCA is frequently used in the social sciences particularly in France and Japan. It can be used in survey analysis to identify question agreement. See Chapter 7, “Multiple Correspondence Analysis”.

- The Structural Equation Models platform enables you to fit a variety of models, including confirmatory factor analysis, path models with or without latent variables, measurement error models, and latent growth curve models. See Chapter 8, “Structural Equation Models”.

- The Factor Analysis platform enables you to construct factors from a larger set of observed variables. These factors are expressed as linear combinations of a subset of the observed variables. Factor analysis enables you to explore the number of factors that are explained by a set of measured, observed variables, and the strength of the relationship between factors and variables. See Chapter 9, “Factor Analysis”.

- The Multidimensional Scaling (MDS) platform enables you to create a visual representation of the pattern of proximities (similarities, dissimilarities, or distances) among a set of objects. See Chapter 10, “Multidimensional Scaling”.
• The Item Analysis platform enables you to fit item response theory models. The Item Response Theory (IRT) method is used for the analysis and scoring of measurement instruments such as tests and questionnaires. IRT uses a system of models to relate a trait or ability to an individual’s probability of endorsing or correctly responding to an item. IRT can be used to study standardized tests, cognitive development, and consumer preferences. See Chapter 11, “Item Analysis”.

• The Hierarchical Cluster platform groups rows together that share similar values across a number of variables. It is a useful exploratory technique to help you understand the clumping structure of your data. See Chapter 12, “Hierarchical Cluster”.

• The KMeans Clustering platform groups observations that share similar values across a number of variables. See Chapter 13, “K Means Cluster”.

• The Normal Mixtures platform enables you to cluster observations when your data come from overlapping normal distributions. See Chapter 14, “Normal Mixtures”.

• The Latent Class Analysis platform finds clusters of observations for categorical response variables. The model takes the form of a multinomial mixture model. See Chapter 15, “Latent Class Analysis”.

• The Cluster Variables platform groups similar variables into representative groups. You can use Cluster Variables as a dimension-reduction method. Instead of using a large set of variables in modeling, the cluster components of the most representative variable in the cluster can be used to explain most of the variation in the data. See Chapter 16, “Cluster Variables”.
Correlations and Multivariate Techniques

Explore the Multidimensional Behavior of Variables

Multivariate data involve many variables instead of one (univariate) or two (bivariate). Use the Multivariate platform to explore how multiple variables relate to each other. The Multivariate platform provides many techniques to summarize and test the strength of the linear relationship between each pair of response variables. Both parametric and nonparametric correlations tests are available in the platform. You can also use graphical features, such as the Scatterplot Matrix and Color Maps, to identify dependencies, outliers, and clusters among the variables.

There are additional multivariate analysis techniques to further examine the relationship between variables, including principal components analysis, outlier analysis, and item reliability. These techniques are available through the Multivariate report. You can also use the Principal Components Analysis and Outlier Analysis platforms in JMP for more in-depth implementations of these techniques.

Example of the Multivariate Platform

This example uses the Body Measurements.jmp sample data table to examine the relationship between different measurements on the body.

1. Select Help > Sample Data Library and open Body Measurements.jmp.
2. Select Analyze > Multivariate Methods > Multivariate.
3. Select all columns except Mass and click Y, Columns.
4. Click OK.

The initial multivariate report contains a correlation matrix and scatterplot matrix. There is also a note that tells you that the Row-wise estimation method was used. All of the variables are positively correlated, but at varying strengths.

5. Click the Multivariate red triangle and deselect Scatterplot Matrix.
6. Click the Multivariate red triangle and select Correlation Probability.
7. Click the Multivariate red triangle and select Color Maps > Color Map on Correlations.
The Color Map on Correlations report provides a more concise version of the information in the Correlation Matrix. The majority of the plot is dark red colors indicating that most of the variables are highly correlated. The two lighter colored rows and columns indicate that height and head measurements are not highly correlated with other variables. This is further supported by the mostly non-significant $p$-values for Height and Head in the Correlation Probability table.
Launch the Multivariate Platform

Launch the Multivariate platform by selecting **Analyze > Multivariate Methods > Multivariate.**

**Figure 3.3** The Multivariate Launch Window

![Multivariate Launch Window](image)

For more information about the options in the Select Columns red triangle menu, see *Using JMP.*

**Y, Columns** Identifies one or more response columns. The response columns must have a numeric data type, but the modeling type can be continuous or ordinal.

**Note:** If you specify an ordinal response variable, a JMP alert appears after you click OK in the launch window. The alert indicates which variables are ordinal and confirms that you intended to include the ordinal variables in the analysis.

**Weight** Identifies one column whose numeric values assign a weight to each row in the analysis.

**Freq** Identifies one column whose numeric values assign a frequency to each row in the analysis.

**By** Produces a separate report of each level of By variable. If more than one By variable is assigned, a separate report is produced for each possible combination of the levels of the By variables.

**Estimation Method** Specifies the method for calculating the correlations. REML and Pairwise are the methods used most frequently. Several of these methods address the treatment of missing data. You can also estimate missing values by using a method other than Row-wise and then selecting the Impute Missing Data command. See “**Impute Missing Data**” on page 45.

**Default** The Default option uses either the Row-wise, Pairwise, or REML methods.

- Row-wise estimation is used for data tables with no missing values.
- Pairwise estimation is used for data tables with missing values and either more than 10 columns, more than 5,000 rows, or more columns than rows.
- REML estimation is used otherwise.

**Note:** When the Default option would otherwise result in REML estimation, but the fit does not converge properly, the platform reverts to the Pairwise method. This can happen when there are missing values in your data table and at least one of the following situations applies: if your data table has fewer than 10 columns, fewer than 5,000 rows, or fewer columns than rows. If the estimation method shown is Pairwise, this means that the REML fit did not converge.

**REML**  Restricted maximum likelihood (REML) estimation uses all of the data, even if missing values are present. Due to a bias-correction factor, this method is slow if the data set is large and there are many missing values. Therefore, REML is most useful for smaller data sets. If there are no missing cells in the data, then the REML and ML estimates are equivalent and equal to the sample covariance matrix. If there are missing cells, REML’s variance and covariance estimates are less biased than the estimates from ML estimation. For statistical details, see “REML” on page 47.

**ML**  Maximum likelihood (ML) estimation uses all of the data, even if missing values are present. Because the estimates from ML are generated quickly, this method is most useful for large data tables with missing data.

**Robust**  Robust estimation uses all of the data, even if missing values are present. This method down-weights extreme values and is therefore useful for data tables that might have outliers. For statistical details, see “Robust” on page 47.

**Row-wise**  Row-wise estimation calculates the Pearson correlation for each pair of columns. For statistical details, see “Pearson Product-Moment Correlation” on page 48. Row-wise estimation does not use rows with missing values. This method is useful for excluding observations with missing data.

**Pair-wise**  Pair-wise estimation uses all of the data, even if missing values are present. This estimation method calculates Pearson correlations for each pair of columns using all observations with nonmissing values for those two columns. For statistical details, see “Pearson Product-Moment Correlation” on page 48. Pair-wise estimation is most useful when a data table has missing values and either more columns than rows, more than 10 columns, or more than 5,000 rows.

**Note:** If you select REML, ML, or Robust and your data table contains more columns than rows and has missing values, JMP switches the Estimation Method to Pairwise.

**Matrix Format**  Select a format option for the Scatterplot Matrix. The Square option displays plots for all ordered combinations of columns. Lower Triangular displays plots below the
diagonal, with the first $n - 1$ columns on the horizontal axis. Upper Triangular displays plots above the diagonal, with the first $n - 1$ columns on the vertical axis.

**The Multivariate Report**

The default multivariate report shows the standard correlation matrix, the scatterplot matrix, and a note that indicates which method was used to estimate the correlations. In some cases, information that explains why the given method was used is also displayed. The platform menu lists additional correlation options and other techniques for looking at multiple variables. See “Multivariate Platform Options” on page 35.

**Multivariate Platform Options**

**Note:** The correlation values and $p$-values in the Multivariate report are formatted using the conditional formatting settings in Preferences. See *Using JMP*.

The Multivariate red triangle menu contains the following options:

**Correlations Multivariate** Shows or hides the Correlations table. The table is a matrix of correlation coefficients that summarizes the strength of the linear relationships between each pair of response ($Y$) variables. This option is on by default. See “Pearson Product-Moment Correlation” on page 48.

**Note:** This correlation matrix is calculated by the method that you select in the launch window.

**Correlation Probability** Shows or hides the Correlation Probability table. The table is a matrix of $p$-values. Each $p$-value corresponds to a test of the null hypothesis that the true correlation between the variables is zero. This is a test of no linear relationship between the two response variables.

**Cl of Correlations** Shows or hides the two-tailed confidence intervals of the correlations.

**Tip:** The default confidence coefficient is 95%. Use the Set $\alpha$ Level option to change the confidence coefficient.

**Inverse Correlations** Shows or hides the Inverse Corr report, which is the inverse correlation matrix. The diagonal elements of the matrix are a function of how closely the variable is a linear function of the other variables. In the inverse correlation table, the diagonal is the value of $1/(1 - R^2)$. $R^2$ is calculated from the simple linear model regressing that variable
on all the other variables. If the multiple correlation is zero, the diagonal inverse element is 1. If the multiple correlation is 1, then the inverse element becomes infinite and is reported missing. For statistical details about inverse correlations, see the “Inverse Correlation Matrix” on page 50.

**Partial Correlations**  Shows or hides the Partial Corr report, which is the partial correlation matrix. The partial correlation matrix shows the measure of the relationship between a pair of variables after adjusting for the effects of all the other variables. The table is the negative of the inverse correlation matrix, scaled to unit diagonal. This means that the matrix is scaled such that the diagonal elements are equal to one.

**Partial Correlation Probability**  Shows or hides the Partial Correlation Probability report, which is a matrix of \( p \)-values. Each \( p \)-value corresponds to a test of the null hypothesis that the true partial correlation between the variables is zero. This is a test of no linear relationship between the two response variables, after adjusting for the effects of the other variables.

**Note:** The Partial Correlation Probability option is not available when there are not enough degrees of freedom. This can occur when there are more variables than observations.

**Covariance Matrix**  Shows or hides the covariance matrix, which measures the degree to which a pair of variables change together.

**Pairwise Correlations**  Shows or hides the Pairwise Correlations table, which lists the Pearson product-moment correlations for each pair of Y variables. The correlations are calculated by the pairwise deletion method. The count values differ if any pair has a missing value for either variable. The Pairwise Correlations report also shows significance probabilities and compares the correlations in a bar chart. All results are based on the pairwise method.

**Note:** This option excludes rows that are missing for either of the variables under consideration.

**Hotelling’s \( T^2 \) Test**  Enables you to conduct a one-sample test for the mean of the multivariate distribution of the variables that you entered as Y. When you select the Hotelling’s \( T^2 \) Test option, a window appears that enables you to specify the mean vector under the null hypothesis. Enter a hypothesized mean for each variable. The test assumes multivariate normality of the Y variables. The Hotelling’s \( T^2 \) Test report gives the following information:

**Variable**  The variables entered as Y.

**Mean**  The sample mean for each variable.
Hypothesized Mean  The null hypothesis means that you specified.

Test Statistic  The value of Hotelling’s $T^2$ statistic.

F Ratio  The value of the test statistic. If you have $n$ rows and $k$ variables, the $F$ ratio is defined as follows:

$$\frac{n-k}{k(n-1)} T^2$$

Prob > F  The $p$-value for the test. Under the null hypothesis the $F$ ratio has an $F$ distribution with $k$ and $n - k$ degrees of freedom.

Note: To remove a report, click the red triangle next to Hotelling’s $T^2$ Test and select Remove Test.

Simple Statistics  This menu contains two options that each show or hide simple statistics (mean, standard deviation, sum, minimum, and maximum) for each column. The univariate and multivariate simple statistics can differ when there are missing values present, or when the Robust method is used.

Univariate Simple Statistics  Shows statistics that are calculated on each column, regardless of values or missing values in other columns. These values match those produced by the Distribution platform.

Multivariate Simple Statistics  Shows statistics that correspond to the estimation method selected in the launch window and the presence or absence of missing data. If there are no missing observations, this option is available only for the Robust method. If there are missing observations, this option is available for all estimation methods except for Pairwise. For the REML, ML, or Robust methods, the mean vector and covariance matrix are estimated by the selected method. For the Row-wise method, all rows with at least one missing value are excluded from the calculation of means and variances.

Nonparametric Correlations  This menu contains three nonparametric measures: Spearman’s Rho, Kendall’s Tau, and Hoeffding’s D. Each option shows or hides a nonparametric report for the corresponding measure. See “Nonparametric Correlations” on page 39.

Set $\alpha$ Level  You can specify any alpha value for the correlation confidence intervals. Four alpha values are listed: 0.01, 0.05, 0.10, and 0.50. Select Other to enter any other value.

Scatterplot Matrix  Shows or hides a scatterplot matrix of each pair of response variables. This option is on by default. See “Scatterplot Matrix” on page 40.
**Color Maps**  The Color Maps menu contains three types of color maps. Each option in the menu shows or hides a color map of the corresponding type. The following types of color maps are available:

**Color Map On Correlations**  Produces a cell plot that shows the correlations among variables on a scale from red (+1) to blue (-1).

**Color Map On p-values**  Produces a cell plot that shows the significance of the correlations on a scale from $p = 0$ (red) to $p = 1$ (blue).

**Cluster the Correlations**  Produces a cell plot that clusters together similar variables. The correlations are the same as for Color Map on Correlations, but the positioning of the variables might be different.

**Color Map on Pairwise Correlations**  Produces a cell plot that shows the pairwise correlations among variables on a scale from red (+1) to blue (-1).

**Color Map on Spearman’s $\rho$**  Produces a cell plot that shows the Spearman’s $\rho$ nonparametric correlations among the variables on a scale from red (+1) to blue (-1).

**Color Map on Kendall’s $\tau$**  Produces a cell plot that shows the Kendall’s $\tau$ nonparametric correlations among the variables on a scale from red (+1) to blue (-1).

**Color Map on Hoeffding’s $D$**  Produces a cell plot that shows the Hoeffding’s $D$ nonparametric correlations among the variables on a scale from red (+1) to blue (-1).

**Parallel Coord Plot**  Shows or hides a parallel coordinate plot of the variables.

**Ellipsoid 3D Plot**  Shows or hides a three-dimensional scatterplot with a 95% confidence ellipsoid. You are prompted to specify three variables and their corresponding axes when you select this option.

**Principal Components**  This menu contains options to show or hide a principal components report. You can select a principal components report based on correlations, covariances, or unscaled values. Selecting one of these options when a principal components report is already shown changes the report to the new option. Select **None** to remove the report.

Principal components is a technique that calculates linear combinations of the original variables. The first principal component has maximum variation, the second principal component has the next most variation, subject to being orthogonal to the first, and so on. See the “Principal Components” chapter on page 55.

**Outlier Analysis**  This menu contains options that each show or hide plots that measure distance in the multivariate sense using one of the following methods: the Mahalanobis distance, jackknife distances, and the $T^2$ statistic. See “Outlier Analysis” on page 42.
Item Reliability  This menu contains options that each show or hide an item reliability report. The reports indicate how consistently a set of instruments measures an overall response, using either Cronbach’s $\alpha$ or Standardized $\alpha$. See “Item Reliability” on page 45.

Impute Missing Data  (Available only if the data table contains missing values.) Produces a new data table that duplicates your data table and replaces all missing values with estimated values. See “Impute Missing Data” on page 45.

Save Imputed Formulas  (Available only if the data table contains missing values.) For columns that contain missing values, saves new columns to the data table that contain the formulas used to estimate the missing values. The new columns are called Imputed_<Column Name>.

See Using JMP for more information about the following options:

Local Data Filter  Shows or hides the local data filter that enables you to filter the data used in a specific report.

Redo  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

Save Script  Contains options that enable you to save a script that reproduces the report to several destinations.

Save By-Group Script  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.

Nonparametric Correlations

The Nonparametric Correlations menu offers three nonparametric measures for pairwise correlations. Each Nonparametric correlation report gives the significance probability for the chosen measure of association and displays the association value on a bar chart. There are three nonparametric correlation measures.

Spearman’s Rho  A correlation coefficient computed on the ranks of the data values instead of on the values themselves.

Kendall’s Tau  Based on the number of concordant and discordant pairs of observations. A pair is concordant if the observation with the larger value of $X$ also has the larger value of $Y$. A pair is discordant if the observation with the larger value of $X$ has the smaller value of $Y$. There is a correction for tied pairs, which are pairs of observations that have equal values of $X$ or equal values of $Y$. 
Hoeffding’s D  A statistical scale that ranges from –0.5 to 1. Large positive values indicate dependence. The statistic approximates a weighted sum over observations of chi-square statistics for two-by-two classification tables. The two-by-two tables are made by setting each data value as the threshold. This statistic detects more general departures from independence.

Note: The nonparametric correlations are calculated using the Pairwise method, even if you selected a different Estimation Method in the launch window.

Note: When a Weight variable is specified, missing and zero-valued weights are excluded from the nonparametric correlation calculations. All other weight values are treated as 1.

For statistical details about these three methods, see the “Nonparametric Measures of Association” on page 48.

Scatterplot Matrix

A scatterplot matrix helps you visualize the correlations between each pair of response variables.

Figure 3.4 Scatterplot Matrix
Turning on the Density Ellipses option shows a 95% bivariate normal density ellipse in each scatterplot. Assuming that each pair of variables has a bivariate normal distribution, this ellipse encloses approximately 95% of the points. The narrowness of the ellipse reflects the degree of correlation of the variables. If the ellipse is fairly round and is not diagonally oriented, the variables are uncorrelated. If the ellipse is narrow and diagonally oriented, the variables are correlated.

**Tips:**

- Re-sizing any cell resizes all the cells.
- Drag a label cell to another label cell to reorder the matrix.
- When you look for patterns in the scatterplot matrix, you can see the variables cluster into groups based on their correlations. Figure 3.4 shows two clusters of correlations: the first two variables (top, left), and the next four (bottom, right).

**Scatterplot Matrix Options**

The red triangle menu for the Scatterplot Matrix lets you customize the matrix with color and density ellipses and by setting the $\alpha$-level.

- **Show Points**  Shows or hides the points in the scatterplot.
- **Fit Line**  Shows or hides the regression line and 95% level confidence curves for the fitted regression line.
- **Density Ellipses**  Shows or hides the 95% density ellipses in the scatterplots. Use the Ellipse $\alpha$ menu to change the $\alpha$-level.
- **Shaded Ellipses**  Colors each ellipse. Use the Ellipses Transparency and Ellipse Color menus to change the transparency and color.
- **Show Correlations**  Shows or hides the correlation of each pair of variables in the upper left corner of each scatterplot.
- **Matrix Options**  (Available only when the Square Matrix Format is selected on the launch window.) Shows a submenu of options to change the appearance of the upper right triangle of the scatterplot matrix. Only one of the following options can be selected at a time.
  - **Significance Circles**  Shows or hides correlation circles in the upper right triangle of the scatterplot matrix. The color of each circle represents the correlation between each pair of variables on a scale from red (+1) to blue (-1). The size of each circle represents the significance test between the variables. A larger circle indicates a more significant relationship.
**Heat Map**  Shows or hides a correlation heat map in the upper right triangle of the scatterplot matrix. The color of each cell in the heat map represents the correlation between each pair of variables on a scale from red (+1) to blue (-1).

**Show Histograms**  Shows or hides horizontal or vertical histograms in the label cells. Once histograms have been added, select **Show Counts** to label each bar of the histogram with its count. Select **Horizontal** or **Vertical** to either change the orientation of the histograms or remove the histograms.

**Ellipse** $\alpha$  Sets the $\alpha$-level used for the ellipses. Select one of the standard $\alpha$-levels in the menu, or select **Other** to enter a different value.

**Ellipses Transparency**  Sets the transparency of the ellipses if they are colored. Select one of the default levels, or select **Other** to enter a different value. The default value is 0.2.

**Ellipse Color**  Sets the color of the ellipses if they are colored. Select one of the colors in the palette, or select **Other** to use another color. The default value is red.

**Nonpar Density**  Shows or hides shaded density contours based on a smooth nonparametric bivariate surface that describes the density of data points. Contours for the 10% and 50% quantiles of the nonparametric surface are shown.

**Outlier Analysis**

The Outlier Analysis menu contains options that each show or hide plots that measure distance in the multivariate sense, with respect to the correlation structure. For example, in Figure 3.5, Point A is an outlier because it is outside the correlation structure, even though it is not an outlier in any of the coordinate directions.

**Figure 3.5**  Example of an Outlier

![Figure 3.5 Example of an Outlier](image)
Each option in the Outlier Analysis menu shows or hides a plot of the corresponding distances. Testing is done at the alpha level that appears at the bottom of the plot. The following options are available:

**Mahalanobis Distances**  Shows or hides the Mahalanobis distance of each point from the multivariate mean (centroid). The standard Mahalanobis distance depends on estimates of the mean, standard deviation, and correlation for the data. The distance is plotted for each observation number. Extreme multivariate outliers can be identified by highlighting the points with the largest distance values. See “Mahalanobis Distance Measures” on page 50.

**Jackknife Distances**  Shows or hides distances that are calculated using a jackknife technique. The distance for each observation is calculated with estimates of the mean, standard deviation, and correlation matrix that do not include the observation itself. The jack-knifed distances are useful when there is an outlier. In this case, the Mahalanobis distance is distorted and tends to disguise the outlier or make other points look more outlying than they are. See “Jackknife Distance Measures” on page 51.

**T²**  Shows or hides distances that are the square of the Mahalanobis distance. This plot is preferred for multivariate control charts. The plot includes the value of the calculated $T^2$ statistic, as well as its upper control limit. Values that fall outside this limit might be outliers. See “T² Distance Measures” on page 51.
Figure 3.6  Outlier Analysis Plots

Saving Distances and Values

You can save any of the distances to the data table by selecting the **Save** option from the red triangle menu for the plot.

**Note:** There is no formula saved with the jackknife distance column. This means that the distance is *not* recomputed if you modify the data table. If you add or delete columns, or change values in the data table, select **Analyze > Multivariate Methods > Multivariate** again to compute new jackknife distances.

In addition to saving the distance values for each row, a column property is created that holds the upper control limit (UCL) value for the Outlier Analysis type specified.
Item Reliability

Item reliability indicates how consistently a set of instruments measures an overall response. Cronbach’s $\alpha$ (Cronbach 1951) is one measure of reliability. Two primary applications for Cronbach’s $\alpha$ are industrial instrument reliability and questionnaire analysis.

Cronbach’s $\alpha$ is based on the average correlation of items in a measurement scale. It is equivalent to computing the average of all split-half correlations in the data table. The Standardized $\alpha$ can be requested if the items have variances that vary widely.

**Note:** Cronbach’s $\alpha$ is not related to a significance level $\alpha$. Also, item reliability is unrelated to survival time reliability analysis.

To look at the influence of an individual item, JMP excludes it from the computations and shows the effect of the Cronbach’s $\alpha$ value. If $\alpha$ increases when you exclude a variable (item), that variable is not highly correlated with the other variables. If the $\alpha$ decreases, you can conclude that the variable is correlated with the other items in the scale.

See “Cronbach’s $\alpha$” on page 52 for more information about computations.

Impute Missing Data

To impute missing data, click the Multivariate red triangle and select **Impute Missing Data**. A new data table is created. This data table is a duplicate of your data table except that the missing values are replaced with estimated values.

Imputed values are expectations conditional on the nonmissing values for each row. The mean and covariance matrix, estimated by the method chosen in the launch window, are used for the imputation calculation. All multivariate tests and options are then available for the imputed data set.
Example of Item Reliability

This example uses the Danger.jmp data in the sample data folder. This table lists 30 items having some level of inherent danger. Three groups of people (students, non-students, and experts) ranked the items according to perceived level of danger. Note that Nuclear power is rated as very dangerous (1) by both students and non-students, but is ranked low (20) by experts. On the other hand, motorcycles are ranked either fifth or sixth by all three judging groups.

You can use Cronbach’s $\alpha$ to evaluate the agreement in the perceived way the groups ranked the items. Note that in this type of example, where the values are the same set of ranks for each group, standardizing the data has no effect.

1. Select Help > Sample Data Library and open Danger.jmp.
2. Select Analyze > Multivariate Methods > Multivariate.
3. Select all the columns except for Activity and click Y, Columns.
4. Click OK.
5. Click the Multivariate red triangle and select Item Reliability > Cronbach’s $\alpha$.
6. (Optional) Click the Multivariate red triangle and select Scatterplot Matrix to hide that plot.

**Figure 3.7** Cronbach’s $\alpha$ Report

The Cronbach’s $\alpha$ results show an overall $\alpha$ of 0.8666, which indicates a high correlation of the ranked values among the three groups. Further, when you remove the experts from the analysis, the Nonstudents and Students ranked the dangers nearly the same, with Cronbach’s $\alpha$ scores of 0.7785 and 0.7448, respectively.
Chapter 3  Correlations and Multivariate Techniques

Multivariate Methods Computations and Statistical Details

- “Estimation Methods”
- “Pearson Product-Moment Correlation”
- “Nonparametric Measures of Association”
- “Inverse Correlation Matrix”
- “Distance Measures”
- “Cronbach’s α”

Estimation Methods

REML

REML (restricted maximum likelihood) estimates are less biased than the ML (maximum likelihood) estimation method when the data contains missing values. The REML method maximizes marginal likelihoods based on error contrasts. The REML method is often used for estimating variances and covariances. The REML method in the Principal Components platform is the same as the REML estimation of mixed models for repeated measures data with an unstructured covariance matrix. See the MIXED Procedure chapter in SAS Institute Inc. (2020e) about REML estimation of mixed models.

Robust

This method essentially ignores any outlying values by substantially down-weighting them. A sequence of iteratively reweighted fits of the data is done using the following weight:

$$w_i = 1.0 \text{ if } Q < K \text{ and } w_i = K/Q \text{ otherwise}$$

Here, K is a constant equal to the 0.75 quantile of a chi-square distribution with the degrees of freedom equal to the number of columns in the data table. Q is defined as follows:

$$Q = (y_i - \mu)^T S^{-2} (y_i - \mu)$$

In this equation, $y_i$ is the response for the $i^{th}$ observation, $\mu$ is the current estimate of the mean vector, $S^2$ is the current estimate of the covariance matrix, and $T$ is the transpose matrix operation. The final step is a bias reduction of the variance matrix.

The trade off of this method is that you can have higher variance estimates when the data do not have many outliers, but can have a much more precise estimate of the variances when the data do have outliers.
Pearson Product-Moment Correlation

The Pearson product-moment correlation coefficient measures the strength of the linear relationship between two variables. For response variables $X$ and $Y$, it is denoted as $r$ and computed as follows:

$$ r = \frac{\sum (x - \bar{x})(y - \bar{y})}{\sqrt{\sum (x - \bar{x})^2} \sqrt{\sum (y - \bar{y})^2}} $$

If there is an exact linear relationship between two variables, the correlation is 1 or –1, depending on whether the variables are positively or negatively related. If there is no linear relationship, the correlation tends toward zero.

Nonparametric Measures of Association

For the Spearman, Kendall, or Hoeffding correlations, the data are first ranked. Computations are then performed on the ranks of the data values. Average ranks are used in case of ties.

**Note:** When a Weight variable is specified, missing and zero-valued weights are excluded from the nonparametric correlation calculations. All other weight values are treated as 1.

Spearman’s $\rho$ (rho) Coefficients

Spearman’s $\rho$ correlation coefficient is computed on the ranks of the data using the formula for the Pearson’s correlation previously described.

Kendall’s $\tau_b$ Coefficients

Kendall’s $\tau_b$ coefficients are based on the number of concordant and discordant pairs. A pair of rows for two variables is *concordant* if they agree in which variable is greater. Otherwise, they are discordant, or tied.

The formula

$$ \tau_b = \frac{\sum_{i<j} \text{sgn}(x_i - x_j) \text{sgn}(y_i - y_j)}{\sqrt{(T_0 - T_1)(T_0 - T_2)}} $$
computes Kendall’s $\tau_b$ where:

\[
T_0 = \frac{n(n-1)}{2}
\]

\[
T_1 = \sum (t_i(t_i-1))/2
\]

\[
T_2 = \sum (u_i(u_i-1))/2
\]

Note the following:

- The sgn(z) is equal to 1 if $z>0$, 0 if $z=0$, and –1 if $z<0$.
- The $t_i$ (the $u_i$) are the number of tied x (respectively y) values in the $i$th group of tied x (respectively y) values.
- The $n$ is the number of observations.
- Kendall’s $\tau_b$ ranges from –1 to 1. If a weight variable is specified, it is ignored.

Computations proceed in the following way:

- Observations are ranked in order according to the value of the first variable.
- The observations are then re-ranked according to the values of the second variable.
- The number of interchanges of the first variable is used to compute Kendall’s $\tau_b$.

**Hoeffding’s D Statistic**

The formula for Hoeffding’s $D$ (1948) is

\[
D = 30\left(\frac{(n-2)(n-3)D_1 + D_2 - 2(n-2)D_3}{n(n-1)(n-2)(n-3)(n-4)}\right)
\]

where:

\[
D_1 = \sum_i(Q_i-1)(Q_i-2)
\]

\[
D_2 = \sum_i(R_i-1)(R_i-2)(S_i-1)(S_i-2)
\]

\[
D_3 = \sum_i(R_i-2)(S_i-2)(Q_i-1)
\]

Note the following:

- The $R_i$ and $S_i$ are ranks of the x and y values.
- The $Q_i$ (sometimes called bivariate ranks) are one plus the number of points that have both x and y values less than the $i$th points.
- A point that is tied on its x value or y value, but not on both, contributes 1/2 to $Q_i$ if the other value is less than the corresponding value for the $i$th point. A point tied on both x and y contributes 1/4 to $Q_i$.

When there are no ties among observations, the $D$ statistic has values between –0.5 and 1, where 1 indicates complete dependence. If a weight variable is specified, it is ignored.
Inverse Correlation Matrix

The inverse correlation matrix provides useful multivariate information. The diagonal elements of the inverse correlation matrix, sometimes called the variance inflation factors (VIF), are a function of how closely the variable is a linear function of the other variables. Specifically, if the correlation matrix is denoted $R$ and the inverse correlation matrix is denoted $R^{-1}$, the diagonal element is denoted $r_{ii}$ and is computed as follows:

$$r_{ii} = \text{VIF}_i = \frac{1}{1 - R_i^2}$$

where $R_i^2$ is the coefficient of variation from the model regressing the $i$th explanatory variable on the other explanatory variables. Thus, a large $r_{ii}$ indicates that the $i$th variable is highly correlated with any number of the other variables.

Distance Measures

The Outlier Analysis plots show the specified distance measure for each point in the data table.

Mahalanobis Distance Measures

The Mahalanobis distance takes into account the correlation structure of the data and the individual scales. For each value, the Mahalanobis distance is denoted $M_i$ and is computed as follows:

$$M_i = \sqrt{(Y_i - \bar{Y})S^{-1}(Y_i - \bar{Y})}$$

where:

- $Y_i$ is the data for the $i$th row
- $\bar{Y}$ is the row of means
- $S$ is the estimated covariance matrix for the data

The UCL reference line (Mason and Young 2002) drawn on the Mahalanobis Distances plot is computed as follows:

$$UCL_{\text{Mahalanobis}} = \sqrt{\frac{(n-1)^2}{n} \beta} \left[ 1 - a, \frac{p}{2}, \frac{n-p-1}{2} \right]$$

where:

- $n = \text{number of observations}$
Chapter 3  
Correlations and Multivariate Techniques

Multivariate Methods Computations and Statistical Details

$p$ = number of variables (columns)

\[
\beta \left[ 1 - \alpha; \frac{n-p-1}{2} \right] = (1-\alpha)^{th} \text{ quantile of a Beta } \left( \frac{p}{2}, \frac{n-p-1}{2} \right) \text{ distribution}
\]

If a variable is an exact linear combination of other variables, then the correlation matrix is singular and the row and the column for that variable are zeroed out. The generalized inverse that results is still valid for forming the distances.

**Jackknife Distance Measures**

The jackknife distance is calculated with estimates of the mean, standard deviation, and correlation matrix that do not include the observation itself. For each value, the jackknife distance is computed as follows:

\[
J_i = \left( \frac{(n-2)n^2}{(n-1)^3} \times \frac{M_i^2}{nM_i^2 - \left(1 - \frac{M_i^2}{(n-1)^2} \right)} \right)^{\frac{1}{2}}
\]

where:

- $n$ = number of observations
- $p$ = number of variables (columns)
- $M_i$ = Mahalanobis distance for the $i^{th}$ observation

The UCL reference line (Penny 1996) drawn on the Jackknife Distances plot is calculated as follows:

\[
UCL_{\text{Jackknife}} = \left( \frac{(n-2)n^2}{(n-1)^3} \times \frac{UCL_{\text{Mahalanobis}}^2}{n \cdot UCL_{\text{Mahalanobis}}^2 - \left(1 - \frac{UCL_{\text{Mahalanobis}}^2}{(n-1)^2} \right)} \right)^{\frac{1}{2}}
\]

**$T^2$ Distance Measures**

The $T^2$ distance is the square of the Mahalanobis distance, so $T_i^2 = M_i^2$.

The UCL on the $T^2$ distance is:

\[
UCL_{T^2} = \frac{(n-1)^2}{n} \beta \left[ 1 - \alpha; \frac{n-p-1}{2} \right] = (UCL_{\text{Mahalanobis}})^2
\]

where

- $n$ = number of observations
Correlations and Multivariate Techniques

Chapter 3
Computations and Statistical Details
Multivariate Methods

$p = \text{number of variables (columns)}$

$$\beta_{\left[1 - \alpha, \frac{p, n-p-1}{2}\right]}^{p, n-p-1} = (1-\alpha)^{\text{th}} \text{quantile of a Beta} \left( \frac{p, n-p-1}{2} \right) \text{ distribution}$$

Multivariate distances are useful for spotting outliers in many dimensions. However, if the variables are highly correlated in a multivariate sense, then a point can be seen as an outlier in multivariate space without looking unusual along any subset of dimensions. In other words, when the values are correlated, it is possible for a point to be unremarkable when seen along one or two axes but still be an outlier by violating the correlation.

**Cronbach’s \( \alpha \)**

Cronbach’s \( \alpha \) is defined as follows:

$$\alpha = \frac{k c}{v + (k-1) c}$$

where

- \( k = \text{the number of items in the scale} \)
- \( c = \text{the average covariance between items} \)
- \( v = \text{the average variance between items} \)

If the items are standardized to have a constant variance, the formula becomes

$$\alpha = \frac{k (r)}{1 + (k-1) r}$$

where

- \( r = \text{the average correlation between items} \)

The larger the overall \( \alpha \) coefficient, the more confident you can feel that your items contribute to a reliable scale or test. The coefficient can approach 1.0 if you have many highly correlated items.
The purpose of principal component analysis is to derive a small number of independent linear combinations (principal components) of a set of measured variables that capture as much of the variability in the original variables as possible. Principal component analysis is a dimension-reduction technique, as well as an exploratory data analysis tool. Principal component analysis is also useful for constructing predictive models, as in principal components analysis regression (also known as PCA regression or PCR).

For data with a very large number of variables, the Principal Components platform provides an estimation method called the Wide method. The Wide method enables you to calculate principal components in short computing times. These principal components can then be used in PCA regression.

For data that contain mostly zeros, also called sparse data, the Principal Components platform provides the Sparse estimation method. Similar to the Wide method, the Sparse method calculates principal components in short computing times. Unlike the Wide method, the Sparse method calculates a fixed, user-defined number of principal components rather than the full set.

The Principal Components platform also supports factor analysis. JMP offers several types of orthogonal and oblique factor analysis-style rotations to help interpret the extracted components. For factor analysis, see the “Factor Analysis” chapter on page 221.

Overview of Principal Component Analysis Platform

A principal component analysis models the variation in a set of variables in terms of a smaller number of independent linear combinations (principal components) of those variables.

If you want to see the arrangement of points across many correlated variables, you can use principal component analysis to show the most prominent directions of the high-dimensional data. Using principal component analysis reduces the dimensionality of a set of data. Principal components is a way to picture the structure of the data as completely as possible by using as few variables as possible.

For \( p \) variables, this is how the \( p \) principal components are formed:

- The first principal component is the linear combination of the standardized original variables that has the greatest possible variance.
- Each subsequent principal component is the linear combination of the variables that has the greatest possible variance and is uncorrelated with all previously defined components.

Each principal component is calculated by taking a linear combination of an eigenvector of the correlation matrix (or covariance matrix or sum of squares and cross products matrix) with the variables. The eigenvalues represent the variance of each component.

The Principal Components platform enables you to conduct your analysis on the correlation matrix, the covariance matrix, or the unscaled data. You can also conduct Factor Analysis within the Principal Components platform. See the “Factor Analysis” chapter on page 221.

Example of Principal Component Analysis

To view an example Principal Component Analysis report for a data table for two factors:

1. Select Help > Sample Data Library and open Solubility.jmp.
2. Select Analyze > Multivariate Methods > Principal Components.
3. Select all of the continuous columns and click Y, Columns.
4. Keep the default Estimation Method and then click OK.
The report gives the eigenvalues and a bar chart of the percent of the variation accounted for by each principal component. In this example, the first principal component accounts for almost 80% of the variation in the data. Together, the first two principal components account for almost all of the variation in the data (95.5%). There is a Score Plot and a Loadings Plot as well. See “Principal Components Report” on page 62.
Launch the Principal Components Platform

Launch the Principal Components platform by selecting **Analyze > Multivariate Methods > Principal Components**. Principal Component analysis is also available using the Multivariate and the Scatterplot 3D platforms.

The example described in “Example of Principal Component Analysis” on page 57 uses all of the continuous variables from the *Solubility.jmp* sample data table.

**Figure 4.3** Principal Components Launch Window

For more information about the options in the Select Columns red triangle menu, see *Using JMP*.

**Y, Columns**  The variables to analyze for components.

**Z, Supplementary Variable**  The supplementary variables to be displayed. Supplementary variables are not included in the calculation of principal components and including them does not affect the results. Supplementary variables that are continuous can be projected on to the loading plot and used to enhance interpretation.

**Weight**  Identifies one column whose numeric values assign a weight to each row in the analysis.

*Note:* The Weight role is ignored for the Wide and Sparse estimation methods.

**Freq**  Identifies one column whose numeric values assign a frequency to each row in the analysis.

*Note:* The Freq role is ignored for the Wide and Sparse estimation methods.
By Creates a Principal Component report for each value specified by the By column so that you can perform separate analyses for each group.

Estimation Method Specifies the method for calculating the correlations. Several of these methods address the treatment of missing data.

Default The Default option uses either the Row-wise, Pairwise, or REML methods. A JMP Alert also recommends switching to the Wide method when appropriate.

- **Row-wise** estimation is used for data tables with no missing values.
- **Pairwise** estimation is used for data tables with missing values and either more than 10 columns, more than 5,000 rows, or more columns than rows.
- **REML** estimation is used otherwise.
- **Wide** estimation is recommended by a JMP Alert window for data tables with more than 500 columns and more columns than rows. This is because computation time can be considerable when you use the other methods with a large number of columns. Click **Wide** to switch to the Wide method or click **Continue** to use the method you originally selected.

REML Restricted maximum likelihood (REML) estimation uses all of the data, even if missing values are present. Due to a bias-correction factor, this method is slow if the dataset is large and there are many missing values. Therefore, REML is most useful for smaller datasets. If there are no missing cells in the data, then the REML and ML estimates are equivalent and equal to the sample covariance matrix. If there are missing cells, REML’s variance and covariance estimates are less biased than the estimates from ML estimation. For statistical details, see “REML” on page 75.

ML Maximum likelihood (ML) estimation uses all of the data, even if missing values are present. Because the estimates from ML are generated quickly, this method is most useful for large data tables with missing data.

Robust Robust estimation uses all of the data, even if missing values are present. This method down-weights extreme values and is therefore useful for data tables that might have outliers. For statistical details, see “Robust” on page 47 in the “Correlations and Multivariate Techniques” chapter.

Row-wise Row-wise estimation calculates the Pearson correlation for each pair of columns. For statistical details, see “Pearson Product-Moment Correlation” on page 48 in the “Correlations and Multivariate Techniques” chapter. Row-wise estimation does not use observations with missing values. This method is useful for excluding any observations that have missing data.
Pair-wise estimation uses all of the data, even if missing values are present. This estimation method calculates Pearson correlations for each pair of columns using all observations with nonmissing values for those two columns. For statistical details, see “Pearson Product-Moment Correlation” on page 48 in the “Correlations and Multivariate Techniques” chapter. Pair-wise estimation is most useful when a data table has missing values and either more columns than rows, more than 10 columns, or more than 5,000 rows.

Wide estimation does not use observations with missing values, so rows that contain missing cells are deleted before the method is applied. This estimation method uses an algorithm based on the full singular value decomposition. The algorithm avoids calculating the covariance matrix and is therefore computationally efficient. It is useful when you have a very large number of columns in your data. For statistical details, see “Wide” on page 75.

Sparse estimation uses all of the data, even if missing values are present. This estimation method uses an algorithm based on the partial singular value decomposition, which computes only the first specified number of singular values and singular value vectors. The algorithm avoids calculating the covariance matrix, as well as unnecessary principal components and is therefore computationally efficient. It is useful when your data are sparse, meaning they contain many zeros, or when there are a large number of columns in the data. For statistical details, see “Sparse” on page 76.

**Note:** If you select REML, ML, or Robust and your data table contains more columns than rows and has missing values, JMP switches the Estimation Method to Pairwise.

**Number of Components** (Available only when Sparse is specified as the Estimation Method.) Specifies the number of components to be estimated. Typically, the Number of Components is much smaller than the dimension of your data.

**Missing Data**

The different estimation methods are equipped to handle missing data in a variety of ways. You can also estimate missing values in the following ways:

- Use the Impute Missing Data option found under **Multivariate Methods > Multivariate**. See “Impute Missing Data” on page 45 in the “Correlations and Multivariate Techniques” chapter.

- Use the Multivariate Normal Imputation or Multivariate SVD Imputation utilities found in **Analyze > Screening > Explore Missing Values**. See *Predictive and Specialized Modeling*. 

Principal Components Report

If you selected any estimation method other than Wide or Sparse, the Principal Components: on Correlations report initially appears. (The title of this report changes if you select on Covariances or on Unscaled for the Principal Components option in the Principal Components red triangle menu.)

If you select the Wide method, the Wide Principal Components report appears. If you select the Sparse method, the Sparse Principal Components report appears.

The initial Principal Components report is for an analysis on Correlations. It summarizes the variation of the specified Y variables with principal components (Figure 4.4). You can switch to an analysis based on the covariance matrix or unscaled data by selecting the Principal Components option from the red triangle menu.

Based on your selection, the principal components are derived from an eigenvalue decomposition of one of the following:

- the correlation matrix
- the covariance matrix
- the sum of squares and cross products matrix for the unscaled and uncentered data

The details in the report show how the principal components absorb the variation in the data. The principal component points are derived from the eigenvector linear combination of the variables.

Figure 4.4 Principal Components on Correlations Report

The report gives the eigenvalues and a bar chart of the percent of the variation accounted for by each principal component. There is a Score Plot and a Loadings Plot as well. The eigenvalues indicate the total number of components extracted based on the amount of variance contributed by each component.
The Score Plot graphs each component’s calculated values in relation to the other, adjusting each value for the mean and standard deviation.

The Loadings Plot graphs the unrotated loading matrix between the variables and the components. The closer the value is to 1, the greater the effect of the component on the variable.

By default, the report shows the Score Plot and the Loadings Plot for the first two principal components. Use the list next to Select component to specify the principal components that are graphed on the Score Plot and the Loadings Plot.

### Principal Components Report Options

The Principal Components red triangle menu contains the following options:

**Note:** Some of the options are not available for the Wide or Sparse estimation methods.

**Principal Components**  (Not available for the Wide or Sparse estimation methods.) Enables you to create the principal components based on **Correlations**, **Covariances**, or **Unscaled**.

**Correlations**  (Not available for the Wide or Sparse estimation methods.) The matrix of correlations between the variables.

**Note:** The values on the diagonals are 1.0.

**Covariance Matrix**  (Not available for the Wide or Sparse estimation methods.) Shows or hides the covariances of the variables.

**Eigenvalues**  Lists the eigenvalue that corresponds to each principal component in order from largest to smallest. The eigenvalues represent a partition of the total variation in the multivariate sample.

The scaling of the eigenvalues depends on which matrix you select for extraction of principal components:

- For the on Correlations option, the eigenvalues are scaled to sum to the number of variables.
- For the on Covariances options, the eigenvalues are not scaled.
- For the on Unscaled option, the eigenvalues are divided by the total number of observations.

If you select the **Bartlett Test** option from the red triangle menu, hypothesis tests (Figure 4.6) are given for each eigenvalue (Jackson 2003).
Principal Components Chapter 4

Figure 4.5  Eigenvalues

**Eigenvectors**  Shows or hides a table of the eigenvectors for each of the principal components, in order, from left to right. Using these coefficients to form a linear combination of the original variables produces the principal component variables. Following the standard convention, eigenvectors have norm 1.

*Note:* The number of eigenvectors shown is equal to the rank of the correlation matrix, or, if the Sparse method is selected, the number of components specified on the launch window.

**Bartlett Test**  (Not available for the Wide or Sparse estimation methods.) Shows or hides the results of the homogeneity test (appended to the Eigenvalues table). The test determines whether the eigenvalues have the same variance by calculating the Chi-square, degrees of freedom (DF), and the $p$-value (prob > ChiSq) for the test. See Bartlett (1937, 1954).

Figure 4.6  Bartlett Test

**Loading Matrix**  Shows or hides a table of the loadings for each component. These values are graphed in the loading plot. The degree of transparency for the table values indicates the distance of the absolute loading value from zero. Absolute loading values that are closer to zero are more transparent than absolute loading values that are farther from zero.

If you specify a supplementary variable, an additional table of coordinates is shown for each supplementary continuous variable and each level of supplementary categorical variable. These values are graphed in the loading plot for continuous supplementary variables.

The scaling of the loadings and coordinates depends on which matrix you select for extraction of principal components:

- For the on Correlations option, the $i^{\text{th}}$ column of loadings is the $i^{\text{th}}$ eigenvector multiplied by the square root of the $i^{\text{th}}$ eigenvalue. The $i,j^{\text{th}}$ loading is the correlation between the $i^{\text{th}}$ variable and the $j^{\text{th}}$ principal component.
For the on Covariances option, the $j^{th}$ entry in the $i^{th}$ column of loadings is the $i^{th}$ eigenvector multiplied by the square root of the $i^{th}$ eigenvalue and divided by the standard deviation of the $j^{th}$ variable. The $i,j^{th}$ loading is the correlation between the $i^{th}$ variable and the $j^{th}$ principal component.

For the on Unscaled option, the $j^{th}$ entry in the $i^{th}$ column of loadings is the $i^{th}$ eigenvector multiplied by the square root of the $i^{th}$ eigenvalue and divided by the standard error of the $j^{th}$ variable. The standard error of the $j^{th}$ variable is the $j^{th}$ diagonal entry of the sum of squares and cross products matrix divided by the number of rows ($X'X/n$).

**Note:** When you are analyzing the unscaled data, the $i,j^{th}$ loading is not the correlation between the $i^{th}$ variable and the $j^{th}$ principal component.

**Formatted Loading Matrix** Shows or hides a table of the loadings for each component. The table is sorted in order of decreasing loadings on the first principal component. Therefore, the variables are listed in the order of decreasing loadings on the first component.

**Figure 4.7** Formatted Loading Matrix

**Suppress Absolute Loading Value Less Than** The value that determines which loadings are unavailable in the Formatted Loading Matrix report. You can use the text box or the slider to dim the loadings whose absolute values fall below the selected value.

**Dim Text** The transparency of the dimmed values in the Formatted Loading Matrix report. You can use the text box or the slider to set the degree of transparency for the dimmed loadings. The degree of transparency ranges from 0 to 1, where lower values are more transparent than higher values. For example, setting the transparency to 0 completely removes the unavailable loadings from the matrix, while the loadings are still available when you set the transparency to 1.

**Squared Cosines of Variables** Shows or hides a table that contains the squared cosines of variables. If you specify a supplementary variable, an additional table of squared cosines of supplementary variables is shown. The sum of the squared cosine values across principal components is equal to one for each variable. The squared cosines enable you to see how well the variables are represented by the principal components. You can also determine how many principal components are necessary to represent certain variables.
This option also shows a plot of the squared cosines for the first three principal components.

**Note:** If the Sparse estimation method is used and the number of components selected is less than three, only the specified number of components are displayed in the plot.

**Partial Contribution of Variables** Shows or hides a table that contains the partial contributions of variables. The partial contributions enable you to see the percentage that each variable contributes to each principal component. This option also shows a plot of the partial contributions for the first three principal components.

**Note:** If the Sparse estimation method is used and the number of components selected is less than three, only the specified number of components are displayed in the plot.

**Summary Plots** Shows or hides the summary information produced in the default report. This summary information includes a plot of the eigenvalues, a score plot, and a loading plot. By default, the report shows the score and loading plots for the first two principal components. There are options in the report to specify which principal components to plot. See “Principal Components Report” on page 62.

**Note:** If your data contain missing values, the imputed scores are plotted on the score plot.

**Tip:** Select the tips of arrows in the loading plot to select the corresponding columns in the data table. Press Ctrl and click an arrow tip to deselect the column.

**Biplot** Shows or hides a plot that overlays the score plot and the loading plot for the specified number of components.

**Note:** If your data contain missing values, the imputed scores are plotted on the Biplot.
Figure 4.8 Biplot

Note: The score plot markers are dots and the loading plot markers are diamonds.

**Scatterplot Matrix** Shows or hides a matrix of score and loading plots for a specified number of principal components. The scatterplot matrix arranges both the score plots and the loading plots in one space. The score plots have a yellow shaded background. The loading plots have a blue shaded background.

Note: If your data contain missing values, the imputed scores are plotted in the Scatterplot Matrix.
Figure 4.9 Scatterplot Matrix

Note: The loading plot matrix displayed in the Scatterplot Matrix is the transpose of the loading plot matrix that you obtain when you select the Loading Plot option.

Scree Plot  Shows or hides a graph of the eigenvalue for each component. This scree plot helps in visualizing the dimensionality of the data space.

Score Plot  Shows or hides a matrix of scatterplots of the scores for pairs of principal components for the specified number of components. This plot is shown in Figure 4.4 (left-most plot).
**Loading Plot**  Shows or hides a matrix of two-dimensional representations of factor loadings for the specified number of components. The loading plot labels variables if the number of variables is 30 or fewer. If there are more than 30 variables, the labels are off by default. This information is shown in Figure 4.4 (right-most plot).

**Tip:** Select the tips of arrows in the loading plot to select the corresponding columns in the data table. Press Ctrl and click an arrow tip to deselect the column.

**Score Plot with Imputation**  (Not available for the Wide or Sparse estimation methods.) Imputes any missing values and creates a score plot. This option is available only if there are missing values.

**3D Score Plot**  (Not available for the Wide or Sparse estimation methods.) Shows or hides a 3D scatterplot of any three principal component scores. When you first invoke the command, the first three principal components are presented.

**Note:** If your data contain missing values, the imputed scores are plotted on the 3D Score Plot.

Figure 4.10  Scatterplot 3D Score Plot
**Plot Source**  The source of the data points in the plot. The available options are Principal Components, Rotated Principal Components, and Data Columns.

**Axis Controls**  The contents of each axis. If the Principal Components option or the Rotated Components option is selected, the options for the Axis Controls are principal components. If the Data Columns option is selected, the options are variables from the analysis.

**Cycle Button**  Cycles through all axis content possibilities.

The variables show as rays in the plot. These rays, called *biplot rays*, approximate the variables as a function of the principal components on the axes. If there are only two or three variables, the rays represent the variables exactly. The ray corresponds to the principal component loadings.

**Score Ellipses**  Shows or hides ellipses on the summary score plot for each pair of principal components. The ellipses are constructed as either confidence ellipses based on the alpha level or a control limit ellipses based on how far the observations are from the center. By default, the ellipses are 95% confidence ellipses.

**Score Ellipse Coverage**  Displays a submenu that enables you to change how the score ellipses are constructed. Specify the score ellipses by confidence level or the distance from the center in terms of $k$-sigma. The relationship between the confidence level, $p$, and $k$-sigma is $p = 1 - \exp(-k^2/2)$.

**Display Options**

**Arrow Lines**  Enables you to show or hide arrows on all plots that can display arrows. Arrows are shown if the number of variables is 1000 or fewer. If there are more than 1000 variables, the arrows are off by default.

**Show Supplementary Variable**  (Available only if you specify a supplementary variable.) Shows or hides the arrow lines for continuous supplementary variables or label markers for categorical supplementary variables in the biplot, score plot, and loading plots.

**Outlier Analysis**  Shows or hides the Outlier Analysis report, which enables you to detect outliers in the data through $T^2$ and contribution statistics. See “Outlier Analysis” on page 73.

**Factor Analysis**  (Not available for the Wide or Sparse estimation methods.) Performs factor analysis-style rotations of the principal components, or factor analysis. See the “Factor Analysis” chapter on page 221.

**Cluster Variables**  (Not available for the Wide or Sparse estimation methods.) Performs a cluster analysis on the variables by dividing the variables into non-overlapping clusters. Variable clustering provides a method for grouping similar variables into representative
groups. Each cluster can then be represented by a single component or variable. The component is a linear combination of all variables in the cluster. Alternatively, the cluster can be represented by the variable identified to be the most representative member in the cluster. See the “Cluster Variables” chapter on page 345.

**Note:** Cluster Variables uses correlation matrices for all calculations, even when you select the on Covariance or on Unscaled options.

**Save Principal Components** Saves the number of principal components that you specify to the data table with a formula for computing each component. The formula cannot evaluate rows with missing values.

The calculation for the principal components depends on which matrix you select for extraction of principal components:

- For the on Correlations option, the $i^{\text{th}}$ principal component is a linear combination of the centered and scaled observations using the entries of the $i^{\text{th}}$ eigenvector as coefficients.
- For the on Covariances options, the $i^{\text{th}}$ principal component is a linear combination of the centered observations using the entries of the $i^{\text{th}}$ eigenvector as coefficients.
- For the on Unscaled option, the $i^{\text{th}}$ principal component is a linear combination of the raw observations using the entries of the $i^{\text{th}}$ eigenvector as coefficients.

**Note:** If the specified number of components exceeds the rank of the correlation matrix, then the number of components saved is set to the rank of the correlation matrix.

**Save Predicteds** Saves the predicted variables, given the specified number of principal components, to new columns in the data table.

**Save DModX** Saves the observation distance to the principal components model (DModX), given the specified number of principal components, to a new column in the data table. Larger DModX values indicate mild to moderate outliers in the data. See “DModX Calculation” on page 76.

**Save Individual Squared Cosines** Saves the individual squared cosines, given the specified number of principal components, to new columns in the data table.

**Save Individual Partial Contributions** Saves the individual partial contributions, given the specified number of principal components, to new columns in the data table.

**Save Rotated Components** (Not available for the Wide or Sparse estimation methods.) Saves the rotated components to the data table, with a formula for computing the components. This option is available only after the Factor Analysis option is used. The formula cannot evaluate rows with missing values.
Save Principal Components with Imputation  (Not available for the Wide or Sparse estimation methods.) Imputes missing values, and saves the principal components to the data table. The column contains a formula for doing the imputation and computing the principal components. This option is available only if there are missing values.

Save Rotated Components with Imputation  (Not available for the Wide or Sparse estimation methods.) Imputes missing values and saves the rotated components to the data table. The column contains a formula for doing the imputation and computing the rotated components. This option is available only after the Factor Analysis option is used and if there are missing values.

Save Imputed Formulas  (Available only if the data table contains missing values.) For columns that contain missing values, saves new columns to the data table that contain the formulas used to estimate the missing values. The new columns are called Imputed_<Column Name>.

Publish Components Formulas  Creates a specified number of principal component formulas and saves them as formula column scripts in the Formula Depot platform. If a Formula Depot report is not open, this option creates a Formula Depot report. See Predictive and Specialized Modeling.

Publish DModX Formula  Saves the DModX formula based on a specified number of principal components as a formula column script in the Formula Depot platform. If a Formula Depot report is not open, this option creates a Formula Depot report. See Predictive and Specialized Modeling.

See Using JMP for more information about the following options:

Local Data Filter  Shows or hides the local data filter that enables you to filter the data used in a specific report.

Redo  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

Save Script  Contains options that enable you to save a script that reproduces the report to several destinations.

Save By-Group Script  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.
Outlier Analysis

Figure 4.11 Outlier Analysis Report

By default, the Outlier Analysis report displays the $T^2$ for $<A>$ Principal Components plot. The plot shows the $T^2$ value for each observation and horizontal lines at the Median and Upper Control Limit (UCL). For more information about how the $T^2$ values, median, and UCL are calculated, see “Calculations for Outlier Analysis” on page 77.

The $\alpha$ level used to calculate the UCL is displayed next to the plot. The number of outliers detected is shown below the plot. This number is the number of observations with $T^2$ values that are greater than the UCL.

**Tip:** Hover over a point in the $T^2$ Plot to view the $T^2$ Contribution Proportion Plot for that observation. Click the $T^2$ Contribution Proportion Plot to add it to the report window.

### Outlier Analysis Report Options

- **$T^2$ Plot**  
  Shows or hides the $T^2$ plot. On by default.

- **Contribution Heat Map**  
  Shows or hides a heat map of the $T^2$ contribution values for all observations.

- **Contribution Proportions Heat Map**  
  Shows or hides a heat map of the $T^2$ contribution values for all observations expressed as a proportion of the individual row’s $T^2$. The proportions for an individual row are obtained by computing the square of the contribution and dividing by the sum of the squares of all contributions for that individual row.

- **Contribution Plots for Selected Samples**  
  (Available only if one or more points is selected in the $T^2$ plot.) Shows a report with a $T^2$ contribution plot for each selected sample. A $T^2$
Principal Components

Chapter 4
Multivariate Methods

Principal Components Report Options

contribution plot shows the contribution of each variable to the sample’s $T^2$ statistic. For more information about how the contributions are calculated, see “Calculations for Outlier Analysis” on page 77. Use contribution plots to investigate outliers. The variables with the largest positive or negative contributions are those that contribute most to a sample having a large $T^2$ value. See “Contribution Plots Report Options” on page 74 for information on red triangle menu options.

**Contribution Proportion Plots for Selected Samples**  (Available only if one or more points is selected in the $T^2$ plot.) Shows a report with a $T^2$ contribution proportion plot for each selected sample. A $T^2$ contribution proportion plot shows the contribution values for the selected observations expressed as a proportion of the individual row’s $T^2$. This is a different presentation of the information found in the Contribution Proportions Heat Map. See “Contribution Plots Report Options” on page 74 for information on red triangle menu options.

**Normalized DModX Plot**  (Available only when the number of components is less than the number of variables.) Shows or hides a plot of the Normalized DModX values. DModX values are useful for detecting moderate outliers in the data.

**Number of Components**  Enables you to specify the number of principal components used in the $T^2$ and $T^2$ contribution statistics. When you change the number of components, the $T^2$ plot, heap map, and normalized DModX plot automatically update.

**Set $\alpha$ level**  Enables you to specify the $\alpha$ level.

**Save $T^2$**  Saves the $T^2$ values to a new column in the data table.

**Save Contributions**  Saves the $T^2$ Contributions to new columns in the data table. There is one column for each Y variable.

**Save Normalized DModX**  (Available only when the number of components is less than the number of variables.) Saves the normalized DModX values to a new column in the data table.

**Contribution Plots Report Options**

The $T^2$ Contribution Plots for Selected Samples, $T^2$ Contribution Proportion Plots for Selected Samples, and $T^2$ Mean Contribution Proportion Plots for Selected Samples contain the following red triangle menu options.

**Bar Label**  Displays a submenu of options to label the bars in the contribution plot. The label options are No Label, Label by Value, and Label by Column.

**Remove Plot**  Removes the contribution plot from the report.
Control Charts for Selected Items  (Available only if one or more bar segments are selected in the contribution plot.) Opens a Control Chart Builder window, with control chart results for each of the selected processes and groups.

Tip: You can also view the control chart by hovering over a bar segment in a contribution plot. Click the control chart to open the Control Chart Builder window.

Statistical Details for the Principal Components Analysis Platform

• “Estimation Methods”
• “DModX Calculation”
• “Calculations for Outlier Analysis”

Estimation Methods

REML

REML (restricted maximum likelihood) estimates are less biased than the ML (maximum likelihood) estimation method when the data contains missing values. The REML method maximizes marginal likelihoods based on error contrasts. The REML method is often used for estimating variances and covariances. The REML method in the Principal Components platform is the same as the REML estimation of mixed models for repeated measures data with an unstructured covariance matrix. See the documentation for SAS PROC MIXED about REML estimation of mixed models.

Wide

The Wide method uses a computationally efficient algorithm that avoids calculating the covariance matrix. The algorithm is based on the singular value decomposition. Consider the following notation:

• \( n \) = number of rows
• \( p \) = number of variables
• \( X = n \times p \) matrix of data values

The number of nonzero eigenvalues, and consequently the number of principal components, equals the rank of the correlation matrix of \( X \). The number of nonzero eigenvalues cannot exceed the smaller of \( n \) and \( p \).
When you select the Wide method, the data are standardized. To standardize a value, subtract its mean and divide by its standard deviation. Denote the \( n \) by \( p \) matrix of standardized data values by \( X_s \). Then the covariance matrix of the standardized data is the correlation matrix of \( X \) and it is defined as follows:

\[
Cov = X_s'X_s / (n - 1)
\]

Using the singular value decomposition, \( X_s \) is written as \( U\text{Diag}(\Lambda)V' \). This representation is used to obtain the eigenvectors and eigenvalues of \( X_s'X_s \). The principal components, or scores, are given by \( X_sV \). For additional background information, see “Wide Linear Methods and the Singular Value Decomposition” on page 361 in the “Statistical Details” appendix.

**Sparse**

Similar to the Wide method, the Sparse method is based on singular value decomposition. Therefore, the algorithm for the Sparse method avoids computing the covariance matrix and is computationally efficient.

Consider the same notation and standardization of \( X \) that is described in “Wide” on page 75. The correlation matrix of \( X \) is represented by the covariance matrix of \( X_s \):

\[
Cov(X_s) = X_s'X_s / (n - 1)
\]

The Sparse method differs from the Wide method in the calculation of the singular value decomposition. The Wide method performs a full singular value decomposition. However, the Sparse method uses an algorithm that computes only the first specified number of singular values and singular vectors in the singular value decomposition. Therefore, only the first specified number of eigenvalues and principal components are returned. For more information about the algorithm, see Baglama and Reichel (2005).

**DModX Calculation**

DModX is the observed distance to the principal components model and is defined as follows:

\[
\text{DModX} = \sqrt{\frac{\sum_{ik} e_{ik}^2}{K - A}}
\]

where

- \( e_{ik} \) = the residuals from the model
- \( K \) = the number of variables
- \( A \) = the number of principal components

Larger values of DModX indicate mild to moderate outliers in the data.
Calculations for Outlier Analysis

The calculations in the Outlier Analysis report use the following notation:

\[ n = \text{number of observations} \]
\[ A = \text{number of principal components} \]
\[ X_{ci} = \text{the standardized data for the } i^{\text{th}} \text{ observation} \]

**T^2 Statistic**

The \( T^2 \) statistic for the \( i^{\text{th}} \) observation is calculated as follows:

\[
T_i^2 = X_{ci} P_A L^{-1} P_A^T X_{ci}^T
\]

where \( P_A \) is a matrix containing the first \( A \) eigenvectors and \( L \) is a diagonal matrix containing the first \( A \) eigenvalues.

The median and UCL for the \( T^2 \) plot are calculated as follows:

\[
CL_{T^2, q} = \frac{(n-1)^2}{n} \beta\left[q, \frac{A}{2}, \frac{n-A-1}{2}\right]
\]

where

\[
\beta\left[q, \frac{A}{2}, \frac{n-A-1}{2}\right] = \text{the } q^{\text{th}} \text{ quantile of the Beta}\left(\frac{A}{2}, \frac{n-A-1}{2}\right) \text{ distribution.}
\]

To calculate the median, use \( q = 0.5 \). To calculate the UCL, use \( q = (1 - \alpha) \).

**Contribution Statistic**

The vector of \( T^2 \) contribution statistics for the \( i^{\text{th}} \) observation is calculated as follows:

\[
\text{con}_i = X_{ci} P_A L^{-1/2} P_A^T
\]

**Note:** The sum of the squared contributions for an individual is equal to \( T_i^2 \) for that individual.
Discriminant analysis predicts membership in a group or category based on observed values of several continuous variables. Specifically, discriminant analysis predicts a classification (X) variable (categorical) based on known continuous responses (Y). The data for a discriminant analysis consist of a sample of observations with known group membership together with their values on the continuous variables.

For example, you might attempt to classify loan applicants into three loan categories (X) based on expected profitability: low interest rate loan, long term loan, or no loan. You might use continuous variables such as current salary, years in current job, age, and debt burden, (Ys) to predict an individual’s most profitable loan category. You could build a predictive model to classify an individual into a loan category using discriminant analysis.

Features of the Discriminant platform include the following:

- A stepwise selection option to help choose variables that discriminate well.
- A choice of fitting methods: Linear, Quadratic, Regularized, and Wide Linear.
- A canonical plot and a misclassification summary.
- Discriminant scores and squared distances to each group.
- Options to save prediction distances and probabilities to the data table.

Overview of the Discriminant Analysis Platform

Discriminant analysis attempts to classify observations described by values on continuous variables into groups. Group membership, defined by a categorical variable \( X \), is predicted by the continuous variables. These variables are called covariates and are denoted by \( Y \).

Discriminant analysis differs from logistic regression. In logistic regression, the classification variable is random and predicted by the continuous variables. In discriminant analysis, the classifications are fixed, and the covariates (\( Y \)) are realizations of random variables. However, in both techniques, the categorical value is predicted by the continuous variables.

The Discriminant platform provides four methods for fitting models. All methods estimate the distance from each observation to each group’s multivariate mean (centroid) using Mahalanobis distance. You can specify prior probabilities of group membership and these are accounted for in the distance calculation. Observations are classified into the closest group.

Fitting methods include the following:

- **Linear**—Assumes that the within-group covariance matrices are equal. The covariate means for the groups defined by \( X \) are assumed to differ.
- **Quadratic**—Assumes that the within-group covariance matrices differ. This requires estimating more parameters than does the Linear method. If group sample sizes are small, you risk obtaining unstable estimates.
- **Regularized**—Provides two ways to impose stability on estimates when the within-group covariance matrices differ. This is a useful option if group sample sizes are small.
- **Wide Linear**—Useful in fitting models based on a large number of covariates, where other methods can have computational difficulties. It assumes that all covariance matrices are equal.

Example of Discriminant Analysis

In Fisher’s Iris data set, four measurements are taken from a sample of Iris flowers consisting of three different species. The goal is to identify the species accurately using the values of the four measurements.

1. Select **Help > Sample Data Library** and open Iris.jmp.
2. Select **Analyze > Multivariate Methods > Discriminant**.
3. Select Sepal length, Sepal width, Petal length, and Petal width and click **Y, Covariates**.
4. Select Species and click **X, Categories**.
5. Click **OK**.
Figure 5.2 Discriminant Analysis Report Window

Because there are three classes for Species, there are two canonical variables. In the Canonical Plot, each observation is plotted against the two canonical coordinates. The plot shows that these two coordinates separate the three species. Since there was no validation set, the Score Summaries report shows a panel for the Training set only. When there is no validation set, the entire data set is considered the Training set. Of the 150 observations, only three are misclassified.
Launch the Discriminant Analysis Platform

Launch the Discriminant platform by selecting Analyze > Multivariate Methods > Discriminant.

Figure 5.3 Discriminant Launch Window for Iris.jmp

For more information about the options in the Select Columns red triangle menu, see Using JMP.

Note: The Validation button appears in JMP Pro only. In JMP, you can define a validation set using excluded rows. See “Validation in JMP and JMP Pro” on page 111.

Y, Covariates  Columns that contain the continuous variables used to classify observations into categories.

X, Categories  A column that contains the categories or groups into which observations are to be classified.

Weight  A column whose values assign a weight to each row for the analysis.

Freq  A column whose values assign a frequency to each row for the analysis. In general terms, the effect of a frequency column is to expand the data table, so that any row with integer frequency \( k \) is expanded to \( k \) rows. You can specify fractional frequencies.

Validation  A numeric column that defines the validation sets. This column should contain at most three distinct values:

- If there are two values, the smaller value defines the training set and the larger value defines the validation set.
- If there are three values, these values define the training, validation, and test sets in order of increasing size.
If the validation column has more than three levels, the rows that contain the smallest three values define the validation sets. All other rows are excluded from the analysis.

The Discriminant platform uses the validation column to train and evaluate the model, unless Stepwise Variable Selection is used. If the Stepwise Variable Selection option is selected in the launch, the Discriminant platform uses the validation column to train and tune the model or to train, tune, and evaluate the model. For more information about validation, see “Validation in JMP Modeling” on page 541 in the “Statistical Details” chapter.

**Tip:** If Stepwise Variable Selection is not used, the validation column should contain only two distinct values.

If you click the Validation button with no columns selected in the Select Columns list, you can add a validation column to your data table. For more information about the Make Validation Column utility, see the *Predictive and Specialized Modeling*.

**By** Performs a separate analysis for each level of the specified column.

**Stepwise Variable Selection** Performs stepwise variable selection using covariance analysis and \( p \)-values. See “Stepwise Variable Selection” on page 85.

If you have specified a validation set, statistics for the validation set also appear. The validation set statistics are used to determine how many steps to take if you use the Go button.

**Note:** This option is not provided for the Wide Linear discriminant method.

**Discriminant Method** Provides four methods for conducting discriminant analysis. See “Discriminant Methods” on page 88.

**Shrink Covariances** Shrinks the off-diagonal elements of the pooled within-group covariance matrix and the within-group covariance matrices. This can improve stability and reduce the variance of prediction. See “Shrink Covariances” on page 91.

**Advanced Options** Contains the following options:

**Uncentered Canonical** Suppresses centering of canonical scores for compatibility with older versions of JMP.

**Use Pseudoinverses** Uses Moore-Penrose pseudoinverses in the analysis when the covariance matrix is singular. The resulting scores involve all covariates. If left unchecked, the analysis drops covariates that are linear combinations of covariates that precede them in the list of \( Y, \) Covariates.

**Cross Validate by Excluded Rows** Specifies that the excluded rows form a validation set for which statistics of fit are calculated.
Chapter 5
Multivariate Methods

Discriminant Analysis

Launch the Discriminant Analysis Platform

Stepwise Variable Selection

Note: Stepwise Variable Selection is not available for the Wide Linear method.

If you select the Stepwise Variable Selection option in the launch window, the Discriminant Analysis report opens, showing the Column Selection panel. You can perform stepwise analysis using the buttons to select variables or selecting them manually with the Lock and Entered check boxes. Based on your selection $F$ ratios and $p$-values are updated. For more information about how these are updated, see “Updating the F Ratio and Prob>F” on page 85.

If you specify any type of validation set, a Go button appears. When you click Go, JMP uses the validation set statistics to determine how many steps to take.

Figure 5.4 Column Selection Panel for Iris.jmp with a Validation Set

Updating the F Ratio and Prob>F

When you enter or remove variables from the model, the F Ratio and Prob>F values are updated based on an analysis of covariance model with the following structure:

- The covariate under consideration is the response.
- The covariates already entered into the model are predictors.
- The group variable is a predictor.

The values for F Ratio and Prob>F given in the Stepwise report are the $F$ ratio and $p$-value for the analysis of covariance test for the group variable. The analysis of covariance test for the group variable is an indicator of its discriminatory power relative to the covariate under consideration.

Statistics

Columns In  The number of columns currently selected for entry into the discriminant model.

Columns Out The number of columns currently available for entry into the discriminant model.
Smallest P to Enter The smallest $p$-value among the $p$-values for all covariates available to enter the model.

Largest P to Remove The largest $p$-value among the $p$-values for all covariates currently selected for entry into the model.

Validation Entropy RSquare Entropy RSquare for the validation set. Larger values indicate better fit. An Entropy RSquare value of 1 indicates that the classifications are perfectly predicted. Because uncertainty in the predicted probabilities is typical for discriminant models, Entropy RSquare values tend to be small.

See “Entropy RSquare” on page 99. Available only if a validation set is used.

Note: It is possible for the Validation Entropy RSquare to be negative.

Validation Misclassification Rate Misclassification rate for the validation set. Smaller values indicate better classification. Available only if a validation set is used.

Buttons

Step Forward Enters the most significant covariate from the covariates not yet entered. If a validation set is used, the Prob>F values are based on the training set.

Step Backward Removes the least significant covariate from the covariates entered but not locked. If a validation set is used, Prob>F values are based on the training set.

Enter All Enters all covariates by checking all covariates that are not locked in the Entered column.

Remove All Removes all covariates that are not locked by deselecting them in the Entered column.

Apply this Model Produces a discriminant analysis report based on the covariates that are checked in the Entered columns. The Select Columns outline is closed and the Discriminant Analysis window is updated to show analysis results based on your selected Discriminant Method.

Tip: After you click Apply this Model, the columns that you select appear at the top of the Score Summaries report.

Go Enters covariates in forward steps until the Validation Entropy RSquare begins to decrease. Entry terminates when two forward steps are taken without improving the Validation Entropy RSquare. Available only with excluded rows in JMP or a validation column in JMP Pro.
Chapter 5
Multivariate Methods

Columns

**Lock** Forces a covariate to stay in its current state regardless of any stepping using the buttons.

Note the following:

- If you enter a covariate and then select **Lock** for that covariate, it remains in the model regardless of selections made using the control buttons. The **Entered** box for the locked covariate shows a dimmed check mark to indicate that it is in the model.

- If you select **Lock** for a covariate that is not Entered, it is not entered into the model regardless of selections made using the control buttons.

**Entered** Indicates which columns are currently in the model. You can manually select columns in or out of the model. A dimmed check mark indicates a locked covariate that has been entered into the model.

**Column** The covariate of interest.

**F Ratio** The $F$ ratio for a test for the group variable obtained using an analysis of covariance model. See “Updating the F Ratio and Prob>F” on page 85.

**Prob > F** The $p$-value for a test for the group variable obtained using an analysis of covariance model. See “Updating the F Ratio and Prob>F” on page 85.

Stepwise Example

For an illustration of how to use Stepwise, consider the Iris.jmp sample data table.

1. Select **Help > Sample Data Library** and open Iris.jmp.
2. Select **Analyze > Multivariate Methods > Discriminant**.
3. Select Sepal length, Sepal width, Petal length, and Petal width and click **Y, Covariates**.
4. Select Species and click **X, Categories**.
5. Select **Stepwise Variable Selection**.
6. Click **OK**.
7. Click **Step Forward** three times.

Three covariates are entered into the model. The Smallest P to Enter appears in the top panel. It is 0.0103288, indicating that the remaining covariate, Sepal length, might also be valuable in a discriminant analysis model for Species.
Figure 5.5 Stepped Model for Iris.jmp

8. Click **Apply This Model**.

   The Column Selection outline is closed. The window is updated to show reports for a fit based on the entered covariates and your selected discriminant method.

   Note that the covariates that you selected for your model are listed at the top of the Score Summaries report.

Figure 5.6 Score Summaries Report Showing Selected Covariates

**Discriminant Methods**

JMP offers these methods for conducting Discriminant Analysis: Linear, Quadratic, Regularized, and Wide Linear. The first three methods differ in terms of the underlying model. The Wide Linear method is an efficient way to fit a Linear model when the number of covariates is large.

**Note:** When you enter more than 500 covariates, a JMP Alert recommends that you switch to the Wide Linear method. This is because computation time can be considerable when you use the other methods with a large number of columns. Click **Wide Linear, Many Columns** to switch to the Wide Linear method. Click **Continue** to use the method you originally selected.
The Linear, Quadratic, and Regularized methods are illustrated in Figure 5.7. The methods are described here briefly. See “Saved Formulas” on page 112.

**Linear, Common Covariance**  Performs linear discriminant analysis. This method assumes that the within-group covariance matrices are equal. See “Linear Discriminant Method” on page 113.

**Quadratic, Different Covariances**  Performs quadratic discriminant analysis. This method assumes that the within-group covariance matrices differ. This method requires estimating
more parameters than the Linear method requires. If group sample sizes are small, you risk obtaining unstable estimates. See “Quadratic Discriminant Method” on page 114.

If a covariate is constant across a level of the X variable, then its related entries in the within-group covariance matrix have zero covariances. To enable matrix inversion, the zero covariances are replaced with the corresponding pooled within covariances. When this is done, a note appears in the report window identifying the problematic covariate and level of X.

**Tip:** A shortcoming of the quadratic method surfaces in small data sets. It can be difficult to construct invertible and stable covariance matrices. The Regularized method ameliorates these problems, still allowing for differences among groups.

**Regularized, Compromise Method** Provides two ways to impose stability on estimates when the within-group covariance matrices differ. This is a useful option when group sample sizes are small. See “Regularized, Compromise Method” on page 90 and “Regularized Discriminant Method” on page 116.

**Wide Linear, Many Columns** Useful in fitting models based on a large number of covariates, where other methods can have computational difficulties. This method assumes that all within-group covariance matrices are equal. This method uses a singular value decomposition approach to compute the inverse of the pooled within-group covariance matrix. See “Description of the Wide Linear Algorithm” on page 112.

**Note:** When you use the Wide Linear option, a few of the features that normally appear for other discriminant methods are not available. This is because the algorithm does not explicitly calculate the very large pooled within-group covariance matrix.

**Regularized, Compromise Method**

Regularized discriminant analysis is governed by two nonnegative parameters.

- The first parameter (*Lambda, Shrinkage to Common Covariance*) specifies how to mix the individual and group covariance matrices. For this parameter, 1 corresponds to Linear Discriminant Analysis and 0 corresponds to Quadratic Discriminant Analysis.
- The second parameter (*Gamma, Shrinkage to Diagonal*) is a multiplier that specifies how much deflation to apply to the non-diagonal elements (the covariances across variables). If you choose 1, then the covariance matrix is forced to be diagonal.

Assigning 0 to each of these two parameters is identical to requesting quadratic discriminant analysis. Similarly, assigning 1 to Lambda and 0 to Gamma requests linear discriminant analysis. Use Table 5.1 to help you decide on the regularization. See Figure 5.7 for examples of linear, quadratic, and regularized discriminant analysis.
Table 5.1  Regularized Discriminant Analysis

Shrink Covariances

In the Discriminant launch window, you can select the option to Shrink Covariances. This option is recommended when some groups have a small number of observations. Discriminant analysis requires inversion of the covariance matrices. Shrinking off-diagonal entries improves their stability and reduces prediction variance. The Shrink Covariances option shrinks the off-diagonal entries by a factor that is determined using the method described in Schafer and Strimmer (2005).

If you select the Shrink Covariances option with the Linear discriminant method in the launch window, this provides a shrinkage of the covariance matrices that is equivalent to the shrinkage provided by the Regularized discriminant method with appropriate Lambda and Gamma values. When you select the Shrink Covariances option and run your analysis, the Shrinkage report gives you an Overall Shrinkage value and an Overall Lambda value. To obtain the same analysis using the Regularized method, enter 1 as Lambda and the Overall Lambda from the Shrinkage report as Gamma in the Regularization Parameters window.

Discriminant Analysis Report

The Discriminant Analysis report provides discriminant results based on your selected Discriminant Method. The Discriminant Method and the Classification variable are shown at the top of the report. If you selected the Regularized method, its associated parameters are also shown.

You can change Discriminant Method by selecting the option from the Discriminant Analysis red triangle menu. The results in the report update to reflect the selected method.
Figure 5.8 Example of a Discriminant Analysis Report

The default Discriminant Analysis report contains the following sections:

- When you select the Wide Linear discriminant method, a Principal Components report appears. See “Principal Components” on page 92.
- The Canonical Plot shows the points and multivariate means in the two dimensions that best separate the groups. See “Canonical Plot and Canonical Structure” on page 93.
- The Discriminant Scores report provides details about how each observation is classified. See “Discriminant Scores” on page 97.
- The Score Summaries report provides an overview of how well observations are classified. See “Discriminant Scores” on page 97.

Principal Components

This report appears only for the Wide Linear method. Consider the following notation:

- Denote the \( n \times p \) matrix of covariates by \( Y \), where \( n \) is the number of observations and \( p \) is the number of covariates.
- For each observation in \( Y \), subtract the covariate mean and divide the difference by the pooled standard deviation for the covariate. Denote the resulting matrix by \( Y_s \).
The report gives the following:

**Number**  The number of eigenvalues extracted. Eigenvalues are extracted until Cum Percent is at least 99.99%, indicating that 99.99% of the variation has been explained.

**Eigenvalue**  The eigenvalues of the covariance matrix for $Y_s$, namely $(Y_s'Y_s)/(n - p)$, arranged in decreasing order.

**Cum Percent**  The cumulative sum of the eigenvalues as a percentage of the sum of all eigenvalues. The eigenvalues sum to the rank of $Y_s'Y_s$.

**Singular Value**  The singular values of $Y_s$ arranged in decreasing order.

**Canonical Plot and Canonical Structure**

The Canonical Plot is a biplot that describes the canonical correlation structure of the variables.

**Canonical Structure**

Each of the levels of the X, Categories column defines an indicator variable. A canonical correlation is performed between the set of indicator variables representing the categories and the covariates. Linear combinations of the covariates, called *canonical variables*, are derived. These canonical variables attempt to summarize the between-category variation.

The first canonical variable is the linear combination of the covariates that maximizes the multiple correlation between the category indicator variables and the covariates. The second canonical variable is a linear combination uncorrelated with the first canonical variable that maximizes the multiples correlation with the categories. If the X, Categories column has $k$ levels, then $k - 1$ canonical variables are obtained.

**Canonical Plot**

Figure 5.9 shows the Canonical Plot for a linear discriminant analysis of the data table Iris.jmp. The points have been colored by Species.
The biplot axes are the first two canonical variables. These define the two dimensions that provide maximum separation among the groups. Each canonical variable is a linear combination of the covariates. (See “Canonical Structure” on page 93.) The biplot shows how each observation is represented in terms of canonical variables and how each covariate contributes to the canonical variables.

- The observations and the multivariate means of each group are represented as points on the biplot. They are expressed in terms of the first two canonical variables.
  - The point corresponding to each multivariate mean is denoted by a plus (“+”) marker.
  - A 95% confidence level ellipse is plotted for each mean. If two groups differ significantly, the confidence ellipses tend not to intersect.
  - An ellipse denoting a 50% contour is plotted for each group. This depicts a region in the space of the first two canonical variables that contains approximately 50% of the observations, assuming normality.
- The set of rays that appears in the plot represents the covariates.
  - For each canonical variable, the coefficients of the covariates in the linear combination can be interpreted as weights.
  - To facilitate comparisons among the weights, the covariates are standardized so that each has mean 0 and standard deviation 1. The coefficients for the standardized covariates are called the canonical weights. The larger the canonical weight of a covariate, the greater its association with the canonical variable.
The length and direction of each ray in the biplot indicates the degree of association of the corresponding covariate with the first two canonical variables. The length of the rays is a multiple of the canonical weights.

The rays emanate from the point (0,0), which represents the grand mean of the data in terms of the canonical variables.

You can obtain the values of the weight coefficients by selecting Canonical Options > Show Canonical Details from the Discriminant Analysis red triangle menu. At the bottom of the Canonical Details report, click Standardized Scoring Coefficients. See “Standardized Scoring Coefficients” on page 107.

Modifying the Canonical Plot

Additional options enable you to modify the biplot:

- Show or hide the 95% confidence ellipses by selecting Canonical Options > Show Means CL Ellipses from the Discriminant Analysis red triangle menu.
- Show or hide the rays by selecting Canonical Options > Show Biplot Rays from the Discriminant Analysis red triangle menu.
- Drag the center of the biplot rays to other places in the graph. Specify their position and scaling by selecting Canonical Options > Biplot Ray Position from the Discriminant Analysis red triangle menu. The default Radius Scaling shown in the Canonical Plot is 1.5, unless an adjustment is needed to make the rays visible.
- Show or hide the 50% contours by selecting Canonical Options > Show Normal 50% Contours from the Discriminant Analysis red triangle menu.
- Color code the points to match the ellipses by selecting Canonical Options > Color Points from the Discriminant Analysis red triangle menu.

Classification into Three or More Categories

For the Iris.jmp data, there are three Species, so there are only two canonical variables. The plot in Figure 5.9 shows good separation of the three groups using the two canonical variables.

The rays in the plot indicate the following:

- Petal length is positively associated with Canonical1 and negatively associated with Canonical2. It carries more weight in defining Canonical1 than Canonical2.
- Petal width is positively associated with both Canonical1 and Canonical2. It carries about the same weight in defining both canonical variates.
- Sepal width is negatively associated with Canonical1 and positively associated with Canonical2. It carries more weight in defining Canonical2 than Canonical1.
- Sepal length is negatively weighted in terms of defining Canonical1 and very weakly associated in defining Canonical2.
Classification into Two Categories

When the classification variable has only two levels, the points are plotted against the single canonical variable, denoted by Canonical1 in the plot. The canonical weights for each covariate relate to Canonical1 only. The rays are shown with a vertical component only in order to separate them. Project the rays onto the Canonical1 axis to compare their relative association with the single canonical variable.

Figure 5.10 shows a Canonical Plot for the sample data table Fitness.jmp. The seven continuous variates are used to classify an individual into the categories M (male) or F (female). Since the classification variable has only two categories, there is only one canonical variable.

The points in the Canonical Plot have been colored by Sex. Note that the two groups are well separated by their values on Canonical1.

Although the rays corresponding to the seven covariates have a vertical component, in this case you must interpret the rays only in terms of their projection onto the Canonical1 axis. You note the following:

- MaxPulse, Runtime, and RunPulse have little association with Canonical1.
- Weight, RstPulse, and Age are positively associated with Canonical1. Weight has the highest degree of association. The covariates RstPulse and Age have a similar, but smaller, degree of association.
- Oxy is negatively associated with Canonical1.
Discriminant Scores

The Discriminant Scores report provides the predicted classification of each observation and supporting information.

**Row**  Row of the observation in the data table.

**Actual**  Classification of the observation as given in the data table.

**SqDist(Actual)**  Value of the saved formula SqDist[<level>] for the classification of the observation given in the data table. See “Score Options” on page 102.

**Note:** Due to an offset term in the formula, SqDist(Actual) can be negative.

**Prob(Actual)**  Estimated probability of the observation’s actual classification.

**-Log(Prob)**  Negative of the log of Prob(Actual). Large values of this negative log-likelihood identify observations that are poorly predicted in terms of membership in their actual categories.

A plot of -Log(Prob) appears to the right of the -Log(Prob) values. A large bar indicates a poor prediction. An asterisk(*) indicates observations that are misclassified.

If you are using a validation or a test set, observations in the validation set are marked with a “v” and those in the test set are marked with a “t”.

**Predicted**  Predicted classification of the observation. The predicted classification is the category with the highest predicted probability of membership.

**Prob(Pred)**  Estimated probability of the observation’s predicted classification.

**Others**  Lists other categories, if they exist, that have a predicted probability that exceeds 0.1.

Figure 5.11 shows the Discriminant Scores report for the Iris.jmp sample data table using the Linear discriminant method. The option **Score Options > Show Interesting Rows Only** option is selected, showing only misclassified rows or rows with predicted probabilities between 0.05 and 0.95.
Figure 5.11 Show Interesting Rows Only

Score Summaries

The Score Summaries report provides an overview of the discriminant scores. The table in Figure 5.12 shows Actual and Predicted classifications. If all observations are correctly classified, the off-diagonal counts are zero.

Figure 5.12 Score Summaries for Iris.jmp

The Score Summaries report provides the following information:

Columns  If you used Stepwise Variable Selection to construct the model, the columns entered into the model are listed (Figure 5.6).

Source    If no validation is used, all observations comprise the Training set. If validation is used, a row is shown for the Training and Validation sets, or for the Training, Validation, and Test sets.

Number Misclassified  Provides the number of observations in the specified set that are incorrectly classified.
Percent Misclassified  Provides the percent of observations in the specified set that are incorrectly classified.

Entropy RSquare  A measure of fit. Larger values indicate better fit. An Entropy RSquare value of 1 indicates that the classifications are perfectly predicted. Because uncertainty in the predicted probabilities is typical for discriminant models, Entropy RSquare values tend to be small.

See “Entropy RSquare” on page 99.

**Note:** It is possible for Entropy RSquare to be negative.

-2LogLikelihood  Twice the negative log-likelihood of the observations in the training set, based on the model. Smaller values indicate better fit. Provided for the training set only. See *Fitting Linear Models*.

Confusion Matrices  Shows matrices of actual by predicted counts for each level of the categorical X. If you are using JMP Pro with validation, a matrix is given for each set of observations. If you are using JMP with excluded rows, the excluded rows are considered the validation set and a separate Validation matrix is given. See “Validation in JMP and JMP Pro” on page 111.

**Entropy RSquare**

The Entropy RSquare is a measure of fit. It is computed for the training set and for the validation and test sets if validation is used.

**Entropy RSquare for the Training Set**

For the training set, Entropy RSquare is computed as follows:

- A discriminant model is fit using the training set.
- Predicted probabilities based on the model are obtained.
- Using these predicted probabilities, the likelihood is computed for observations in the training set. Call this $Likelihood_{FullTraining}$.
- The reduced model (no predictors) is fit using the training set.
- The predicted probabilities for the levels of X from the reduced model are used to compute the likelihood for observations in the training set. Call this quantity $Likelihood_{ReducedTraining}$.
- The Entropy RSquare for the training set is:

$$EntropyRSquare_{Training} = 1 - \frac{\log(Likelihood_{FullTraining})}{\log(Likelihood_{ReducedTraining})}.$$
Entropy RSquare for Validation and Test Sets

For the validation set, Entropy RSquare is computed as follows:

- A discriminant model is fit using only the training set.
- Predicted probabilities based on the training set model are obtained for all observations.
- Using these predicted probabilities, the likelihood is computed for observations in the validation set. Call this $\text{Likelihood}_{\text{FullValidation}}$.
- The reduced model (no predictors) is fit using only the training set.
- The predicted probabilities for the levels of $X$ from the reduced model are used to compute the likelihood for observations in the validation set. Call this quantity $\text{Likelihood}_{\text{ReducedValidation}}$.
- The Validation Entropy RSquare is:

$$\text{Validation Entropy RSquare} = 1 - \frac{\log(\text{Likelihood}_{\text{FullValidation}})}{\log(\text{Likelihood}_{\text{ReducedValidation}})}$$

The Entropy RSquare for the test set is computed in a manner analogous to the Entropy RSquare for the Validation set.

Discriminant Analysis Options

The Discriminant Analysis red triangle menu contains the following options:

**Stepwise Variable Selection**  (Not available for the Wide Linear method.) Shows or hides the Column Selection control panel. This control panel contains options that enable you to perform stepwise variable selection using covariance analysis and $p$-values. See “Stepwise Variable Selection” on page 85.

**Discriminant Method**  Specifies the discriminant method. Choose from Linear, Quadratic, Regularized, and Wide Linear. See “Discriminant Methods” on page 88.

**Discriminant Scores**  Shows or hides a table of the discriminant scores for each row.

**Score Options**  Provides options for the scoring of the observations. In particular, you can save the scoring formulas. See “Score Options” on page 102.

**Canonical Plot**  Shows or hides the Canonical Plot. See “Canonical Plot and Canonical Structure” on page 93.

**Canonical Options**  Provides options that affect the Canonical Plot. See “Canonical Options” on page 104.
**Canonical 3D Plot**  Shows a three-dimensional canonical plot. This option is available only when there are four or more levels of the categorical X. See “Example of a Canonical 3D Plot” on page 107.

**Specify Priors**  Enables you to specify prior probabilities for each level of the X variable. See “Specify Priors” on page 109.

**Consider New Levels**  Specifies that some points might not fit into any known group and should be considered to be from an unscored new group. See “Consider New Levels” on page 109.

**Show Within Covariances**  Shows or hides these reports:

- A Covariance Matrices report that gives the pooled-within covariance and correlation matrices.
- For the Quadratic and Regularized methods, a Correlations for Each Group report that shows the within-group correlation matrices.
  
  For each group, the log of the determinant of the within-group covariance matrix is also shown.
- For the Quadratic discriminant method, adds a Group Covariances outline to the Covariance Matrices report that shows the within-group covariance matrices.

Show Within Covariances is not available for the Wide Linear discriminant method.

**Show Group Means**  Shows or hides the Group Means report that provides the mean of each covariate. Means for each level of the X variable and overall means appear.

**Save Discrim Matrices**  Saves a script called `Discrim Results` to the data table. The script is a list of the following objects for use in JSL:

- a list of the covariates (Ys)
- the categorical variable X
- a list of the levels of X
- a matrix of the means of the covariates by the levels of X
- the pooled-within covariance matrix

Save Discrim Matrices is not available for the Wide Linear discriminant method. See “Save Discrim Matrices” on page 109.

**Scatterplot Matrix**  Opens a Scatterplot Matrix report that shows a matrix with a scatterplot for each pair of covariates. The option invokes the Scatterplot Matrix platform with shaded density ellipses for each group. The scatterplots include all observations in the data table, even if validation is used. See “Scatterplot Matrix” on page 110.

Not available for the Wide Linear discriminant method.
Profiler  Shows or hides an interactive profiler report where the categorical probabilities are combined into a single profiler row. Changes in the factor values are reflected in the estimated classification probabilities. For more information about the options in the red triangle menu, see Profilers.

See Using JMP for more information about the following options:

Local Data Filter  Shows or hides the local data filter that enables you to filter the data used in a specific report.

Redo  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

Save Script  Contains options that enable you to save a script that reproduces the report to several destinations.

Save By-Group Script  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.

Score Options

Score Options provides the following selections that deal with scores:

Show Interesting Rows Only  In the Discriminant Scores report, shows only rows that are misclassified and those with predicted probability between 0.05 and 0.95.

Show Classification Counts  Shows or hides the confusion matrices and confusion rates matrices in the Score Summaries report. A confusion matrix is a two-way classification of actual and predicted responses. A confusion rates matrix is equal to the confusion matrix, with the numbers divided by the row totals. By default, the Score Summaries report shows a confusion matrix and a confusion rates matrix for each level of the categorical X. If you are using JMP Pro with validation, a matrix is given for each set of observations. If you are using JMP with excluded rows, these rows are considered the validation set and a separate Validation matrix is given. See “Validation in JMP and JMP Pro” on page 111.

Show Distances to Each Group  Shows or hides a report that contains each observation’s squared Mahalanobis distance to each group mean.

Show Probabilities to Each Group  Shows or hides a report that contains the probability that an observation belongs to each of the groups defined by the categorical X.

ROC Curve  Shows or hides a Receiver Operating Characteristic (ROC) curve to the Score Summaries report. For more information about the ROC Curve, see Predictive and Specialized Modeling.
Select Misclassified Rows  Selects the misclassified rows in the data table and in report windows that display a listing by row.

Select Uncertain Rows  Selects rows with uncertain classifications in the data table and in report windows that display a listing by row. An uncertain row is one whose probability of group membership for any group is neither close to 0 nor close to 1.

When you select this option, a window opens where you can specify the range of predicted probabilities that reflect uncertainty. By default, any row whose probability differs from 0 or 1 by more than 0.1 is defined to be uncertain. Therefore, the default selects rows with probabilities between 0.1 and 0.9.

Save Formulas  Saves distance, probability, and predicted membership formulas to the data table. See “Saved Formulas” on page 112.

- The distance formulas are SqDist0 and SqDist[<level>], where <level> represents a level of X. The distance formulas produce intermediate values connected with the Mahalanobis distance calculations.
- The probability formulas are Prob[<level>], where <level> represents a level of X. Each probability column gives the posterior probability of an observation’s membership in that level of X. The Response Probability column property is saved to each probability column. For more information about the Response Probability column property, see Using JMP.
- The predicted membership formula is Pred <X> and contains the “most likely level” classification rule.
- The Wide Linear method also saves a Discrim Data Matrix column containing the vector of covariates and a Discrim Prin Comp formula. See “Wide Linear Discriminant Method” on page 117.

Note: For any method other than Wide Linear, when you Save Formulas, a RowEdit Prob script is saved to the data table. This script selects uncertain rows in the data table. The script defines any row whose probability differs from 0 or 1 by more than 0.1 as uncertain. The script also opens a Row Editor window that enables you to examine the uncertain rows. If you fit a new model (other than Wide Linear) and select Save Formulas, any existing RowEdit Prob script is replaced with a script that applies to the new fit.

Make Scoring Script  (Available only in JMP Standard.) Creates a script that constructs the formula columns saved by the Save Formulas option. You can save this script and use it, perhaps with other data tables, to create the formula columns that calculate membership probabilities and predict group membership.

Publish Probability Formulas  (Available only in JMP Pro.) Creates probability formulas and saves them as formula column scripts in the Formula Depot platform. If a Formula
Depot report is not open, this option creates a Formula Depot report. See *Predictive and Specialized Modeling*.

**Canonical Options**

The first options listed below relate to the appearance of the Canonical Plot or the Canonical 3D Plot. The remaining options provide detail on the calculations related to the plot.

**Note:** The Canonical 3D Plot is available only when there are three or more covariates and when the grouping variable has four or more categories.

### Options Relating to Plot Appearance

**Show Points**  Shows or hides the points in the Canonical Plot and the Canonical 3D Plot.

**Show Means CL Ellipses**  Shows or hides 95% confidence ellipses for the mean of each group in the Canonical Plot and the Canonical 3D Plot, assuming normality.

**Show Normal 50% Contours**  Shows or hides a 50% prediction ellipse or ellipsoid for each group. In the Canonical Plot, each ellipse depicts a region in the space of the first two canonical variables that estimates where 50% of the observations for each group should fall, assuming multivariate normality. In the Canonical 3D Plot, each ellipsoid depicts a region in the space of the first three canonical variables that estimates where 50% of the observations should fall, assuming multivariate normality.

**Show Biplot Rays**  Shows or hides the biplot rays in the Canonical Plot and the Canonical 3D Plot. The labeled rays show the directions of the covariates in the canonical space. They represent the degree of association of each covariate with each canonical variable.

**Biplot Ray Position**  Enables you to specify the position and radius scaling of the biplot rays in the Canonical Plot and in the Canonical 3D Plot.

- By default, the rays emanate from the point (0,0), which represents the grand mean of the data in terms of the canonical variables. In the Canonical Plot, you can drag the rays or use this option to specify coordinates.
- The default Radius Scaling in the canonical plots is 1.5, unless an adjustment is needed to make the rays visible. Radius Scaling is done relative to the Standardized Scoring Coefficients.

**Color Points**  Colors the points in the Canonical Plot and the Canonical 3D Plot based on the levels of the X variable. Color markers are added to the rows in the data table. This option is equivalent to selecting **Rows > Color or Mark by Column** and selecting the X variable. It is also equivalent to right-clicking the graph and selecting **Row Legend**, and then coloring by the classification column.
Options Relating to Calculations

Show Canonical Details  Shows or hides the Canonical Details report. See “Show Canonical Details” on page 105.

Show Canonical Structure  Shows or hides the Canonical Structures report. See “Show Canonical Structure” on page 107. Not available for the Wide Linear discriminant method.

Save Canonical Scores  Creates columns in the data table that contain canonical score formulas for each observation. The column for the $k$th canonical score is named Canon[$k$].

Tip: In a script, sending the scripting command Save to New Data Table to the Discriminant object saves the following to a new data table: group means on the canonical variables; the biplot rays with 1.5 Radius Scaling of the Standardized Scoring Coefficients; and the canonical scores. Not available for the Wide Linear discriminant method.

Show Canonical Details

The Canonical Details report shows tests that address the relationship between the covariates and the grouping variable X. Relevant matrices are presented at the bottom of the report.

Figure 5.13  Canonical Details for Iris.jmp

Note: The matrix used in computing the results in the report is the pooled within-covariance matrix (given as the Within Matrix). This matrix is used as a basis for the Canonical Details report for all discriminant methods. The statistics and tests in the Canonical Details report are the same for all discriminant methods.
**Statistics and Tests**

The Canonical Details report lists eigenvalues and gives a likelihood ratio test for zero eigenvalues. Four tests are provided for the null hypothesis that the canonical correlations are zero.

**Eigenvalue**   Eigenvalues of the product of the Between Matrix and the inverse of the Within Matrix. These are listed from largest to smallest. The size of an eigenvalue reflects the amount of variance explained by its associated discriminant function.

**Percent**   Proportion of the sum of the eigenvalues represented by the given eigenvalue.

**Cum Percent**   Cumulative sum of the proportions.

**Canonical Corr**   Canonical correlations between the covariates and the groups defined by the categorical X. Suppose that you define numeric indicator variables to represent the groups defined by X. Then perform a canonical correlation analysis using the covariates as one set of variables and the indicator variables representing the groups in X as the other. The Canonical Corr values are the canonical correlation values that result from this analysis.

**Likelihood Ratio**   Likelihood ratio statistic for a test of whether the population values of the corresponding canonical correlation and all smaller correlations are zero. The ratio equals the product of the values (1 - Canonical Corr^2) for the given and all smaller canonical correlations.

**Test**   Lists four standard tests for the null hypothesis that the means of the covariates are equal across groups: Wilk’s Lambda, Pillai’s Trace, Hotelling-Lawley, and Roy’s Max Root. See “Multivariate Tests” on page 119 and “Approximate F-Tests” on page 120 in the “Discriminant Analysis” appendix.

**Approx. F**   The F value associated with the corresponding test. For certain tests, the F value is approximate or an upper bound. See “Approximate F-Tests” on page 120 in the “Discriminant Analysis” appendix.

**NumDF**   The numerator degrees of freedom for the corresponding test.

**DenDF**   The denominator degrees of freedom for the corresponding test.

**Prob>F**   The p-value for the corresponding test.

**Matrices**

Four matrices that relate to the canonical structure are presented at the bottom of the report. To view a matrix, click the disclosure icon beside its names. To hide it, click the name of the matrix.

**Within Matrix**   Pooled within-covariance matrix.
**Between Matrix**  Between groups covariance matrix, $S_B$. See “Between Groups Covariance Matrix” on page 121.

**Scoring Coefficients**  Coefficients used to compute canonical scores in terms of the raw data. These are the coefficients used for the option **Canonical Options > Save Canonical Scores**. For more information about how these are computed, see the CANDISC Procedure chapter in SAS Institute Inc. (2020b).

**Standardized Scoring Coefficients**  Coefficients used to compute canonical scores in terms of the standardized data. Often called *canonical weights*. For more information about how these are computed, see the CANDISC Procedure chapter in SAS Institute Inc. (2020b).

**Show Canonical Structure**

The Canonical Structure report gives three matrices that provide correlations between the canonical variables and the covariates. Another matrix shows means across the levels of the group variable. To view a matrix, click the disclosure icon beside its names. To hide it, click the name of the matrix.

**Figure 5.14**  Canonical Structure for Iris.jmp Showing between Canonical Structure

**Total Canonical Structure**  Correlations between the canonical variables and the covariates. Often called *loadings*.

**Between Canonical Structure**  Correlations between the group means on the canonical variables and the group means on the covariates.

**Pooled Within Canonical Structure**  Partial correlations between the canonical variables and the covariates, adjusted for the group variable.

**Class Means on Canonical Variables**  Provides means across the levels of the group variable for each canonical variable.

**Example of a Canonical 3D Plot**

1. Select **Help > Sample Data Library** and open Owl Diet.jmp.
2. Select rows 180 through 294.
   These are the rows for which *species* is missing. Hide and exclude these rows.
3. Select **Rows > Hide and Exclude**.
4. Select **Rows > Color or Mark by Column**.
5. Select species.
6. From the Colors menu, select **JMP Dark**.
7. Check **Make Window with Legend**.
8. Click **OK**.

   A small Legend window appears. The rows in the data table are assigned colors by species.

9. Select **Analyze > Multivariate Methods > Discriminant**.
10. Specify skull length, teeth row, palatine foramen, and jaw length as **Y, Covariates**.
11. Specify species as **X, Categories**.
12. Click **OK**.
13. Click the Discriminant Analysis red triangle and click **Canonical 3D Plot**.

   **Tip:** Click categories in the Legend to highlight those points in the Canonical 3D plot. Click and drag inside the 3D plot to rotate it.

**Figure 5.15** Canonical 3D Plot with Legend Window
Specify Priors

The following options are available for specifying priors:

Equal Probabilities Assigns equal prior probabilities to all groups. This is the default.

Proportional to Occurrence Assigns prior probabilities to the groups that are proportional to their frequency in the observed data.

Other Enables you to specify custom prior probabilities.

Consider New Levels

Use the Consider New Levels option if you suspect that some of your observations are outliers with respect to the specified levels of the categorical variable. When you select the option, a menu asks you to specify the prior probability of the new level.

Observations that would be better fit using a new group are assigned to the new level, called “Other”. Probability of membership in the Other group assumes that these observations have the distribution of the entire set of observations where no group structure is assumed. This leads to correspondingly wide normal contours associated with the covariance structure. Distance calculations are adjusted by the specified prior probability.

Save Discrim Matrices

Save Discrim Matrices creates a global list (DiscrimResults) for use in the JMP scripting language. The list contains the following, calculated for the training set:

- YNames, a list of the covariates (Ys)
- XName, the categorical variable
- XValues, a list of the levels of X
- YMeans, a matrix of the means of the covariates by the levels of X
- YPartialCov, the within covariance matrix

Consider the analysis obtained using the Discriminant script in the Iris.jmp sample data table. If you select Save Discrim Matrices from the Discriminant Analysis red triangle menu, the script Discrim Results is saved to the data table.
Figure 5.16  Discrim Results Table Script for Iris.jmp

Note: In a script, you can send the scripting command Get Discrim Matrices to the Discriminant platform object. This obtains the same values as Save Discrim Matrices, but does not store them in the data table.

Scatterplot Matrix

The Scatterplot Matrix command invokes the Scatterplot Matrix platform in a separate window containing a lower triangular scatterplot matrix for the covariates. Points are plotted for all observations in the data table.

Ellipses with 90% coverage are shown for each level of the categorical variable X. For the Linear discriminant method, these are based on the pooled within covariance matrix. Figure 5.17 shows the Scatterplot Matrix window for the Iris.jmp sample data table.

Figure 5.17  Scatterplot Matrix for Iris.jmp
The options in the Scatterplot Matrix red triangle menu are described in *Essential Graphing*.

---

**Validation in JMP and JMP Pro**

In JMP, you can specify a validation set by excluding the rows that form the validation set. Select the rows that you want to use as your validation set and then select **Rows > Exclude/Unexclude**. The unexcluded rows are treated as the training set.

**Note:** In JMP Pro, you can specify a Validation column in the Discriminant launch window. A validation column must have a numeric data type and should contain at least two distinct values.

Notice the following:

- If the column contains two values, the smaller value defines the training set and the larger value defines the validation set.
- If the column contains three values, the values define the training, validation, and test sets in order of increasing size.
- If the column contains four or more distinct values, only the smallest three values and their associated observations are used to define the training, validation, and test sets, in that order.

When a validation set is specified, the Discriminant platform does the following:

- Models are fit using the training data.
- The Stepwise Variable Selection option gives the Validation Entropy RSquare and Validation Misclassification Rate statistics for the model. See “Statistics” on page 85 and “Entropy RSquare for Validation and Test Sets” on page 100.
- The Discriminant Scores report shows an indicator identifying rows in the validation and test sets.
- The Score Summaries report shows actual by predicted classifications for the training, validation, and test sets.
Statistical Details for the Discriminant Analysis Platform

- “Description of the Wide Linear Algorithm”
- “Saved Formulas”
- “Multivariate Tests”
- “Approximate F-Tests”
- “Between Groups Covariance Matrix”

Description of the Wide Linear Algorithm

Wide Linear discriminant analysis is performed as follows:

- The data are standardized by subtracting group means and dividing by pooled standard deviations.
- The singular value decomposition is used to obtain a principal component transformation matrix from the set of singular vectors.
- The number of components retained represents a minimum of 0.9999 of the sum of the squared singular values.
- A linear discriminant analysis is performed on the transformed data, where the data are not shifted by group means. This is a fast calculation because the pooled-within covariance matrix is diagonal.

Saved Formulas

This section gives the derivation of formulas saved by Score Options > Save Formulas. The formulas depend on the Discriminant Method.

For each group defined by the categorical variable X, observations on the covariates are assumed to have a $p$-dimensional multivariate normal distribution, where $p$ is the number of covariates. The notation used in the formulas is given in Table 5.2.

<table>
<thead>
<tr>
<th>$p$</th>
<th>number of covariates</th>
</tr>
</thead>
<tbody>
<tr>
<td>$T$</td>
<td>total number of groups (levels of X)</td>
</tr>
</tbody>
</table>

**Linear Discriminant Method**

In linear discriminant analysis, all within-group covariance matrices are assumed equal. The common covariance matrix is estimated by $S_p$. See Table 5.2 for notation.

The Mahalanobis distance from an observation $y$ to group $t$ is defined as follows:

$$d_t^2 = (y - \bar{y}_t)'S_p^{-1}(y - \bar{y}_t)$$
The likelihood for an observation \( y \) in group \( t \) is estimated as follows:

\[
I_t(y) = (2\pi)^{-T/2} |S_p|^{-1/2} \exp\left(-\frac{(y - \bar{y}_t)'S_p^{-1}(y - \bar{y}_t)}{2}\right) = (2\pi)^{-T/2} |S_p|^{-1/2} \exp(-d_t^2/2)
\]

Note that the number of parameters that must be estimated for the pooled covariance matrix is \( p(p+1)/2 \) and for the means is \( Tp \). The total number of parameters that must be estimated is \( p(p+1)/2 + Tp \).

The posterior probability of membership in group \( t \) is defined as follows:

\[
p(t|y) = \frac{\sum_{t=1}^{T} q_tI_t(y)}{1 + \sum_{u \neq t} \exp\left(-[(d_u^2 - 2\log(q_u)) - (d_t^2 - 2\log(q_t))]/2\right)}
\]

An observation \( y \) is assigned to the group for which its posterior probability is the largest.

The formulas saved by the Linear discriminant method are defined as follows:

| SqDist[0] | \( y'S_p^{-1}y \) |
| SqDist[<group t>] | \( d_t^2 - 2\log(q_t) \) |
| Prob[<group t>] | \( p(t|y) \) |
| Pred <X> | \( t \) for which \( p(t|y) \) is maximum, \( t = 1, ..., T \) |

**Quadratic Discriminant Method**

In quadratic discriminant analysis, the within-group covariance matrices are not assumed equal. The within-group covariance matrix for group \( t \) is estimated by \( S_t \). This means that the number of parameters that must be estimated for the within-group covariance matrices is \( Tp(p+1)/2 \) and for the means is \( Tp \). The total number of parameters that must be estimated is \( Tp(p+3)/2 \).
When group sample sizes are small relative to \( p \), the estimates of the within-group covariance matrices tend to be highly variable. The discriminant score is heavily influenced by the smallest eigenvalues of the inverse of the within-group covariance matrices. See Friedman (1989). For this reason, if your group sample sizes are small compared to \( p \), you might want to consider the Regularized method, described in “Regularized Discriminant Method” on page 116.

See Table 5.2 for notation. The Mahalanobis distance from an observation \( y \) to group \( t \) is defined as follows:

\[
d^2_t = (y - \bar{y}_t)'S_t^{-1}(y - \bar{y}_t)
\]

The likelihood for an observation \( y \) in group \( t \) is estimated as follows:

\[
l_t(y) = (2\pi)^{-T/2}\|S_t\|^{-1/2}\exp(-(y - \bar{y}_t)'S_t^{-1}(y - \bar{y}_t)/2)
\]

\[
= (2\pi)^{-T/2}\|S_t\|^{-1/2}\exp(-d^2_t/2)
\]

The posterior probability of membership in group \( t \) is the following:

\[
p(t|y) = \frac{(q_t l_t(y))}{\left(\sum_{u=1}^{T} q_u l_u(x)\right)}
\]

\[
= \frac{1}{1 + \sum_{u \neq t} \exp(-[(d^2_u + \log|S_u| - 2\log(q_u)) - (d^2_t + \log|S_t| - 2\log(q_t))/2])}
\]

An observation \( y \) is assigned to the group for which its posterior probability is the largest.

The formulas saved by the Quadratic discriminant method are defined as follows:

\[
\begin{array}{l}
\text{SqDist[group } t\text{]} \\
\quad d^2_t + \log|S_t| - 2\log(q_t)
\end{array}
\]

\[
\begin{array}{l}
\text{Prob[group } t\text{]} \\
\quad p(t|y)
\end{array}
\]

\[
\begin{array}{l}
\text{Pred } <X> \\
\quad t \text{ for which } p(t|y) \text{ is maximum, } t = 1, \ldots, T
\end{array}
\]

\textbf{Note:} SqDist[group } t\text{] can be negative.
Regularized Discriminant Method

Regularized discriminant analysis allows for two parameters: $\lambda$ and $\gamma$.

- The parameter $\lambda$ balances weights assigned to the pooled covariance matrix and the within-group covariance matrices, which are not assumed equal.
- The parameter $\gamma$ determines the amount of shrinkage toward a diagonal matrix.

This method enables you to leverage two aspects of regularization to bring stability to estimates for quadratic discriminant analysis. See Friedman (1989). See Table 5.2 for notation.

For the regularized method, the covariance matrix for group $t$ is:

$$
\Sigma_t = (1 - \gamma)(\lambda S_p + (1 - \lambda) S_t) + \gamma \text{Diag}((\lambda S_p + (1 - \lambda) S_t))
$$

The Mahalanobis distance from an observation $y$ to group $t$ is defined as follows:

$$
d_t^2 = (y - \bar{y}_t)'\Sigma_t^{-1}(y - \bar{y}_t)
$$

The likelihood for an observation $y$ in group $t$ is estimated as follows:

$$
l_t(y) = (2\pi)^{-T/2} |\Sigma_t|^{-1/2} \exp(-(y - \bar{y}_t)'\Sigma_t^{-1}(y - \bar{y}_t)/2)
$$

$$
= (2\pi)^{-T/2} |\Sigma_t|^{-1/2} \exp(-d_t^2/2)
$$

The posterior probability of membership in group $t$ given by the following:

$$
p(t|y) = \frac{(q_t l_t(y))}{\sum_{u=1}^{T} q_u l_u(x)}
$$

$$
= \frac{1}{1 + \sum_{u \neq t} \exp(-[(d_u^2 + \log|\Sigma_u| - 2\log(q_u)) - (d_t^2 + \log|\Sigma_t| - 2\log(q_t))]/2)}
$$

An observation $y$ is assigned to the group for which its posterior probability is the largest.

The formulas saved by the Regularized discriminant method are defined below:

<table>
<thead>
<tr>
<th>Formula</th>
<th>Expression</th>
</tr>
</thead>
<tbody>
<tr>
<td>SqDist[t]</td>
<td>$d_t^2 + \log</td>
</tr>
<tr>
<td>Prob[t]</td>
<td>$p(t</td>
</tr>
<tr>
<td>Pred &lt;X&gt;</td>
<td>$t$ for which $p(t</td>
</tr>
</tbody>
</table>
Wide Linear Discriminant Method

The Wide Linear method is useful when you have a large number of covariates and, in particular, when the number of covariates exceeds the number of observations \((p > n)\). This approach centers around an efficient calculation of the inverse of the pooled within-covariance matrix \(S_p\) or of its transpose, if \(p > n\). It uses a singular value decomposition approach to avoid inverting and allocating space for large covariance matrices.

The Wide Linear method assumes equal within-group covariance matrices and is equivalent to the Linear method if the number of observations equals or exceeds the number of covariates.

Wide Linear Calculation

See Table 5.2 for notation. The following steps are used in the Wide Linear calculation:

1. Compute the \(T \times p\) matrix \(M\) of within-group sample means. The \((t, j)\)th entry of \(M\), \(m_{tj}\) is the sample mean for members of group \(t\) on the \(j\)th covariate.
2. For each covariate \(j\), calculate the pooled standard deviation across groups. Call this \(s_{jj}\).
3. Denote the diagonal matrix with diagonal entries \(s_{jj}\) by \(S_{\text{diag}}\).
4. Center and scale values for each covariate:
   - Subtract the mean for the group to which the observation belongs.
   - Divide the difference by the pooled standard deviation.

   Using notation, for an observation \(i\) in group \(t\), the group-centered and scaled value for the \(j\)th covariate is:
   \[
y_{ij}^* = \frac{y_{ij} - m_{t(i)j}}{s_{jj}}
   \]

   The notation \(t(i)\) indicates the group \(t\) to which observation \(i\) belongs.
5. Denote the matrix of \(y_{ij}^*\) values by \(Y_s\).
6. Denote the pooled within-covariance matrix for the group-centered and scaled covariates by \(R\). The matrix \(R\) is given by the following:
   \[
   R = \frac{(Y_s'Y_s)}{(n - T)}
   \]
7. Apply the singular value decomposition to \(Y_s\):
   \[
   Y_s = UDV'
   \]
where \( U \) and \( V \) are orthonormal and \( D \) is a diagonal matrix with positive entries (the singular values) on the diagonal. See “The Singular Value Decomposition” on page 361 in the “Statistical Details” appendix.

Then \( R \) can be written as follows:

\[
R = (Y_s 'Y_s)/(n - T) = (VD^2V')/(n - T)
\]

8. If \( R \) is of full rank, obtain \( R^{-1/2} \) as follows:

\[
R^{-1/2} = (VD^{-1}V')/\sqrt{n - T}
\]

where \( D^{-1} \) is the diagonal matrix whose diagonal entries are the inverses of the diagonal entries of \( D \).

If \( R \) is not of full rank, define a pseudo-inverse for \( R \) as follows:

\[
R^* = (VD^{-2}V')/(n - T)
\]

Then define the inverse square root of \( R \) as follows:

\[
(R^{-1/2}) = (VD^{-1}V')/\sqrt{n - T}
\]

9. If \( R \) is of full rank, it follows that \( R^* = R^{-1} \). So, for completeness, the discussion continues using pseudo-inverses.

Define a \( p \) by \( p \) matrix \( T_s \) as follows:

\[
T_s = (S_{diag}^{-1}VD^-)/\sqrt{n - T}
\]

Then:

\[
(T_sT_s^{'}) = (S_{diag}^{-1}VD^-2V'S_{diag}^{-1})/(n - T) = S_{diag}^{-1}R^{-1}S_{diag}^{-1} = S_p^*
\]

where \( S_p^* \) is a generalized inverse of the pooled within-covariance matrix for the original data that is calculated using the SVD.

**Mahalanobis Distance**

The formulas for the Mahalanobis distance, the likelihood, and the posterior probabilities are identical to those in “Linear Discriminant Method” on page 113. However, the inverse of \( S_p \) is replaced by a generalized inverse computed using the singular value decomposition.
When you save the formulas, the Mahalanobis distance is given in terms of the decomposition. For an observation $y$, the squared distance to group $t$ is the following, where $\text{SqDist}[0]$ and $\text{Discrim Prin Comp}$ in the last equality are defined in “Saved Formulas” on page 119:

$$
\begin{align*}
   d_t^2 &= (y - \bar{y}_t)' S_p^{-1} (y - \bar{y}_t) \\
   &= (y - \bar{y}_t)' T_s' T_s' (y - \bar{y}_t) \\
   &= ((y - \bar{y}) - (\bar{y}_t - \bar{y}))' T_s' T_s' ((y - \bar{y}) - (\bar{y}_t - \bar{y})) \\
   &= (T_s'(y - \bar{y}))'(T_s'(y - \bar{y})) - 2(T_s'(\bar{y}_t - \bar{y}))'(T_s'(y - \bar{y})) + (T_s'(\bar{y}_t - \bar{y}))'(T_s'(\bar{y}_t - \bar{y})) \\
   &= \text{SqDist}[0] - 2(T_s'(\bar{y}_t - \bar{y}))'\text{Discrim Prin Comp} + (T_s'(\bar{y}_t - \bar{y}))'(T_s'(\bar{y}_t - \bar{y}))
\end{align*}
$$

**Saved Formulas**

These are the formulas saved by the Wide Linear discriminant method:

<table>
<thead>
<tr>
<th>Discrim Data Matrix</th>

**Multivariate Tests**

In the following, $E$ is the residual cross product matrix and $H$ is the model cross product matrix. Diagonal elements of $E$ are the residual sums of squares for each variable. Diagonal elements of $H$ are the sums of squares for the model for each variable. In the discriminant analysis literature, $E$ is often called $W$, where $W$ stands for within.
Test statistics in the multivariate results tables are functions of the eigenvalues $\lambda$ of $E^{-1}H$. The following list describes the computation of each test statistic.

**Note:** After specification of a response design, the initial $E$ and $H$ matrices are premultiplied by $M'$ and postmultiplied by $M$.

- Wilks’ Lambda
  $$\Lambda = \frac{\det(E)}{\det(H + E)} = \prod_{i=1}^{n} \left( \frac{1}{1 + \lambda_i} \right)$$

- Pillai’s Trace
  $$V = \text{Trace}[H(H + E)^{-1}] = \sum_{i=1}^{n} \frac{\lambda_i}{1 + \lambda_i}$$

- Hotelling-Lawley Trace
  $$U = \text{Trace}(E^{-1}H) = \sum_{i=1}^{n} \lambda_i$$

- Roy’s Max Root
  $$\Theta = \lambda_1$$, the maximum eigenvalue of $E^{-1}H$.

$E$ and $H$ are defined as follows:

$$E = YY' - b'(XX)b$$
$$H = (Lb)'(L(X'X)^{-1}L')^{-1}(Lb)$$

where $b$ is the estimated vector for the model coefficients and $A^{-}$ denotes the generalized inverse of a matrix $A$.

The whole model $L$ is a column of zeros (for the intercept) concatenated with an identity matrix having the number of rows and columns equal to the number of parameters in the model. $L$ matrices for effects are subsets of rows from the whole model $L$ matrix.

### Approximate F-Tests

To compute $F$-values and degrees of freedom, let $p$ be the rank of $H + E$. Let $q$ be the rank of $L(X'X)^{-1}L'$, where the $L$ matrix identifies elements of $X'X$ associated with the effect being tested. Let $v$ be the error degrees of freedom and $s$ be the minimum of $p$ and $q$. Also let $m = 0.5(|p - q| - 1)$ and $n = 0.5(v - p - 1)$.
Table 5.3 on page 121, gives the computation of each approximate F from the corresponding test statistic.

Table 5.3 Approximate F-statistics

</tr>
</tbody>
</table>

Between Groups Covariance Matrix

Using the notation in Table 5.2, this matrix is defined as follows:

$$S_B = \frac{1}{T - 1} \sum_{t=1}^{T} \left( \frac{n_t}{n} \right) (\bar{y}_t - \bar{y}_{bar})(\bar{y}_t - \bar{y}_{bar})'$$
Partial Least Squares Models

Develop Models Using Correlations between Ys and Xs

The Partial Least Squares (PLS) platform fits linear models based on factors, namely, linear combinations of the explanatory variables (Xs). These factors are obtained in a way that attempts to maximize the covariance between the Xs and the response or responses (Ys). PLS exploits the correlations between the Xs and the Ys to reveal underlying latent structures.

JMP Pro provides additional functionality, enabling you to conduct PLS Discriminant Analysis (PLS-DA), include a variety of model effects, use several validation methods, impute missing data, and obtain bootstrap estimates of the distributions of various statistics.

Partial least squares performs well in situations such as the following, where the use of ordinary least squares does not produce satisfactory results: More X variables than observations; highly correlated X variables; a large number of X variables; several Y variables and many X variables.

Overview of the Partial Least Squares Platform

In contrast to ordinary least squares, PLS can be used when the predictors outnumber the observations. PLS is used widely in modeling high-dimensional data in areas such as spectroscopy, chemometrics, genomics, psychology, education, economics, political science, and environmental science.

The PLS approach to model fitting is particularly useful when there are more explanatory variables than observations or when the explanatory variables are highly correlated. You can use PLS to fit a single model to several responses simultaneously. See Garthwaite (1994), Wold (1994), Wold et al. (2001), Eriksson et al. (2006), and Cox and Gaudard (2013).

Two model fitting algorithms are available: nonlinear iterative partial least squares (NIPALS) and a “statistically inspired modification of PLS” (SIMPLS). For more information about NIPALS, see Wold (1980). For more information about SIMPLS, see De Jong (1993). For a description of both methods, see Boulesteix and Strimmer (2007). The SIMPLS algorithm was developed with the goal of solving a specific optimality problem. For a single response, both methods give the same model. For multiple responses, there are slight differences.

In JMP, the PLS platform is accessible only through Analyze > Multivariate Methods > Partial Least Squares. In JMP Pro, you can also access the Partial Least Squares personality through Analyze > Fit Model.

In JMP Pro, you can do the following:

- Conduct PLS-DA (PLS discriminant analysis) by fitting responses with a nominal modeling type, using the Partial Least Squares personality in Fit Model.
- Fit polynomial, interaction, and categorical effects, using the Partial Least Squares personality in Fit Model.
- Select among several methods for validation and cross validation.
- Impute missing data.
- Obtain bootstrap estimates of the distributions of various statistics. Right-click in the report of interest. For more information about bootstrap estimates, see Basic Analysis.

Partial Least Squares uses the van der Voet $T^2$ test and cross validation to help you choose the optimal number of factors to extract.

- In JMP, the platform uses the leave-one-out method of cross validation. You can also choose not to use validation.
- In JMP Pro, you can choose KFold, Leave-One-Out, or random holdback cross validation, or you can specify a validation column. You can also choose not to use validation.
Example of Partial Least Squares

This example is from spectrometric calibration, which is an area where partial least squares is very effective. Suppose you are researching pollution in the Baltic Sea. You would like to use the spectra of samples of sea water to determine the amounts of three compounds that are present in these samples.

The three compounds of interest are:

- lignin sulfonate (ls), which is pulp industry pollution
- humic acid (ha), which is a natural forest product
- an optical whitener from detergent (dt)

The amounts of these compounds in each of the samples are the responses. The predictors are spectral emission intensities measured at a range of wavelengths (v1–v27).

For the purposes of calibrating the model, samples with known compositions are used. The calibration data consist of 16 samples of known concentrations of lignin sulfonate, humic acid, and detergent. Emission intensities are recorded at 27 equidistant wavelengths. Use the Partial Least Squares platform to build a model for predicting the amount of the compounds from the spectral emission intensities.

1. Select Help > Sample Data Library and open Baltic.jmp.

   **Note:** The data in the Baltic.jmp data table are reported in Umetrics (1995). The original source is Lindberg, Persson, and Wold (1983).

2. Select Analyze > Multivariate Methods > Partial Least Squares.
3. Assign ls, ha, and dt to the Y, Response role.
4. Assign Intensities, which contains the 27 intensity variables v1 through v27, to the X, Factor role.
5. Click OK.
   
   The Partial Least Squares Model Launch control panel appears.
6. Select Leave-One-Out as the Validation Method.
7. Click Go.

Since the van der Voet test is a randomization test, your Prob > van der Voet T2 values may differ slightly.
The Root Mean PRESS (predicted residual sum of squares) Plot shows that Root Mean PRESS is minimized when the number of factors is 7. This is stated in the note beneath the Root Mean PRESS Plot. A report called **NIPALS Fit with 7 Factors Using Fast SVD** is produced. A portion of that report is shown in Figure 6.3.

The van der Voet $T^2$ statistic tests to determine whether a model with a different number of factors differs significantly from the model with the minimum PRESS value. A common practice is to extract the smallest number of factors for which the van der Voet significance level exceeds 0.10 (SAS Institute Inc 2020f; Tobias 1995). If you were to apply this thinking here, you would fit a new model by entering 6 as the **Number of Factors** in the **Model Launch** panel.
8. Click the NIPALS Fit with 7 Factors Using Fast SVD red triangle and select **Diagnostics Plots**.

   This gives a report showing actual by predicted plots and three reports showing various residual plots. The Actual by Predicted Plot shows the degree to which predicted compound amounts agree with actual amounts.

**Figure 6.4 Diagnostics Plots**

9. Click the NIPALS Fit with 7 Factors Using Fast SVD red triangle and select **VIP vs Coefficients Plot**.
Chapter 6
Partial Least Squares Models

Launch the Partial Least Squares Platform

There are two ways to launch the Partial Least Squares platform:

- Select **Analyze > Multivariate Methods > Partial Least Squares**.
- Select **Analyze > Fit Model** and select **Partial Least Squares** from the Personality menu. This approach enables you to do the following:
  - Enter categorical variables as Ys or Xs. Conduct PLS-DA by entering categorical Ys.
  - Add interaction and polynomial terms to your model.
  - Use the Standardize X option to construct higher-order terms using centered and scaled columns.
  - Save your model specification script.

Some features on the Fit Model launch window are not applicable for the Partial Least Squares personality:

- Weight, Nest, Attributes, Transform, and No Intercept.

**Tip:** You can transform a variable by right-clicking it in the Select Columns box and selecting a Transform option.

- The following Macros: Mixture Response Surface, and Scheffé Cubic.

---

Figure 6.5 VIP vs Coefficients Plot

The VIP vs Coefficients plot helps identify variables that are influential relative to the fit for the various responses. For example, v23, v2, and v26 have both VIP values that exceed 0.8 and relatively large coefficients.
Launch the Partial Least Squares Platform Multivariate Methods

Figure 6.6 JMP Pro Partial Least Squares Launch Window (Imputation Method EM Selected)

Figure 6.7 JMP Pro Fit Model Partial Least Squares Launch Window

For more information about the Fit Model launch options, see *Fitting Linear Models*.

For more information about the options in the Select Columns red triangle menu, see *Using JMP*.
The Partial Least Squares launch window contains the following options:

**Y, Response**  Enter numeric response columns. If you enter multiple columns, they are modeled jointly.

In JMP Pro, you can enter nominal response columns in the Fit Model launch window to conduct PLS-DA. See “PLS Discriminant Analysis (PLS-DA)” on page 155.

**X, Factor**  Enter the predictor columns. The Partial Least Squares launch window allows only numeric predictors.

In JMP Pro, you can enter nominal and ordinal model effects in the Fit Model launch window. Ordinal effects are treated as nominal.

**Freq**  If your data are summarized, enter the column whose values contain counts for each row.

**Validation**  A numeric column that defines the validation sets. A validation column must contain only consecutive integer values:

- If the validation column has two levels, the smaller value defines the training set and the larger value defines the validation set.
- If the validation column has three levels, the values define the training, validation, and test sets in order of increasing size.
- If the validation column has more than three levels, then KFold Cross Validation is used. For information about other validation options, see “Validation Method” on page 134.

The PLS platform uses the validation column to train and tune the model or to train, tune, and evaluate the model. For more information about validation, see “Validation in JMP Modeling” on page 541 in the “Statistical Details” chapter.

**Note:** If you click the Validation button with no columns selected in the Select Columns list, you can add a validation column to your data table. For more information about the Make Validation Column utility, see the Predictive and Specialized Modeling.

**By**  Enter a column that creates a report consisting of separate analyses for each level of the variable. If more than one By variable is assigned, a separate analysis is produced for each possible combination of the levels of the By variables.

**Centering**  Centers all Y variables and model effects by subtracting the mean from each column. See “Centering and Scaling” on page 133.

**Scaling**  Scales all Y variables and model effects by dividing each column by its standard deviation. See “Centering and Scaling” on page 133.
Standardize X  (Available only in the Fit Model launch window.) Centers and scales all columns that are used in the construction of model effects. If this option is not selected, higher-order effects are constructed using the original data table columns. Then each higher-order effect is centered or scaled, based on the selected Centering and Scaling options. Note that Standardize X does not center or scale Y variables. See “Standardize X” on page 133.

Impute Missing Data  Replaces missing data values in Ys or Xs with nonmissing values. Select the appropriate method from the Imputation Method list.

If Impute Missing Data is not selected, rows that are missing observations on any X variable are excluded from the analysis and no predictions are computed for these rows. Rows with no missing observations on X variables but with missing observations on Y variables are also excluded from the analysis, but predictions are computed.

Imputation Method  (Appears only when Impute Missing Data is selected.) Select from the following imputation methods:

Mean  For each model effect or response column, replaces the missing value with the mean of the nonmissing values.

EM  Uses an iterative Expectation-Maximization (EM) approach to impute missing values. On the first iteration, the specified model is fit to the data with missing values for an effect or response replaced by their means. Predicted values from the model for Y and the model for X are used to impute the missing values. For subsequent iterations, the missing values are replaced by their predicted values, given the conditional distribution using the current estimates.

For the purpose of imputation, polynomial terms are treated as separate predictors. When a polynomial term is specified, that term is calculated from the original data, or, if Standardize X is checked, from the standardized column values. If a row has a missing value for a column involved in the definition of the polynomial term, then that entry is missing for the polynomial term. Imputation is conducted using polynomial terms defined in this way.

For more information about the EM approach, see Nelson, Taylor, and MacGregor (1996).

Max Iterations  (Appears only when EM is selected as the Imputation Method.) Enables you to set the maximum number of iterations used by the algorithm. The algorithm terminates if the maximum difference between the current and previous estimates of missing values is bounded by $10^{-8}$.

After completing the launch window and clicking OK, the Model Launch control panel appears. See “Model Launch Control Panel” on page 134.
Centering and Scaling

The Centering and Scaling options are selected by default. This means that predictors and responses are centered and scaled to have mean 0 and standard deviation 1. Centering the predictors and the responses places them on an equal footing relative to their variation. Without centering, both the variable’s mean and its variation around that mean are involved in constructing successive factors. To illustrate, suppose that Time and Temp are two of the predictors. Scaling them indicates that a change of one standard deviation in Time is approximately equivalent to a change of one standard deviation in Temp.

Standardize X

When the Partial Least Square personality is selected in the Fit Model window, the Standardize X option is selected by default. This ensures that all columns entered as model effects and that all columns that are involved in an interaction or polynomial term are standardized.

Suppose that you have two columns, X1 and X2, and you enter the interaction term X1*X2 as a model effect in the Fit Model window. When the Standardize X option is selected, both X1 and X2 are centered and scaled before forming the interaction term. The interaction term that is formed is calculated as follows:

\[
\frac{(X1 - \text{mean}(X1)) \times (X2 - \text{mean}(X2))}{\text{std}(X1) \times \text{std}(X2)}
\]

All model effects are then centered or scaled, in accordance with your selections of the Centering and Scaling options, prior to inclusion in the model.

If the Standardize X option is not selected, and Centering and Scaling are both selected, then the term that is entered into the model is calculated as follows:

\[
\frac{X1 \times X2 - \text{mean}(X1 \times X2)}{\text{std}(X1 \times X2)}
\]
After you click **OK** in the platform launch window (or **Run** in the Fit Model window), the Model Launch control panel appears.

**Figure 6.8** Partial Least Squares Model Launch Control Panel

![Model Launch Control Panel](image)

**Note:** The Validation Method portion of the Model Launch control panel appears differently in JMP Pro.

The Model Launch control panel contains the following selections:

**Method Specification** Select the type of model fitting algorithm. There are two algorithm choices: **NIPALS** and **SIMPLS**. The two methods produce the same coefficient estimates when there is only one response variable. See “Statistical Details for the Partial Least Squares Platform” on page 150 for more information about differences between the two algorithms.

**Validation Method** Select the validation method. Validation is used to determine the optimum number of factors to extract. For JMP Pro, if a validation column is specified on the platform launch window, these options do not appear.

- **Holdback** Randomly selects the specified proportion of the data for a validation set, and uses the other portion of the data to fit the model. The random selection is based on stratified sampling across the model factors to attempt to create training and validation sets that are more balanced than ones based on simple random sampling.

- **K-fold** Partitions the data into *K* subsets, or *folds*. In turn, each fold is used to validate the model that is fit to the rest of the data, fitting a total of *K* models. This method is best for small data sets because it makes efficient use of limited amounts of data.

- **Leave-One-Out** Performs leave-one-out cross validation.
None  Does not use validation to choose the number of factors to extract. The number of factors is specified in the Factor Search Range.

Factor Search Range  Specifies how many latent factors to extract if not using validation. If validation is being used, this is the maximum number of factors the platform attempts to fit before choosing the optimum number of factors. The maximum number of factors is the minimum of the number of non-missing rows and the number of factors. Then, the initial number of factors is the minimum of 15 and the maximum number of factors.

Factor Specification  Appears once you click Go to fit an initial model. Specify a number of factors to be used in fitting a new model.

Go  Launches the model fit with the given specifications.

Partial Least Squares Options

The Partial Least Squares red triangle menu contains some options that are useful before clicking Go in the Model Launch Control Panel.

Set Random Seed  Sets the seed for the randomization process used for KFold and Holdback validation. This is useful if you want to reproduce an analysis. Set the seed to a positive value, save the script, and the seed is automatically saved in the script. Running the script always produces the same cross validation analysis. This option does not appear when Validation Method is set to None, or when a validation column is used.

SVD  Shows a submenu that enables you to choose between a fast or classical implementation of the SVD algorithm in the model fitting algorithm. The default is Fast SVD.

See Using JMP for more information about the following options:

Local Data Filter  Shows or hides the local data filter that enables you to filter the data used in a specific report.

Redo  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

Save Script  Contains options that enable you to save a script that reproduces the report to several destinations.

Save By-Group Script  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.
Partial Least Squares Report

The first time you click Go in the Model Launch control panel (Figure 6.8), the Validation Method panel is removed from the Model Launch window. If you specified a Validation column or if you selected Holdback in the Validation Method panel, all model fits in the report are based on the training data. Otherwise, all model fits are based on the entire data set.

If you used validation, three reports appear:

- Model Comparison Summary
- Cross Validation Report
- NIPALS (or SIMPLS) Fit with <N> Factors

If you selected None as the CV method, two reports appear:

- Model Comparison Summary
- NIPALS (or SIMPLS) Fit with <N> Factors

To fit additional models, specify the desired numbers of factors in the Model Launch panel.

Model Comparison Summary

The Model Comparison Summary shows summary results for each fitted model.

Figure 6.9 Model Comparison Summary

The report includes the following summary information:

- **Method**  Shows the analysis method that you specified in the Model Launch control panel.
- **SVD**  Shows the implementation of the SVD algorithm that you specified.
- **Number of rows**  Shows the number of observations used in the training set.
- **Number of factors**  Shows the number of extracted factors.
- **Percent Variation Explained for Cumulative X**  Shows the percent of variation in X that is explained by the model.
- **Percent Variation Explained for Cumulative Y**  Shows the percent of variation in Y that is explained by the model.
**Number of VIP>0.8**  Shows the number of model effects with VIP (variable importance for projection) values greater than 0.8. The VIP score is a measure of a variable’s importance relative to modeling both X and Y (Wold 1994; Eriksson et al. 2006).

**Cross Validation Report**

This report appears only when a form of cross validation is selected as a Validation Method in the Model Launch control panel. The report title is dynamically named `<Cross Validation Method> With <Method = Method Specification>`, depending on the cross validation and method options selected in the control panel. It shows summary statistics for models fit, using from 0 to the maximum number of extracted factors, as specified in the Model Launch control panel. The report also provides a plot of Root Mean PRESS values. See “Root Mean PRESS Plot” on page 140. An optimum number of factors is identified using the minimum Root Mean PRESS statistic.
When the **Standardize X** option is selected, the standardization is applied once to the entire data table. It is not reapplied to the individual training sets. However, when any combination of the **Centering** or **Scaling** options are selected, this combination of selections is applied to each cross validation training set. Cross validation proceeds by using the training sets, which are individually centered and scaled if these options are selected.

The following statistics are shown in the report. If any form of validation or cross validation is used, the reported results are summaries of the training set statistics.

**Number of Factors**  The number of factors used in fitting the model.

**Root Mean PRESS**  The square root of the average of the PRESS values across all responses. See “**Root Mean PRESS**” on page 141.
van der Voet $T^2$ The test statistic for the van der Voet test, which tests whether models with different numbers of extracted factors differ significantly from the optimum model. The null hypothesis for each van der Voet $T^2$ test states that the model based on the corresponding number of factors does not differ from the optimum model. The alternative hypothesis is that the model does differ from the optimum model. See “van der Voet $T^2$” on page 151.

Prob > van der Voet $T^2$ The $p$-value for the van der Voet $T^2$ test. See “van der Voet $T^2$” on page 151.

$Q^2$ Dimensionless measure of predictive ability defined by subtracting the ratio of the PRESS value divided by the total sum of squares for $Y$ from one:

$$1 - \frac{PRESS}{SSY}$$

See “Calculation of $Q^2$” on page 141.

Cumulative $Q^2$ Indicator of the predictive ability of models with the given number of factors or fewer. For a given number of factors, $f$, Cumulative $Q^2$ is defined as follows:

$$1 - \prod_{i=1}^{f} \left(\frac{PRESS_i}{SSY_i}\right)$$

Here PRESS$_i$ and SSY$_i$ correspond to their values for $i$ factors.

$R^2_X$ Percent of $X$ variation explained by the specified factor. A component with a large $R^2_X$ explains a large amount of the variation in the $X$ variables. See “Calculation of $R^2_X$ and $R^2_Y$ When Validation Is Used” on page 142.

Cumulative $R^2_X$ Percent of $X$ variation explained by the model with the given number of factors. This is the sum of the $R^2_X$ values for $i = 1$ to the given number of factors.

$R^2_Y$ Percent of $Y$ variation explained by the specified factor. A component with a large $R^2_Y$ explains a large amount of the variation in the $Y$ variables. See “Calculation of $R^2_X$ and $R^2_Y$ When Validation Is Used” on page 142.

Cumulative $R^2_Y$ Percent of $Y$ variation explained by the model with the given number of factors. This is the Sum of the $R^2_Y$ values for $i = 1$ to the given number of factors.

Interpretation of $Q^2$ and Cumulative $R^2_Y$

The statistics $Q^2$ and Cumulative $R^2_Y$ both measure the predictive ability of the model, but in different ways.

- Cumulative $R^2_Y$ increases as the number of factors increases. This is because, as factors are added to the model, more variation is explained.
• $Q^2$ tends to increase and then decrease, or at least discontinue increasing, as the number of factors increases. This is because, as more factors are added, the model becomes tuned to the training set and does not generalize well to new data, causing the PRESS statistic to decrease.

Analysis of $Q^2$ and Cumulative $R^2_Y$ provides an alternative to using the van der Voet test for determining how many factors to include in your model. Select a number of factors for which $Q^2$ is large and has not started decreasing. You also want Cumulative $R^2_Y$ to be large.

Figure 6.11 shows plots of Cumulative $R^2_Y$ and $Q^2$ against the number of factors for the Penta.jmp data table, using Leave-One-Out as the validation method. Cumulative $R^2_Y$ increases and levels off for about four factors. The statistic $Q^2$ is largest for two factors and then begins to level off. The plot suggests that a model with two factors explains a large portion of the variation in $Y$ without overfitting the data.

**Figure 6.11** Cumulative $R^2_Y$ and $Q^2$ for Penta.jmp

---

**Root Mean PRESS Plot**

This bar chart shows the number of factors along the horizontal axis and the Root Mean PRESS values on the vertical axis. It is equivalent to the horizontal bar chart that appears to the right of the Root Mean PRESS column in the Cross Validation report (Figure 6.10).
Root Mean PRESS

For a specified number of factors, \( a \), the Root Mean PRESS is calculated using the following steps:

1. Fit a model with \( a \) factors to each training set.
2. Apply the resulting prediction formula to the observations in the validation set.
3. For each \( Y \):
   - For each validation set, compute the squared difference between each observed validation set value and its predicted value (the squared prediction error).
   - For each validation set, average these squared differences and divide the result by a variance estimate for the response. For the KFold and Leave-One-Out validation methods, divide by the variance of the entire response column. For Holdback validation, divide by the variance of the response values in the training set.
   - Sum these means and, in the case of more than one validation set, divide their sum by the number of validation sets minus one. This is the PRESS statistic for the given \( Y \).
4. Root Mean PRESS for \( a \) factors is the square root of the average of the PRESS values across all responses.
5. The PRESS statistic for multiple \( Y \)s is obtained by averaging the PRESS statistic, obtained in step 3, across all responses.

Calculation of \( Q^2 \)

The statistic \( Q^2 \) is defined as \( 1 - \frac{PRESS}{SSY} \). The PRESS statistic is the predicted error sum of squares averaged across all responses for the model developed based on the training data, but evaluated on the validation set. The value of \( SSY \) is the sum of squares for \( Y \) averaged across all responses and based on the observations in the validation set.

The statistic \( Q^2 \) in the Cross Validation report is computed in the following ways, depending on the selected Validation Method:

**Leave-One-Out**  \( Q^2 \) is the average of the values \( 1 - \frac{PRESS}{SSY} \) computed for the validation sets based on the models constructed by leaving out one observation at a time.

**KFold**  \( Q^2 \) is the average of the values \( 1 - \frac{PRESS}{SSY} \) computed for the validation sets based on the \( K \) models constructed by leaving out each of the \( K \) folds.

**Holdback or Validation Set**  \( Q^2 \) is the value of \( 1 - \frac{PRESS}{SSY} \) computed for the validation set based on the model constructed using the single set of training data.
Calculation of $R^2_X$ and $R^2_Y$ When Validation Is Used

The statistics $R^2_X$ and $R^2_Y$ in the Cross Validation report are computed in the following ways, depending on the selected Validation Method:

**Note:** For all of these computations, $R^2_Y$ is calculated analogously.

**Leave-One-Out**  $R^2_X$ is the average of the Percent Variation Explained for $X$ Effects for the models constructed by leaving out one observation at a time.

**KFold**  $R^2_X$ is the average of the Percent Variation Explained for $X$ Effects for the $K$ models constructed by leaving out each fold.

**Holdback or Validation Set**  $R^2_X$ is the Percent Variation Explained for $X$ Effects for the model constructed using the training data.

Model Fit Report

The Model Fit Report shows detailed results for each fitted model. The fit uses either the optimum number of factors based on cross validation, or the specified number of factors if no cross validation methods are specified. The report title indicates whether NIPALS or SIMPLS was used, whether Fast SVD or Classical SVD was used, and gives the number of extracted factors.

**Figure 6.12** Model Fit Report

The Model Fit report includes the following summary information:

**X-Y Scores Plots**  Scatterplots of the $X$ and $Y$ scores for each extracted factor.
**Percent Variation Explained**  Shows the percent variation and cumulative percent variation explained for both X and Y. Results are given for each extracted factor.

**Model Coefficients for Centered and Scaled Data**  For each Y, shows the coefficients of the Xs for the model based on the centered and scaled data.

---

**Model Fit Options**

The Model Fit red triangle menu contains the following options:

**Percent Variation Plots**  Adds two plots entitled Percent Variation Explained for X Effects and Percent Variation Explained for Y Effects. These show stacked bar charts representing the percent variation explained by each extracted factor for the Xs and Ys.

**Variable Importance Plot**  Plots the VIP values for each X variable. VIP scores appear in the Variable Importance Table. See “Variable Importance Plot” on page 145.

**VIP vs Coefficients Plots**  Plots the VIP statistics against the model coefficients. You can show only those points corresponding to your selected Ys. Additional labeling options are provided. There are plots for both the centered and scaled data and the original data. See “VIP vs Coefficients Plots” on page 146.

**Set VIP Threshold**  Sets the threshold level for the Variable Importance Plot, Variance Importance Table, and the VIP vs Coefficients Plots.

**Coefficient Plots**  Plots the model coefficients for each response across the X variables. You can show only those points corresponding to your selected Ys. There are plots for both the centered and scaled data and the original data.

**Loading Plots**  Plots X and Y loadings for each extracted factor. There are separate plots for the Xs and Ys.

**Loading Scatterplot Matrices**  Shows scatterplot matrices of the X loadings and the Y loadings.

**Correlation Loading Plot**  Shows either a single scatterplot or a scatterplot matrix of the X and Y loadings overlaid on the same plot. When you select the option, you specify how many factors you want to plot.

– If you specify two factors, a single correlation loading scatterplot appears. Select the two factors that define the axes beneath the plot. Click the right arrow button to successively display each combination of factors on the plot.
– If you specify more than two factors, a scatterplot matrix appears with a cell for pair of factors up to the number that you selected.

In both cases, use check boxes to control labeling.

**X-Y Score Plots** Includes the following options:

**Fit Line** Shows or hides a fitted line through the points on the X-Y Scores Plots.

**Show Confidence Band** Shows or hides 95% confidence bands for the fitted lines on the X-Y Scores Plots.

**Score Scatterplot Matrices** Shows a scatterplot matrix of the X scores and a scatterplot matrix of the Y scores. Each X score scatterplot displays a 95% confidence ellipse, which can be used for outlier detection. For statistical details about the confidence ellipses, see “Confidence Ellipses for X Score Scatterplot Matrix” on page 152.

**Distance Plots** Shows plots of the following:

– the distance from each observation to the X model
– the distance from each observation to the Y model
– a scatterplot of distances to both the X and Y models

In a good model, both X and Y distances are small, so the points are close to the origin (0,0). Use the plots to look for outliers relative to either X or Y. If a group of points clusters together, then they might have a common feature and could be analyzed separately. When a validation set or a validation and test set are in use, separate reports are provided for these sets and for the training set.

**T Square Plot** Shows a plot of T^2 statistics for each observation, along with a control limit. An observation’s T^2 statistic is calculated based on that observation’s scores on the extracted factors. For more information about the computation of T^2 and the control limit, see “T^2 Plot” on page 152.

**Diagnostics Plots** Shows diagnostic plots for assessing the model fit. Four plot types are available: Actual by Predicted Plot, Residual by Predicted Plot, Residual by Row Plot, and a Residual Normal Quantile Plot. Plots are provided for each response. When a validation set or a validation and test set are in use, separate reports are provided for these sets and for the training set.

**Profiler** Shows a profiler for each Y variable.

**Spectral Profiler** Shows a single profiler where all of the response variables appear in the first cell of the plot. This profiler is useful for visualizing the effect of changes in the X variables on the Y variables simultaneously.

**Save Columns** Includes options for saving various formulas and results. See “Save Columns” on page 146.
**Remove Fit**  Removes the model report from the main platform report.

**Make Model Using VIP**  Opens and populates a launch window with the appropriate responses entered as Ys and the variables whose VIPs exceed the specified threshold entered as Xs. Performs the same function as the button in the VIP vs Coefficients for Centered and Scaled Data report. See “VIP vs Coefficients Plots” on page 146.

**Model Driven Multivariate Control Chart for Saved X Scores**  Saves the formulas for each X Score and launches the Model Driven Multivariate Control Chart (MDMCC) launch window. In the MDMCC launch window, the score formulas are assigned as the process columns. You can add or remove processes, add a time ID, or set where historical data ends before clicking OK. See the “Model Driven Multivariate Control Charts” chapter on page 303.

**Variable Importance Plot**

The Variable Importance Plot graphs the VIP values for each X variable. The Variable Importance Table shows the VIP scores. A VIP score is a measure of a variable’s importance in modeling both X and Y. If a variable has a small coefficient and a small VIP, then it is a candidate for deletion from the model (Wold 1994). A value of 0.8 is generally considered to be a small VIP (Eriksson et al. 2006) and a red dashed line is drawn on the plot at 0.8.

**Figure 6.13**  Variable Importance Plot
VIP vs Coefficients Plots

Two options to the right of the plot facilitate variable reduction and model building:

**Make Model Using VIP**  Opens and populates a launch window with the appropriate responses entered as Ys and the variables whose VIPs exceed the specified threshold entered as Xs.

**Make Model Using Selection**  Enables you to select Xs directly in the plot and then enters the Ys and only the selected Xs into a launch window.

To use another platform based on your current column selection, open the desired platform. Notice in the launch window that the selections are retained. Click the role button and the selected columns are populated.

![VIP vs Coefficients Plot for Centered and Scaled Data](image)

**Save Columns**

**Save Prediction Formula**  For each Y variable, saves a column to the data table called Pred Formula <response> that contains the prediction formula.

**Save Prediction as X Score Formula**  For each Y variable, saves a column to the data table called Pred Formula <response> that contains the prediction formula in terms of the X scores.

**Save Standard Errors of Prediction Formula**  For each Y variable, saves a column to the data table called PredSE <response> that contains the standard error of the predicted mean. See “Standard Error of Prediction and Confidence Limits” on page 153.

**Save Mean Confidence Limit Formula**  For each Y variable, saves two columns to the data table called Lower 95% Mean <response> and Upper 95% Mean <response>. These columns contain 95% confidence limits for the response mean. See “Standard Error of Prediction and Confidence Limits” on page 153.
**Save Indiv Confidence Limit Formula**  For each Y variable, saves two columns to the data table called Lower 95% Indiv <response> and Upper 95% Indiv <response>. These columns contain 95% prediction limits for individual values. See “Standard Error of Prediction and Confidence Limits” on page 153.

**Save Score Formula**  Saves two sets of columns to the data table:
- Columns called X Score <N> Formula containing the formulas for each X Score.
- Columns called Y Score <N> Formula containing the formulas for each Y Score

See “Partial Least Squares” on page 150.

**Save Y Predicted Values**  Saves the predicted values for the Y variables to columns in the data table.

**Save Y Residuals**  Saves the residual values for the Y variables to columns in the data table.

**Save X Predicted Values**  Saves the predicted values for the X variables to columns in the data table.

**Save X Residuals**  Saves the residual values for the X variables to columns in the data table.

**Save Percent Variation Explained For X Effects**  Saves the percent variation explained for each X variable across all extracted factors to a new data table.

**Save Percent Variation Explained For Y Responses**  Saves the percent variation explained for each Y variable across all extracted factors to a new data table.

**Save Scores**  Saves the X and Y scores for each extracted factor to the data table.

**Save Loadings**  Saves the X and Y loadings to new data tables.

**Save Standardized Scores**  Saves the X and Y standardized scores used in constructing the Correlation Loading Plot to the data table. For the formulas, see “Standardized Scores and Loadings” on page 154.

**Save Standardized Loadings**  Saves the X and Y standardized loadings used in constructing the Correlation Loading Plot to new data tables. For the formulas, see “Standardized Scores and Loadings” on page 154.

**Save T Square**  Saves a column to the data table that contains the $T^2$ formulas. The values in this column are also used in the $T$ Square Plot.

**Save Distance**  Saves the Distance to X Model (DModX) and Distance to Y Model (DModY) values to the data table. These are the values used in the Distance Plots.

**Save X Weights**  Saves the weights for each X variable across all extracted factors to a new data table.
Save Validation  Saves a new column to the data table describing how each observation was used in validation. For Holdback validation, the column identifies if a row was used for training or validation. For KFold validation, the column identifies the number of the subgroup to which the row was assigned.

Save Imputation  If Impute Missing Data is selected, opens a new data table that contains the data table columns specified as X and Y, with missing values replaced by their imputed values. Columns for polynomial terms are not shown. If a Validation column is specified, the validation column is also included.

Publish Prediction Formula  Creates prediction formulas and saves them as formula column scripts in the Formula Depot platform. If a Formula Depot report is not open, this option creates a Formula Depot report. See Predictive and Specialized Modeling.

Publish Score Formula  Creates X and Y score formulas and saves them as formula column scripts in the Formula Depot platform. If a Formula Depot report is not open, this option creates a Formula Depot report. See Predictive and Specialized Modeling.

Additional Example of Partial Least Squares

In this example, you will use the Partial Least Squares personality in Fit Model to perform an analysis for a categorical response and a large number of variables. Using Partial Least Squares through Fit Model also enables you to use K Fold Crossvalidation. The example data set consists of serum samples collected from 165 men. 84 of the men have prostate cancer and 81 of the men do not. The goal of the analysis is to be able to determine which men have prostate cancer based on the serum samples.

1. Select Help > Sample Data Library and open Prostate Cancer.jmp.
2. Select Analyze > Fit Model.
3. Select Status and click Y.
4. Select the Proteins column group and click Add.
5. From the Personality list, select Partial Least Squares.
6. Click Run.
7. (Optional) Click the Partial Least Squares red triangle and select Set Random Seed.
8. (Optional) Next to Specify random seed, enter 1234.
   Specifying a random seed enables you to reproduce the results shown in this example.
9. (Optional). Click OK.
10. In the Model Launch, click Go.
The Root Mean PRESS Plot shows that Root Mean PRESS is minimized when the number of factors is 5. This is stated in the note beneath the Root Mean PRESS Plot. A report called NIPALS Fit with 5 Factors Using Fast SVD is produced.
Statistical Details for the Partial Least Squares Platform

This section provides details about some of the methods used in the Partial Least Squares platform. See Hoskuldsson (1988), Garthwaite (1994), or Cox and Gaudard (2013).

- “Partial Least Squares”
- “van der Voet T^2”
- “T^2 Plot”
- “Confidence Ellipses for X Score Scatterplot Matrix”
- “Standard Error of Prediction and Confidence Limits”
- “Standardized Scores and Loadings”
- “PLS Discriminant Analysis (PLS-DA)”

Partial Least Squares

Partial least squares fits linear models based on linear combinations, called factors, of the explanatory variables (Xs). These factors are obtained in a way that attempts to maximize the covariance between the Xs and the response or responses (Ys). In this way, PLS exploits the correlations between the Xs and the Ys to reveal underlying latent structures. The factors address the combined goals of explaining response variation and predictor variation. Partial least squares is particularly useful when you have more X variables than observations or when the X variables are highly correlated.

NIPALS

The NIPALS method works by extracting one factor at a time. Let $X = X_0$ be the centered and scaled matrix of predictors and $Y = Y_0$ the centered and scaled matrix of response values. The PLS method starts with a linear combination $t = X_0 \mathbf{w}$ of the predictors, where $t$ is called a score vector and $\mathbf{w}$ is its associated weight vector. The PLS method predicts both $X_0$ and $Y_0$ by regression on $t$:

$$\hat{X}_0 = tp', \text{ where } p' = (t't)^{-1}t'X_0$$
$$\hat{Y}_0 = tc', \text{ where } c' = (t't)^{-1}t'Y_0$$

The vectors $p$ and $c$ are called the X- and Y-loadings, respectively.
The specific linear combination \( t = X_0w \) is the one that has maximum covariance \( t'u \) with some response linear combination \( u = Y_0q \). Another characterization is that the \( X \)- and \( Y \)-weights, \( w \) and \( q \), are proportional to the first left and right singular vectors of the covariance matrix \( X_0'Y_0 \). Or, equivalently, the first eigenvectors of \( X_0'Y_0'X_0 \) and \( Y_0'X_0'Y_0 \) respectively.

This accounts for how the first PLS factor is extracted. The second factor is extracted in the same way by replacing \( X_0 \) and \( Y_0 \) with the \( X \)- and \( Y \)-residuals from the first factor:

\[
X_1 = X_0 - \hat{X}_0 \\
Y_1 = Y_0 - \hat{Y}_0
\]

These residuals are also called the deflated \( X \) and \( Y \) blocks. The process of extracting a score vector and deflating the data matrices is repeated for as many extracted factors as desired.

**SIMPLS**

The SIMPLS algorithm was developed to optimize a statistical criterion: it finds score vectors that maximize the covariance between linear combinations of \( X \)s and \( Y \)s, subject to the requirement that the \( X \)-scores are orthogonal. Unlike NIPALS, where the matrices \( X_0 \) and \( Y_0 \) are deflated, SIMPLS deflates the cross-product matrix, \( X_0'Y_0 \).

In the case of a single \( Y \) variable, these two algorithms are equivalent. However, for multivariate \( Y \), the models differ. SIMPLS was suggested by De Jong (1993).

**van der Voet \( T^2 \)**

The van der Voet \( T^2 \) test helps determine whether a model with a specified number of extracted factors differs significantly from a proposed optimum model. The test is a randomization test based on the null hypothesis that the squared residuals for both models have the same distribution. Intuitively, one can think of the null hypothesis as stating that both models have the same predictive ability.

To obtain the van der Voet \( T^2 \) statistic given in the Cross Validation report, the calculation below is performed on each validation set. In the case of a single validation set, the result is the reported value. In the case of Leave-One-Out and KFold validation, the results for each validation set are averaged.

Denote by \( R_{i,jk} \) the \( j \)th predicted residual for response \( k \) for the model with \( i \) extracted factors. Denote by \( R_{opt,jk} \) is the corresponding quantity for the model based on the proposed optimum number of factors, \( opt \). The test statistic is based on the following differences:

\[
D_{i,jk} = R_{i,jk}^2 - R_{opt,jk}^2
\]
Suppose that there are $K$ responses. Consider the following notation:

$$d_{i,j} = (D_{i,j,1}, D_{i,j,2}, \ldots, D_{i,j,K})'$$

$$d_{i,.} = \sum_j d_{i,j}$$

$$S_i = \sum_j d_{i,j}d_{i,j}'$$

The van der Voet statistic for $i$ extracted factors is defined as follows:

$$C_i = d_{i,.}'S_i^{-1}d_{i,.}$$

The significance level is obtained by comparing $C_i$ with the distribution of values that results from randomly exchanging $R^2_{i,j,k}$ and $R^2_{opt,j,k}$. A Monte Carlo sample of such values is simulated and the significance level is approximated as the proportion of simulated critical values that are greater than or equal to $C_i$.

**T$^2$ Plot**

The $T^2$ value for the $i^{th}$ observation is computed as follows:

$$T^2_i = (n - 1) \sum_{j=1}^{p} \left( \frac{2}{n} \sum_{k=1}^{n} t_{kj}^2 \right)$$

where $t_{ij}$ = X score for the $i^{th}$ row and $j^{th}$ extracted factor, $p$ = number of extracted factors, and $n$ = number of observations used to train the model. If validation is not used, $n$ = total number of observations.

The control limit for the $T^2$ Plot is computed as follows:

$$((n-1)^2/n)\text{BetaQuantile}(0.95, p/2, (n-p-1)/2)$$

where $p$ = number of extracted factors, and $n$ = number of observations used to train the model. If validation is not used, $n$ = total number of observations. See Tracy et al. (1992).

**Confidence Ellipses for X Score Scatterplot Matrix**

The Score Scatterplot Matrices option adds 95% confidence ellipses to the X Score scatterplots. The X scores are uncorrelated because both the NIPALS and SIMPLE algorithms produce orthogonal score vectors. The ellipses assume that each pair of X scores follows a bivariate normal distribution with zero correlation.
Consider a scatterplot for score $i$ on the vertical axis and score $j$ on the horizontal axis. The coordinates of the top, bottom, left, and right extremes of the ellipse are defined as follows:

- the top and bottom extremes are $+/-\sqrt{\text{var}(\text{score } i)\cdot z}$
- the left and right extremes are $+/-\sqrt{\text{var}(\text{score } j)\cdot z}$

where $z = ((n-1)\cdot(n-1)/n)\cdot\text{BetaQuantile}(0.95, 1, (n-3)/2)$. For background on the $z$ value, see Tracy et al. (1992).

**Standard Error of Prediction and Confidence Limits**

Let $X$ denote the matrix of predictors and $Y$ the matrix of response values, which might be centered and scaled based on your selections in the launch window. Assume that the components of $Y$ are independent and normally distributed with a common variance $\sigma^2$.

Hoskuldsson (1988) observes that the PLS model for $Y$ in terms of scores is formally similar to a multiple linear regression model. He uses this similarity to derive an approximate formula for the variance of a predicted value. See also Umetrics (1995). However, Denham (1997) points out that any value predicted by PLS is a non-linear function of the $Y$s. He suggests bootstrap and cross validation techniques for obtaining prediction intervals. The PLS platform uses the normality-based approach described in Umetrics (1995).

Denote the matrix whose columns are the scores by $T$ and consider a new observation on $X$, $x_0$. The predictive model for $Y$ is obtained by regressing $Y$ on $T$. Denote the score vector associated with $x_0$ by $t_0$.

Let $a$ denote the number of factors. Define $s^2$ to be the sum of squares of residuals divided by $df = n - a - 1$ if the data are centered and $df = n - a$ if the data are not centered. The value of $s^2$ is an estimate of $\sigma^2$.

**Standard Error of Prediction Formula**

The standard error of the predicted mean at $x_0$ is estimated by the following:

$$SE(\bar{Y}_{x_0}) = s \sqrt{\frac{1}{n} + t_0'(T'T)^{-1}t_0'}$$

**Mean Confidence Limit Formula**

Let $t_{0.975, df}$ denote the 0.975 quantile of a $t$ distribution with degrees of freedom $df = n - a - 1$ if the data are centered and $df = n - a$ if the data are not centered.

The 95% confidence interval for the mean is computed as follows:

$$\bar{Y}_{x_0} \pm t_{0.975, df}SE(\bar{Y}_{x_0})$$
Indiv Confidence Limit Formula

The standard error of a predicted individual response at $x_0$ is estimated by the following:

$$SE(\hat{Y}_{x_0}) = s \sqrt{\frac{1}{n} + 1 + t_0(T'T)^{-1}t_0}$$

Let $t_{0.975, df}$ denote the 0.975 quantile of a $t$ distribution with degrees of freedom $df = n - a - 1$ if the data are centered and $df = n - a$ if the data are not centered.

The 95% prediction interval for an individual response is computed as follows:

$$\bar{Y}_{x_0} \pm t_{0.975, df} SE(\hat{Y}_{x_0})$$

Standardized Scores and Loadings

Consider the following notation:

- $n_{tr}$ is the number of observations in the training set
- $m$ is the number of effects in $X$
- $k$ is the number of responses in $Y$
- $VarX_i$ is the percent variation in $X$ explained by the $i$th factor
- $VarY_i$ is the percent variation in $Y$ explained by the $i$th factor
- $XScore_i$ is the vector of $X$ scores for the $i$th factor
- $YScore_i$ is the vector of $Y$ scores for the $i$th factor
- $XLoad_i$ is the vector of $X$ loadings for the $i$th factor
- $YLoad_i$ is the vector of $Y$ loadings for the $i$th factor

Standardized Scores

The vector of $i$th Standardized $X$ Scores is defined as follows:

$$XScore_i = \frac{(n_{tr} - 1)\sqrt{mVarX_i/n_{tr}}}{(n_{tr} - 1)\sqrt{kVarY_i/n_{tr}}}$$

The vector of $i$th Standardized $Y$ Scores is defined as follows:

$$YScore_i = \frac{(n_{tr} - 1)\sqrt{kVarY_i/n_{tr}}}{(n_{tr} - 1)\sqrt{kVarY_i/n_{tr}}}$$
Standardized Loadings

The vector of \( i^{th} \) Standardized X Loadings is defined as follows:

\[
XLoad_i \sqrt{mVarX_i}
\]

The vector of \( i^{th} \) Standardized Y Loadings is defined as follows:

\[
YLoad_i \sqrt{kVarY_i}
\]

PLS Discriminant Analysis (PLS-DA)

When a categorical variable is entered as Y in the launch window, it is coded using indicator coding. If there are \( k \) levels, each level is represented by an indicator variable with the value 1 for rows in that level and 0 otherwise. The resulting \( k \) indicator variables are treated as continuous and the PLS analysis proceeds as it would with continuous Ys.
Multiple Correspondence Analysis (MCA) takes multiple categorical variables and seeks to identify associations between levels of those variables. MCA extends correspondence analysis from two variables to many. It can be thought of as analogous to principal component analysis for quantitative variables. Similar to other multivariate methods, it is a dimension reducing method; it represents the data as points in 2- or 3-dimensional space.

Multiple correspondence analysis is frequently used in the social sciences. It can be used in survey analysis to identify question agreement. It is also used in consumer research to identify potential markets for products.

For more information about multiple correspondence analysis, see LeRoux and Rouanet (2010).

Example of Multiple Correspondence Analysis

This example uses data collected from 55 JMP employees about their preferences, or tastes, in these areas:

- Preferred TV program (8 categories): news, comedy, police, nature, sport, film, drama, or soap operas.
- Preferred film (8 categories): action, comedy, costume drama, documentary, horror, musical, romance, or SciFi.
- Preferred type of art (7 categories): performance, landscape, renaissance, still life, portrait, modern, or impressionism.
- Preferred place to eat out (6 categories): fish & chips, pub, Indian restaurant, Italian restaurant, French restaurant, or steak house.

The data also include demographics about the individuals polled. You want to explore the associations between the 55 responses to the four questions. This can lead to an understanding of different groups of employees.

**Note:** The measures for preferences are based on questions from LeRoux and Rouanet (2010).

1. Select **Help > Sample Data Library** and open Employee Taste.jmp.
2. Select **Analyze > Multivariate Methods > Multiple Correspondence Analysis**.
3. Select TV, Film, Art, and Restaurant and click **Y, Response**.
   In MCA, as in principal component analysis, factors are typically considered responses rather than some being responses and others explanatory.
4. Click **OK**.
Figure 7.2 Completed Multiple Correspondence Analysis Launch Window

Figure 7.3 Part of the Initial Multiple Correspondence Analysis Report
Tip: Click and drag overlapping labels to rearrange them.

5. Below the plot, select **Proportional marker size**.
   The marker size indicates the relative proportion of responses in that category.
   The Correspondence Analysis report shows the projection of categories of the four
   variables onto the first two principal axes, or dimensions. Use the controls to change the
   dimensions plotted. The distance between points represents the dissimilarity between
   response patterns of the employees.
   From this graph, you can use your knowledge of the subject matter to interpret the
   findings:
   – Grouped near the Burgers and Fries restaurant preference, there is a cluster of the Sport
     and Police TV program preferences. This cluster could be called the “popular culture”
     group.
   – Looking at Dimension 2, individual tastes move from the popular culture group to
     what could be classified as more “sophisticated” taste - those who like films such as
     documentaries, prefer TV dramas, and specialized restaurants, such as French and
     Indian cuisines.
   To obtain the scores for individuals, add the subject as the **X, Factor**:

6. Open the Variable Summary outline.
   The Variable Summary panel allows you to modify your analysis without relaunching the
   platform. It also provides a concise view of the completed analysis.

7. Select **Subject** and click **Add X**. The analysis automatically updates.
Figure 7.4 Multiple Correspondence Analysis Report with Subjects

Including the subjects highlights a cluster of employees with similar taste in the lower left quadrant of the plot. These employees fall in the area we identified as popular culture.
Launch the Multiple Correspondence Analysis Platform

Launch the Multiple Correspondence Analysis platform by selecting Analyze > Multivariate Methods > Multiple Correspondence Analysis.

**Figure 7.5 Multiple Correspondence Analysis Launch Window**

For more information about the options in the Select Columns red triangle menu, see *Using JMP*.

**Y, Response** Assigns the categorical columns to be analyzed. In MCA, you are generally interested in the associations between variables, but there are not explicit “explanatory” and “response” variables.

**X, Factor** Assigns one or more categorical columns to be used as factor, or explanatory, variables.

**Note:** Use a subject ID column as a single X to obtain scores on individuals.

**Z, Supplementary Variable** Assigns the columns to be used as supplementary variables. These variables are those you are interested in identifying associations with but not include in the calculations. Supplementary variables are used to improve data interpretation.

**Supplementary ID** Assigns the column that identifies rows to be used as supplementary. A supplementary ID column usually has 1s and 0s. The rows associated with ID 0 are treated as supplementary rows. The Supplementary ID column is ignored if there are levels of the
X or Y variables present in the supplementary rows that are not present in the non-supplementary rows.

**Note:** Only one of the Supplementary ID and Z, Supplementary Variable roles can be specified at one time.

**Freq** Assigns a frequency variable to this role. This is useful if your data are summarized.

**By** Produces a separate report for each level of the By variable. If more than one By variable is assigned, a separate report is produced for each possible combination of the levels of the By variables.

**Note:** The Multiple Correspondence Analysis platform handles missing values differently than many other JMP platforms. The analysis uses all nonmissing pairs of cells in a row. It does not remove entire rows from the computation.

---

**The Multiple Correspondence Analysis Report**

The initial Multiple Correspondence Analysis report shows the variable summary, correspondence analysis plot, and details of the dimensions of the data in order of importance. From the plot of the cloud of categories or individuals, you can identify associations that exist within the data. The details provide information about whether the two dimensions shown in the plot are sufficient to interpret the relationships within the data.

The Variable Summary in an interactive panel that allows you to modify your analysis without relaunching the platform. The panel shows the columns and roles used in the analysis. If you select the Show Controls check box, a list of the columns in the data table appears to the left. You can change the columns in the analysis either by selecting a column and clicking Add Y, Add X, Add Z, or Add ID. Or you can drag the column to the header in the variable summary table. This enables you to modify the analysis without returning to the launch window.
Multiple Correspondence Analysis Platform Options

The Multiple Correspondence Analysis red triangle menu options give you the ability to customize reports according to your needs. The reports available are determined by the type of analysis that you conduct.

**Cross Table**  Shows or hides a Burt or contingency table as appropriate for variable roles selected. See “Cross Table” on page 171.

**Correspondence Analysis**  Shows or hides the correspondence analysis reports. These reports give the plots, details, coordinates, and summary statistics. See “Additional Examples of the Multiple Correspondence Analysis Platform” on page 172.
Cross Table of Supplementary Rows  (Available when one or more supplementary Z and X variables are specified or when an ID is specified.) Shows or hides a Burt or contingency table, dependent on the following rules:

- When one or more X and Z variables are specified, shows or hides a contingency table of the X variable(s) versus the response variable(s).
- When an ID and no X variables are specified, shows or hides a Burt table for the supplementary observations. The supplementary observations are those observations for which the ID variable is equal to 0.
- When an ID and one or more X variables are specified, shows or hides a contingency table for the supplementary observations. The supplementary observations are those observations for which the ID variable is equal to 0.

Cross Table of Supplementary Columns  (Available when one or more supplementary Z variables are specified.) Shows or hides a contingency table dependent on the following rules:

- When no X variable is specified, shows or hides a contingency table of the Response variable(s) versus the supplementary variable(s).
- When one or more X variables are specified, shows or hides a contingency table of the X variable(s) versus the supplementary variable(s).

Mosaic Plot  (Available only when there is one X variable and one Y variable.) Shows or hides a mosaic plot Y versus X. A mosaic plot is a stacked bar chart where each segment is proportional to its group’s frequency count.

Tests for Independence  (Available only when there is one X variable and one Y variable.) Shows or hides the tests for independence between the X and Y variables. There are two versions of this test, the Pearson form and the Likelihood Ratio form, both with chi-square statistics.

See Using JMP for more information about the following options:

Local Data Filter  Shows or hides the local data filter that enables you to filter the data used in a specific report.

Redo  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

Save Script  Contains options that enable you to save a script that reproduces the report to several destinations.

Save By-Group Script  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.
Correspondence Analysis Options

The reports available under Correspondence Analysis are determined by the type of multiple correspondence analysis that you conduct. Several of these reports are shown by default.

**Show Plot** Shows the two-dimensional cloud of categories in the plane described by the first two principal axes. This plot appears by default. The plot uses isometric scaling.

**Show Detail** Provides the details of the analysis including the singular values, inertias, ChiSquare statistics, percent, and cumulative percent. This report appears by default. See “Show Detail” on page 168.

**Show Adjusted Inertia** Provides reports of the Benzecri and Greenacre adjusted inertia. See Benzécri (1979) and Greenacre (1984). This option is not available when there are one or more X variables. See “Show Adjusted Inertia” on page 169.

**Show Coordinates** Provides a report of up to the first three principal coordinates for the categories in the analysis, as appropriate. See “Show Coordinates” on page 169.

**Show Summary Statistics** Provides a report of the summary statistics, Quality, Mass, and Inertia, for each category in the analysis. See “Show Summary Statistics” on page 170.

**Show Partial Contributions to Inertia** Provides a report of the contribution of each category to the inertia for each of up to the first three dimensions. See “Show Partial Contributions to Inertia” on page 170.

**Show Squared Cosines** Provides a report of the squared cosines of each category for each of up to the first three dimensions. The report includes a bar chart that shows, for each level of each Y variable, the squared cosine values for each of up to the first three dimensions. See “Show Squared Cosines” on page 171.

**Cochran’s Q Test** (Available only when all of the Y variables have the same set of only two levels and the X variable has a unique value for each row.) Provides Cochran’s Q statistic, which tests that the marginal probability of a specific response is unchanged across the Y variables. Cochran’s Q statistic is a generalization of McNemar’s statistic for more than two response variables. See Agresti (2013). See “Cochran’s Q Test” on page 171.

**3D Correspondence Analysis** Shows the three-dimensional cloud of categories of the Y, X, and Z variables in the space described by the first three principal axes. This option is not available if there are less than three dimensions.

**Save Coordinates** Saves the principal coordinates to one or more JMP data tables. Column coordinates, row coordinates, supplementary column coordinates, and supplementary row coordinates are saved to separate JMP data tables. You can choose how many columns to save.
Save Coordinate Formula: Saves formula columns to the data table for the principal coordinates in multiple dimensions. The value for each observation is the average of the coordinates for the Y variables scaled by the singular value for each dimension. You can choose how many columns to save.

Show Plot

The plot displays a projection of the projection of categories or individuals onto the plane described by the first two principal axes. The plot uses isometric scaling. You can toggle the dimensions shown in the plot using the Select Dimension controls below the plot. The first control defines the horizontal axis of the plot, and the second control defines the vertical axis of the plot. Click the arrow button to cycle through the dimensions shown in the plot. Use the Proportional marker size check box to specify if the size of the points in the plot should be proportional to the count of observations corresponding to each point.

Note: Selecting a point in the correspondence analysis plot also selects the corresponding rows in other tables in the report window. However, rows in the data table are not selected. To select all of the points in the plot associated with a particular variable, select the name of the variable in the plot legend.

Show Detail

Shows the table of singular values.

Singular Value: Shows the singular values in the singular value decomposition of the contingency table or Burt table. For the formula, see “Details Report” on page 177.

Inertia: Lists the square of the singular values, reflecting the relative variation accounted for in the canonical dimensions.

ChiSquare: Lists the portion of the overall Chi-square for the Burt or contingency table represented by the dimension.

Percent: Portion of inertia with respect to the total inertia.

Cumulative Percent: Shows the cumulative portion of inertia. If the first two singular values capture the bulk of the inertia, then the 2-D correspondence analysis plot is sufficient to show the relationships in the table.
Show Adjusted Inertia

The principal inertias of a Burt table in MCA are the eigenvalues. The problem with these inertias is that they provide a pessimistic indication of fit. Benzécri proposed an inertia adjustment. Greenaccre argued that the Benzécri adjustment overestimates the quality of fit and proposed an alternate adjustment. Both adjustments are calculated for your reference. See “Adjusted Inertia” on page 178.

**Inertia**  Lists the square of the singular values, reflecting the relative variation accounted for in the canonical dimensions.

**Adjusted Inertia**  Lists the adjusted inertia according to either the Benzécri or Greenaccre adjustment.

**Percent**  Portion of adjusted inertia with respect to the total inertia.

**Cumulative Percent**  Shows the cumulative portion of adjusted inertia. If the first two singular values capture the bulk of the inertia, then the 2-D correspondence analysis plot is sufficient to show the relationships in the table.

Show Coordinates

Shows the Column Coordinates table or the Row and Column Coordinates tables.

**X**  Lists the columns specified as X, Factor variables.

**Y**  Lists the columns specified as Y, Response variables.

**Z**  Lists the columns specified as Z, Supplementary Variables.

**Category**  Lists the levels of the X, Y, or Z variables.

**Dimension 1, Dimension 2, Dimension 3**  For each level or each response, lists its coordinate along the indicated principal axis. By default, the tables show coordinates for up to the first three dimensions. Coordinate columns for additional dimensions are hidden. To show these optional columns, right-click in a table and select the dimension columns from the **Columns** submenu.

**Note:** If there are columns specified as X, Factor variables, the Coordinates report displays tables of both X and Y with the same report headings. If a Z, Supplementary Variable is specified, the coordinates are listed below the X and Y coordinates as applicable.
Show Summary Statistics

Shows the Summary Statistics for the Column Points table or the Summary Statistics for the Row and Column Points tables. The Y table gives Quality, Mass, and Inertia for each level of each response, called a column point. The X table gives Quality, Mass, and Inertia for each level of the X, Factor variables. See “Summary Statistics” on page 178.

**X**  Lists the columns specified as X, Factor variables.

**Y**  Lists the columns specified as Y, Response variables.

**Category**  Lists the levels of the X or Y variables.

**Quality(dim=2)**  Lists the quality of the representation of the level by the solution.

**Mass**  Lists the row frequency for the level of the response divided by the total frequency. In the Burt table, this is the Total % for each row.

**Inertia**  Lists the proportion of the total inertia accounted for by the level of the response. The inertia values sum to one across the levels and their responses.

**Note:** If there are columns specified as X, Factor variables, the Summary Statistics report displays tables of both X and Y with the same report headings.

Show Partial Contributions to Inertia

Shows the Partial Contributions to Inertia for the Column Points table or the Partial Contributions to Inertia for the Row and Column Points tables. Also shows the Plot of Partial Contributions to Inertia for the Column Points. This is a bar chart that shows, for each level of each Y variable, its partial contributions to each of the dimensions shown in the table.

**X**  Lists the columns specified as X, Factor variables.

**Y**  Lists the columns specified as Y, Response variables.

**Category**  Lists the levels of the X or Y variables.

**Dimension 1, Dimension 2, Dimension 3**  Lists the contribution of the response or factor level to the inertia of the indicated dimension. By default, the tables show columns for up to the first three dimensions. Additional columns are hidden. To show these optional columns, right-click a table and select the dimension columns from the Columns submenu.

Each level of each response contributes to the inertia of each dimension. The partial contributions within each dimension sum to 1.
Note: If there are columns specified as X, Factor variables, the Partial Contributions to Inertia report displays tables of both X and Y with the same report headings. See “Partial Contributions to Inertia” on page 179.

Show Squared Cosines

Shows the Squared Cosines for the Column Points table or the Squared Cosines for the Row and Column Points. Also shows the Plot of Squared Cosines for the Column Points. This is a bar chart that shows, for each level of each Y variable, the squared cosine values for each of up to the first three dimensions shown.

X  Lists the columns specified as X, Factor variables.

Y  Lists the columns specified as Y, Response variables.

Category  Lists the levels of the X or Y variables.

Dimension 1, Dimension 2, Dimension 3  Lists the quality of the representation of the level by the indicated dimension. By default, the tables show results for up to the first three dimensions. Additional columns are hidden. To show these optional columns, right-click a table and select the dimension columns from the Columns submenu.

The values indicate the quality of each point for the indicated dimension. The squared cosine can be interpreted as the squared correlation of the point with the dimension. The sum of the squared cosines of the first two dimensions equals \( \text{Quality(dim=2)} \) in the Summary Statistics report. See “Summary Statistics” on page 178.

Note: If there are columns specified as X, Factor variables, the Squared Cosines report displays tables of both X and Y with the same report headings.

Cochran’s Q Test

Cochran’s Q test is a nonparametric test for homogeneity across matched samples for three or more binary outcomes. You can use it to test for differences in proportions in matched pairs. Cochran’s Q test is an extension of the McNemar test used for two outcomes.

Cross Table

The cross table option hides or shows a Burt table or a contingency table. When you select multiple Y, Response columns with no X, Factor columns, the Burt table is created. If you select any X, Factor columns, a traditional contingency table is created instead of a Burt table. The outline node title reflects the structure of the cross table.
The Burt table is the basis of the multiple correspondence analysis. It is a partitioned symmetric table of all pairs of categorical variables. The diagonal partitions are diagonal matrices (a cross-table of a variable with itself). The off-diagonal partitions are ordinary contingency tables.

The red triangle menu for the Burt or contingency table contains the following options of statistics to display in the table.

**Count**  Cell frequency, margin total frequencies, and grand total (total sample size). This appears by default.

**Total %**  Percent of cell counts and margin totals to the grand total. This appears by default.

**Cell Chi Square**  Chi-square values computed for each cell as \((O - E)^2 / E\).

**Col %**  Percent of each cell count to its column total.

**Row %**  Percent of each cell count to its row total.

**Expected**  Expected frequency \((E)\) of each cell under the assumption of independence. Computed as the product of the corresponding row total and column total divided by the grand total.

**Deviation**  Observed cell frequency \((O)\) minus the expected cell frequency \((E)\).

**Col Cum**  Cumulative column total.

**Col Cum %**  Cumulative column percentage.

**Row Cum**  Cumulative row total.

**Row Cum %**  Cumulative row percentage.

**Make Into Data Table**  Creates one data table for each statistic shown in the table.

---

**Additional Examples of the Multiple Correspondence Analysis Platform**

- “Example Using a Supplementary Variable”
- “Example Using a Supplementary ID”
- “Example of Cochran’s Q Test”
Example Using a Supplementary Variable

This example uses the sample data on JMP employee preferences described in “Example of Multiple Correspondence Analysis” on page 159.

You want to explore relationships between employee job and their preferences.

1. Select Help > Sample Data Library and open Employee Taste.jmp.
2. Select Analyze > Multivariate Methods > Multiple Correspondence Analysis.
3. Select TV, Film, Art, and Restaurant and click Y, Response.
4. Select Job and click Z, Supplementary Variable.
5. Click OK.

**Note:** Since Job is a supplementary variable, it is not used in the calculations. Job type is plotted after the calculations are complete.

Figure 7.7 MCA with Supplementary Variable Report
You can see from the plot that the data points for the R&D (research and development) and the S&M (sales and marketing) employees are close together. We interpret this to mean that there is not a strong difference in terms of preferences due to employee job function. In other words, the employee’s job role is not a significant factor in their preferences.

**Example Using a Supplementary ID**

The United States census allows for examining population growth over the last century. The US Regional Population.jmp sample data table contains populations of the 50 US states grouped into regions for each of the census years from 1920 to 2010. Alaska and Hawaii are treated as supplementary regions because they were not states during the entire time, and they are not part of the contiguous United States. You are interested in whether the population growth in these two states differs from the rest of the US.

1. Select **Help > Sample Data Library** and open US Regional Population.jmp.
2. Select **Analyze > Multivariate Methods > Multiple Correspondence Analysis**.
3. Select **Year** and click **Y, Response**.
4. Select **Region** and click **X, Factor**.
5. Select **ID** and click **Supplementary ID**.
6. Select **Population** and click **Freq**.
7. Click **OK**.

The Details report shows that the association between years and regions is almost entirely explained by the first dimension. The plot shows that years are in the correct order on the first dimension. This ordering occurs naturally through the correspondence analysis; there is no information about the order provided to the analysis. The plot highlights the isometric scale used to plot the data.

Notice that the ordering of the regions reflects the population shift from the Midwest to the Northeast to the South and finally to the Mountain and West.

Alaska and Hawaii were not used in the computation of the analysis but are plotted based on the results. Their growth pattern is most similar to the Pacific states. Alaska’s growth is even more extreme than the Pacific region.
Example of Cochran’s Q Test

This example uses a simulated data table to evaluate the ease of completion of three tasks for 30 subjects. Task 1 was simulated to have an 80% completion rate. Tasks 2 and 3 were simulated to have the same result as Task 1 for 95% and 80% of subjects respectively.

1. Select Help > Sample Data Library and open Cohcrans Q.jmp.
2. Select Analyze > Multivariate Methods > Multiple Correspondence Analysis.
3. Select Task 1, Task 2, and Task 3 and click Y, Response.
4. Select Subject and click X, Factor.
5. Click OK.
6. Click the Multiple Correspondence Analysis red triangle menu and select Correspondence Analysis > Cochran’s Q Test.
Figure 7.9 Cochran’s Q Test

The correspondence plot shows the similarity between Task 1 and Task 2 as the Pass and Fail outcomes cluster together. However, Task 3 is farther away from Tasks 1 and 2. Cochran’s Q test statistic of 6.889 has an associated $p$-value of 0.0319. This $p$-value supports the rejection of the hypothesis that the pass rates are the same across all tasks at a 0.05 significance level.
Statistical Details for the Multiple Correspondence Analysis Platform

- “Details Report”
- “Adjusted Inertia”
- “Summary Statistics”
- “Partial Contributions to Inertia”
- “Cochran’s Q Statistic”

Details Report

When a simple Correspondence Analysis is performed, the report lists the singular values from the following singular value decomposition:

\[ D_r^{-0.5} (P - re') D_c^{-0.5} = U \text{diag}(\Lambda) V' \]

where:
- \( P \) is the matrix of counts divided by the total frequency
- \( r \) and \( c \) are the row and column sums of \( P \)
- the \( D \) matrices are diagonal matrices of the values of \( r \) and \( c \)
- \( \Lambda \) is the column vector of singular values

When Multiple Correspondence Analysis is performed, the singular value decomposition extends to the following equation:

\[ D^{0.5} (C - dd') D^{-0.5} = U \text{diag}(\Lambda) V' \]

where:
- \( C \) is the Burt table
- \( d \) is a column vector of the column sums of \( C \) (\( d \) is also the row sums, since \( C \) is symmetric)
- \( D \) is a diagonal matrix of the values of \( d \)

In the Details report, the inertia is the column vector \( \Lambda \). The singular value is the square root of the inertia vector. The column coordinates are calculated as follows:

\[ D^{-0.5} V \text{diag}(\Lambda^{0.5}) \]
Adjusted Inertia

The usual principal inertias of a Burt table constructed from \( m \) categorical variables in MCA are the eigenvalues \( \lambda_k \) from \( \Lambda^2 \). These inertias provide a pessimistic indication of fit. Benzécri (1979) proposed the following inertia adjustment; it is also described by Greenacre (1984, p. 145):

\[
\left( \frac{m}{m-1} \right)^2 \times \left( \frac{\lambda_k - \frac{1}{m}}{m} \right)^2 \text{ for } \lambda_k > \frac{1}{m}
\]

This adjustment computes the percent of adjusted inertia relative to the sum of the adjusted inertias for all inertias greater than \( 1/m \).

Greenacre (1984, p. 156) argues that the Benzécri adjustment overestimates the quality of fit. Greenacre proposes instead to compute the percentage of adjusted inertia relative to:

\[
\frac{m}{m-1} \left( \text{tr}(\text{Diag}(\Lambda^4)) - \frac{n_c - m}{m^2} \right)
\]

for all inertias greater than \( 1/m \), where \( \text{tr}(\text{Diag}(\Lambda^4)) \) is the sum of squared inertias and \( n_c \) is the total number of categories across the \( m \) variables.

Summary Statistics

*Quality* is the ratio of the squared distance of a point from the origin in the space defined by the specified number of dimensions to the distance from the origin in the space with the maximum number of dimensions. For the Chi-Square metric, a point’s quality in a given dimension can be obtained from the cosine that its vector makes with the vector that defines the dimension. Quality is also equal to the ratio of the sum of inertias in the specified dimensions to the sum of the inertias in all dimensions. Quality indicates how well the point is represented in the lower-dimensional space.

*Mass* is the proportion of row or column total frequency to the total frequency.

*Inertia* is analogous to variance in principal component analysis. The overall inertia is the total Pearson Chi-square for a two-way frequency table divided by the sum of all observations in the table.
