![SVD Scatterplots of Document and Term Spaces](image)

*Figure 12.11 SVD Scatterplots of Document and Term Spaces*
Cluster Documents  Shows or hides a hierarchical clustering analysis of the documents in the data. To the right of the dendrogram, there are options to do the following: set the number of clusters, save the clusters to a column in the data table, and show the documents in a selected branch of the dendrogram plot.

Select Near Neighbors  Finds and selects the nearest neighbors of the selected points in the document SVD plot. The algorithm uses the $U$ matrix from the singular value decomposition to find the nearest neighbors. When you select this option, you must specify the number of nearest neighbors to select. By default, the option selects the 10 nearest neighbors.

Save Document Singular Vectors  Saves a user-specified number of singular vectors from the document singular value decomposition as columns to the data table. The first two saved columns represent the points plotted in the document SVD plot. See “Latent Semantic Analysis (SVD)” on page 410.

Save Singular Vector Formula  Saves a formula column with the Vector modeling type that contains the document singular value decomposition to the data table. The resulting column uses the Text Score() JSL function. For more information about this function, see Help > Scripting Index.

Save Term Singular Vectors  Saves a user-specified number of singular vectors from the terms singular value decomposition as columns to a new data table where each row corresponds to a term. If a Term Table data table is already open, this option saves the columns to that data table. The first two saved columns represent the points plotted in the term SVD plot. See “Latent Semantic Analysis (SVD)” on page 410.

Remove  Removes the SVD report from the Text Explorer report window.

The Topic Analysis, Rotated SVD option performs a varimax rotation on the partial singular value decomposition (SVD) of the document term matrix (DTM). You must specify a number of rotated singular vectors, which corresponds to the number of topics that you want to retain from the DTM. After you specify a number of topics, the Topic Analysis report appears.

Topic analysis is equivalent to a rotated principal component analysis (PCA). The varimax rotation takes a set of singular vectors and rotates them to make them point more directly in the coordinate directions (toward the terms). This rotation makes the vectors help explain the text as each rotated vector orients toward a set of terms. Negative values indicate a repulsion force. The terms with negative values occur in a topic less frequently compared to the terms with positive values.
The Topic Analysis report shows the terms that have the largest loadings in each topic after rotation. There are additional reports that show the components of the rotated singular value decomposition.

The Top Loadings by Topic report shows a table of terms for each topic. The terms in each table are the ones that have the largest loadings in absolute value for each topic. Each table is sorted in descending order by the absolute value of the loading. These tables can be used to determine conceptual themes that correspond to each topic.

The Topic Analysis report also contains the following reports:

**Topic Loadings**  Contains a matrix of the loadings across topics for each term. This matrix is equivalent to the factor loading matrix in a rotated PCA.

**Word Clouds by Topic**  Contains a matrix of word clouds, one for each topic.

**Topic Scores**  Contains a matrix of document scores for each topic. Documents with higher scores in a topic are more likely to be associated with that topic.

**Topic Scores Plots**  Contains a Show Text button and a plot of topic scores for each document. The Show Text button opens a window that contains the text of the selected documents.

The Topic Scores Plots report is a visual representation of the matrix in the Topic Scores report. Each panel in the plot corresponds to one of the topics, or one of the columns of the Topic Scores matrix. Within each panel, each point corresponds to one of the documents in the corpus, or one of the rows of the Topic Scores matrix.

**Variance Explained by Each Topic**  Contains a table of the variance explained by each topic. The table also contains columns for the percent and cumulative percent of the variation explained by each topic.

**Rotation Matrix**  Contains the rotation matrix for the varimax rotation.

The Topic Analysis report options:

The Topic Analysis red triangle menu in the Text Explorer platform contains the following options:

**Topic Scatterplot Matrix**  Shows or hides a scatterplot matrix of the rotated singular value decomposition vectors. The Show Text button opens a window that contains the text of the selected documents.
**Display Options**  Contains options to show or hide content that appears in the Topic Analysis report. See “Topic Analysis Report” on page 415.

**Rename Topics**  Enables you to add descriptive names for one or more of the topics.

**Save Document Topic Vectors**  Saves a user-specified number of singular vectors from the rotated singular value decomposition as columns to the data table.

**Save Topic Vector Formula**  Saves a formula column with the Vector modeling type that contains the rotated singular value decomposition to the data table. The resulting column uses the `Text Score()` JSL function. For more information about this function, see Help > Scripting Index.

**Save Term Topic Vectors**  Saves the topic vectors as columns to the data table created by the Save Term Table option.

**Remove**  Removes the Topic Analysis report from the SVD report.

---

**Discriminant Analysis**

Discriminant analysis predicts membership of each document in a group or category based on the columns in the document term matrix (DTM). Specifically, discriminant analysis predicts a classification of each document into a category of a response column. When you select the Discriminant Analysis option, you must select a response column that contains categories or groups. Group membership is predicted by the columns of the DTM. For more information about discriminant analysis, see *Multivariate Methods*.

The discriminant analysis method in the Text Explorer platform is based on a singular value decomposition of the centered DTM. Each group of the response column has its own group mean that is used to center the DTM. The discriminant analysis method in the Text Explorer platform is faster than the Discriminant Analysis platform because it takes advantage of the sparsity of the DTM.

**Discriminant Analysis Specifications Window**

The Discriminant Analysis option in the Text Explorer platform is based on the Document Term Matrix (DTM). The DTM is formed by creating a column for each term in the Term List (up to a specified Maximum Number of Terms). Each text document (equivalent to a row in the data table) corresponds to a row of the DTM. The values in the cells of the DTM depend on the type of weighting specified by the user in the Specifications window.
When you select the Discriminant Analysis option from the Text Explorer red triangle menu, the Specifications window appears with the following options:

**Maximum Number of Terms**  The maximum number of terms included in the discriminant analysis.

**Minimum Term Frequency**  The minimum number of occurrences a term must have to be included in the discriminant analysis.

**Weighting**  The weighting scheme that determines the values that go into the cells of the document term matrix. The weighting scheme options are described in “Document Term Matrix Specifications Window” on page 407.

**Number of Singular Vectors**  The number of singular vectors in the discriminant analysis. The default value is the minimum of the number of documents, the number of terms, or 100.

**Discriminant Analysis Report**

By default, the Discriminant Analysis report in the Text Explorer platform contains two open reports: the Classification Summary and the Discriminant Scores. The other reports are initially closed.

The Discriminant Analysis report contains the following reports:

**Term Means**  Provides a table of the terms used in the discriminant analysis. The terms correspond to the columns of the DTM. The table contains the means in each group for each term, as well as the overall mean and weighted standard deviation for each term.

**Squared Distances to Each Group**  Provides a table that contains the squared Mahalanobis distances to each group for each document. For more information about Mahalanobis distances, see *Multivariate Methods*.

**Probabilities to Each Group**  Provides a table that contains the probability that a document belongs to each group.

**Classification Summary**  Provides a report that summarizes the discriminant scores. This report corresponds to the Score Summaries report in the Discriminant Analysis platform report.

**Discriminant Scores**  Provides a table of the predicted classification of each document and other supporting information. This table corresponds to the Discriminant Scores table in the Discriminant Analysis platform report.
Discriminant Analysis Report Options

The Discriminant Analysis red triangle menu contains the following options:

**Canonical Plot**  Shows or hides a plot of the documents and group means in canonical space. Canonical space is the space that most separates the groups. If there are more than two levels of the response variable, you must specify the number of canonical coordinates. If you specify more than two canonical coordinates, this option produces a matrix of canonical plots.

**Save Probabilities**  Saves a probability column to the data table for each response level as well as a column that contains the most likely response. The Most Likely response column contains the level with the highest probability based on the model.

Each probability column gives the posterior probability of an observation’s membership in that level of the response. The Response Probability column property is saved to each probability column. For more information about the Response Probability column property, see *Using JMP*.

**Save Probability Formulas**  Saves formula columns to the data table for the prediction of the most likely response. The first saved column contains a formula that uses the Text Score() function to calculate the probability for each response level. There are also columns that contain probabilities for each response level as well as a column that contains the predicted response.

**Save Canonical Scores**  Saves columns to the data table that contain the scores from canonical space for each observation. Canonical space is the space that most separates the groups. The column for the $k$th canonical score is named $\text{Canonical}<k>$.

**Remove**  Removes the Discriminant Analysis report from the Text Explorer report window.

Term Selection

Term selection identifies which terms best explain different responses. The analysis uses the Generalized Regression platform to perform variable selection on the document term matrix (DTM) and to identify terms that most impact the response. Term selection can be used with binary responses, similar to sentiment analysis, as well as other types of responses. The fitted model uses an appropriate response distribution for the specified response column.

**Tip:** For an example of Term Selection, select Help > Sample Data Library, open Chips.jmp, and run the Text Explorer - Term Selection table script.
Term Selection Settings

The Settings report enables you to select a response column, specify the target level of the response, and adjust the settings for the model. When you have specified the model settings, click the Run button to run the model. The fitted model then appears in the Summary report. See “Term Selection Summary Report” on page 421.

Target Level

After you choose a response column, the Target Level outline appears.

- For nominal responses, choose one level of the response to be the target level in a logistic regression model; the response in the logistic regression model is the target level versus all of the other levels combined.
- For ordinal responses, all response levels are initially included in the model. Using the local data filter, you can select levels of the response to be excluded from the model; the underlying numeric values of the included levels are modeled with a normal response distribution.

**Note:** For ordinal responses, the term selection model can be fit only when the data type of the response column is numeric.

- For continuous responses, use the local data filter histogram to select values of the response to be excluded from the model; the included values are modeled with a normal response distribution.
- For response columns with the Multiple Response modeling type, choose one or more levels of the response to be the target level in a binary logistic regression model. If you choose more than one level, a document belongs to the target level if any of the levels are present in the response column for that document. Select the **Combine with AND** option to require that all selected levels are present in a document’s response column for that document to be included in the target level.

Model Settings

By default, the Generalized Regression model uses the Elastic Net estimation method with early stopping and the AICc validation method. You can change these settings in the Model Settings outline. See *Fitting Linear Models*.

**Note:** If a Validation column is specified in the Text Explorer launch window, the Generalized Regression platform in the Term Selection report uses the Validation column as the Validation method.
Term Settings

The Term Settings define the document term matrix (DTM) that is used in the regression model. You can change the weighting technique as well as the maximum number of terms included in the DTM; each term corresponds to a column of the DTM. Note that terms that have fewer than 10 occurrences in the corpus are not included in the DTM used by the model. For more information about the DTM options, see “Document Term Matrix Specifications Window” on page 407.

Term Selection Report

After you run an analysis, the Term Selection report consists of three sections. The Settings report contains controls for specifying an analysis. See “Term Selection Settings” on page 419. Below the Settings report, there are initially closed Generalized Regression reports for each analysis that you have run. See Fitting Linear Models. The last section of the report is the Summary report.
**Figure 12.12 Term Selection Report**

The **Term Selection Summary Report** contains a Model Comparison table, a Summary table and histogram, a Document Scores table, a Term Scores table, and a text box.

The Model Comparison table contains a row for each fitted model. The rest of the Summary report shows results from the currently selected model in this table.
The Summary table shows counts and mean scores for the documents, overall and by the predicted value of the response from the model. The Mean Contribution is the average of the contribution values in the Document Scores table. The Summary histogram shows the distribution of the overall contribution values of the documents. The histogram is interactive, so you can click on a bar to highlight the corresponding documents in the Document Scores table.

The Document Scores table shows the positive and negative contribution values for each document, as well as predicted and actual values for each document. For binomial response models, the predicted values are probabilities of the document being in the target level; for normal response models, the predicted values are the predictions from the fitted model for each document. If you select a row of the table, the text of the corresponding document appears in the text box below the table.

The Term Scores table lists each term that was selected by the fitted model, its coefficient from the model, its LogWorth, and the count of occurrences of the term in the corpus. If you select a row of the table, the text of the corresponding document appears in the text box below the table.

The text box shows the text of documents that are selected in the Document Scores table or the context of terms that are selected in the Term Scores table.

**Term Selection Report Options**

The Term Selection red triangle menu contains the following options:

**Save Document Scores**  (Available only when an analysis is selected in the Summary table.)
Saves the columns from the Document Scores table to new columns in the data table. The new columns contain the positive and negative contributions, as well as the predicted value for each document.

**Save Term Score DTM**  (Available only when an analysis is selected in the Summary table.)
Saves columns to the data table for each relevant term in the currently selected analysis. The columns contain the term scores for each document, using the Weighting specified in the Term Selection Term Settings.

**Save Prediction Formulas**  (Available only when an analysis is selected in the Summary table.)
Saves columns to the data table that contain the prediction formulas for the currently selected analysis.

**Show Term Cloud**
Shows or hides a word cloud in the Summary report. The word cloud shows the coefficient terms in the currently selected analysis. The words are sized by the absolute value of their coefficients and colored by the sign of their coefficients.

**Remove**
Removes the Term Selection report from the Text Explorer report window.
Sentiment analysis identifies sentiment terms in documents using lexical analysis and scores documents for positive, negative, and overall sentiment. The analysis assumes that each document is free text with binary sentiment on a single topic. Sentiment Analysis incorporates basic natural language processing (NLP) into the results. For more information about natural language processing, see https://opennlp.apache.org/. If you prefer to not use NLP, deselect the Parse Documents option.

**Tip:** For an example of Sentiment Analysis, select Help > Sample Data Library, open Chips.jmp, and run the Text Explorer - Sentiment Analysis table script.

**Notes:**

- In Sentiment Analysis, a word can take effect in only one class of terms: negation, intensifier, or sentiment.
- Sentiment Analysis recognizes some emoticons, or sequences of characters that are treated as a single unit. You can see the built-in emoticons and their default sentiment scores in the Sentiment Terms report or in the Manage Sentiment Terms window.
- If you specify a word as a negation, intensifier, or sentiment term and it is already specified as a stop word, the word is temporarily removed as a stop word as long as the Sentiment Analysis report is open. This temporary removal affects the entire Text Explorer report. It is restored as a stop word when the Sentiment Analysis report closes.
Sentiment Analysis Report

By default, the Sentiment Analysis report in the Text Explorer platform contains one open report: the Sentiment Summary. The other reports are initially closed.

Figure 12.13 Sentiment Analysis Report

The Sentiment Analysis report contains the following reports:

**Negation Terms**
Contains a list of the negation terms in the current sentiment analysis. Right-click the list to see a menu of additional options. You can select terms in the list to remove them.
Intensifier Terms

Contains a list of the intensifier terms and their corresponding multiplier values. Right-click the list to see a menu of additional options. You can select terms in the list to remove them.

Sentiment Terms

Contains a list of the sentiment terms and their corresponding score values. This report also enables you to add new sentiment terms. The Possible Sentiment table contains counts of terms that you might consider adding as sentiment terms. To add a term as a sentiment term, select it in the Possible Sentiment table and click one of the buttons below +Sentiment. To choose a sentiment score value that is not listed, you can edit the score value after you have added it to the list of sentiment terms.

When you select a term in the Possible Sentiment table, documents that contain that term appear on the right side of the Sentiment Terms report. This provides context for how the term is used in the corpus.

Features

Contains options to score features in the corpus. A feature is something that is being described by the sentiment terms. Click the Search button to generate a list of possible feature terms. When you select one or more terms from the Possible Feature table, excerpts of the documents that contain those terms appear in the text box to the right of the table. Click the Score Selected Features button to update the Sentiment Summary report to show the results of scoring the selected feature terms.

Note: If you select the Parse Documents option, the Features report scores words when they occur within the same umbrella clause as a sentiment.

Sentiment Summary

Contains the results of the sentiment analysis based on the current settings. This report contains a Summary table and histogram, a Document Scores table, a Sentiment Terms table, a text box, and a control panel that enables you to add more sentiment and intensifier terms.

The Summary table shows counts and mean scores for the documents, broken down by how the documents were scored. The Mean Score is determined by the setting of the Scoring option. See “Sentiment Analysis Report Options” on page 426. The Summary histogram shows the distribution of the overall sentiment scores of the documents. The histogram is interactive, so you can click on a bar to highlight the corresponding documents in the Document Scores table.
The Document Scores table shows the positive and negative sentiment score sums and means, as well as the overall sentiment score for each document. If you select a row of the table, the text of the corresponding document appears in the text box below the table. If you specify a Score Column, the table contains the values from the scoring column.

Tip: You can hover over the cells in the Document Scores table to see the scoring calculations that were used to produce the table results.

The Sentiment Terms table lists each sentiment term, its score value, and the count of occurrences of the term in the corpus.

Tip: For sentiment terms with multiple words, you can hover over the cells in the Score column to see the calculations that were used to produce the score.

The text box shows the text of documents that are selected in the Document Scores table or the context of terms that are selected in the Sentiment Terms table. When you select a document in the Document Scores table, a list of the sentiments in that document appears to the right of the text box.

Tip: When you hover over a term in the text box that is classified as a negation, intensifier, or sentiment term, a box appears that shows the classification and contains a Remove button. Click the Remove button to quickly remove that term from the list of negation, intensifier, or sentiment terms.

The control panel activates when you select a term in the text box. To add a term as a sentiment term, select it in the text box and click one of the buttons below +Sentiment. To add a term as an intensifier term, select it in the text box and click one of the buttons below ×Intensifier.

Sentiment Analysis Report Options

The Sentiment Analysis red triangle menu contains the following options:

Scoring

Contains the following options for calculating the Overall Scores for documents:

Scaled
Scores of positive and negative phrases are summed. The sum is then divided by the number of phrases in the document to determine the Overall Score.

MinMax
The Overall Score is calculated as the sum of the maximum positive score and the minimum negative score.

Score Column
Specifies a data table column that contains known information that can be compared with the calculated sentiment. The score column is added to the Document Scores table.
Tip: You can visually compare the Overall Score column and the score column to assess the sentiment scoring.

**Parse Documents** Specifies if natural language processing (NLP) is used to parse the documents. For more information about natural language processing, see https://opennlp.apache.org/.

**Save Document Scores** Saves the columns from the Document Scores table to new columns in the data table. The new columns contain the positive and negative sentiment score sums and means, as well as the overall sentiment score for each document.

**Save Count of Sentiment Scores by Document** Saves a column to the data table for each sentiment term. Each column contains counts of the occurrences of each sentiment term in each document.

**Show Negation Terms** Shows or hides the Negation Terms report.

**Show Intensifier Terms** Shows or hides the Intensifier Terms report.

**Show Sentiment Terms** Shows or hides the Sentiment Terms report.

**Show Feature Finder** Shows or hides the Features report.

**Show Sentiment Cloud** Shows or hides a word cloud of the sentiment terms in the Sentiment Summary report.

**Include Builtin Negation Terms** Specifies if the negation terms used in the sentiment analysis include built-in negation terms or not.

**Include Builtin Intensifier Terms** Specifies if the intensifier terms used in the sentiment analysis include built-in intensifier terms or not.

**Include Builtin Sentiment Terms** Specifies if the sentiment terms used in the sentiment analysis include built-in sentiment terms or not.

**Manage Negation Terms** Shows a window that enables you to add or remove negation terms. The changes made can be applied at the User, Column, and Local levels. You can also specify Local Exceptions that exclude negation terms that are specified in any of the other levels. See “Term Options Management Windows” on page 401.

**Manage Intensifier Terms** Shows a window that enables you to add or remove intensifier terms. The changes made can be applied at the User, Column, and Local levels. You can also specify Local Exceptions that exclude intensifier terms that are specified in any of the other levels. See “Term Options Management Windows” on page 401.

**Manage Sentiment Terms** Shows a window that enables you to add or remove sentiment terms. The changes made can be applied at the User, Column, and Local levels. You can
also specify Local Exceptions that exclude sentiment terms that are specified in any of the other levels. See “Term Options Management Windows” on page 401.

Additional Example of the Text Explorer Platform

This example looks at aircraft incident reports from the National Transportation Safety Board for events occurring in 2001 in the United States. You want to explore the text that contains a description of the results of the investigation into the cause of each incident. You also want to find themes in the collection of incident reports.

1. Select Help > Sample Data Library and open Aircraft Incidents.jmp.
2. Select Rows > Color or Mark by Column.
3. Select Fatal from the columns list and click OK.
   The rows that contain accidents involving fatalities are colored red.
4. Select Analyze > Text Explorer.
5. Select Narrative Cause from the Select Columns list and click Text Columns.
6. From the Language list, select English.
7. From the Stemming list, select Stem All Terms.
8. From the Tokenizing list, select Basic Words.
9. Click OK.
From the report, you see that there are almost 51,000 tokens and about 1,900 unique terms.

10. Right-click pilot· in the Term List and select **Select Rows**.

From the number of selected rows in the data table, you see that some form of the word “pilot” occurs in more than 1,300 of the incident reports.

11. Right-click pilot· and select **Add Stop Word**.

Because some form of the word “pilot” occurs frequently compared to other terms, these terms do not provide much information to differentiate among documents. All of the terms that stem to pilot· are added to the stop word list.

*The remaining steps of this example can be completed only in JMP Pro.*

12. Click the red triangle next to Text Explorer for Narrative Cause and select **Latent Semantic Analysis, SVD**.

This is the first analysis step toward topic analysis, which performs a rotation of the SVD.

13. In the Specifications window, type 50 for Minimum Term Frequency.

Because there are approximately 51,000 tokens, this frequency is equivalent to a term that represents at least 0.1% of all the terms.

14. **Click OK.**
There is not a lot of difference in the document SVD plot between fatal and non-fatal incidents.

15. Click the red triangle next to SVD Centered and Scaled TF IDF and select **Topic Analysis, Rotated SVD**.
   You want to look for groups of terms that form topics.

16. Type 5 for Number of Topics.

17. Click **OK**.

The terms for each topic with the highest loadings enable you to interpret whether the topic is capturing a theme in the incident reports.
For example, Topic 1 has high loadings for power, loss, and engine, indicating a theme of losing power to the engine as a cause of the incident. This corresponds to the phrase “loss of engine power” occurring 273 times in the set of incident reports.

Based on the words with high loadings in Topic 2, it can be described as being related to incidents that involved darkness or low altitude.

At this stage of the text analysis, you have many choices in how to proceed. Text analysis is an iterative process, so you might use topic information to further curate your term list by adding stop words or specifying phrases. You might save the weighted document-term matrix, the vectors from the SVD or rotated SVD as numeric columns in your data table and use them in other JMP analysis platforms. When you use these columns in other platforms, you can also include other columns from your data table in further analyses.

Essential Graphing

“The real voyage of discovery consists not in seeking new landscapes, but in having new eyes.”

Marcel Proust
Get the Most from JMP

Whether you are a first-time or a long-time user, there is always something to learn about JMP.

Visit JMP.com to find the following:

- live and recorded webcasts about how to get started with JMP
- video demos and webcasts of new features and advanced techniques
- details on registering for JMP training
- schedules for seminars being held in your area
- success stories showing how others use JMP
- the JMP user community, resources for users including examples of add-ins and scripts, a forum, blogs, conference information, and so on

Essential Graphing describes all of the different graphs and elements you can use to visualize your data:

- Graph Builder interactively creates many different types of graphs. See Chapter 3, “Graph Builder” and Chapter 4, “Graph Builder Examples”.
- Bubble Plot creates a scatterplot that represents its points as circles, or bubbles. Bubble plots can be dynamic (animated over time) or static (fixed bubbles that do not move). See Chapter 5, “Bubble Plots”.
- Scatterplot Matrix shows an ordered collection of bivariate graphs. See Chapter 6, “Scatterplot Matrix”.
- Parallel Plot draws connected line segments that represent each row in a data table. See Chapter 7, “Parallel Plots”.
- Cell Plot draws a rectangular array of cells where each cell corresponds to a data table entry. See Chapter 8, “Cell Plots”.
- 3D Scatterplot shows the values of numeric columns in the associated data table in a rotatable, three-dimensional view. See Chapter 9, “Scatterplot 3D”.
- Contour Plot constructs contours of a response in a rectangular coordinate system. See Chapter 10, “Contour Plots”.
- Ternary Plot display the distribution and variability of three-part compositional data. See Chapter 11, “Ternary Plots”.
- Maps can be used in Graph Builder, but also in other platforms, as background maps. See Chapter 12, “Maps”.

Chapter 2
Introduction to Interactive Graphing
Overview of Data Visualization
Chapter 3

Graph Builder
Interactive Data Visualization

Use Graph Builder to interactively explore your data. You can quickly create and experiment with plots until you find the one you want. Then, you can share your results with others.

This chapter shows you how to use Graph Builder. For detailed examples using Graph Builder, see “Graph Builder Examples” on page 119.

  - Options for Axes, Variable Labels, or Graph Titles ................................ 111
Options for the Dividing Line between Multiple Graphs ......................... 113
Legend Options ................................................................. 113
How to Use Graph Builder

1. Open the data table containing the data that you want to graph.
2. Select **Graph > Graph Builder**.
3. Drag columns from the Variables list into zones. See “Move or Remove Variables in Zones” on page 39 and “Graph Zones” on page 102.
4. Click element type icons to choose different types of graphs or elements. See “Element Types and Options” on page 53.
5. (Optional) Customize the selected element types. See “Element Types and Options” on page 53.
6. (Optional) Customize the legend. See “Legend Options” on page 113.
7. When you are satisfied with the graph, click **Done**.

About the Graph Builder Window

To launch Graph Builder, open your data table and then select **Graph > Graph Builder**. The Variables list contains the columns in your data table, which you can drag into zones.

**Figure 3.2** Graph Builder Window for Big Class.jmp
To re-create and modify the graph in Figure 3.2, follow these steps:

1. Select Help > Sample Data Library and open Big Class.jmp.
2. Select Graph > Graph Builder.
3. Select height and drag it to the Y zone.
4. Select weight and drag it to the X zone.
5. Select age and drag it to the Overlay zone.
The graph in Figure 3.2 appears. The relationship between height and weight for each value of age is shown using color in a single graph.

Now you want to see separate graphs for each value of age.

6. Select age in the Overlay zone and drag it to the Wrap zone.

Figure 3.3 Height and Weight Grouped by Age

For each value of age, the relationship between height and weight is shown in a separate graph.

Example of Features in Graph Builder

The following example gets you started using some of the features in Graph Builder. This example uses fuel economy data collected for hybrid and non-hybrid cars. You want to get an understanding of miles per gallon (MPG), a measure of fuel economy, and to see which factors might be influencing MPG. This example shows you how to plot several factors of interest:

- “Get an Overall Picture of Combined Miles per Gallon” on page 33
- “Plot Mileage Stratified by Engine and Driving Type” on page 34
- “Find the Relationship between Hwy and City MPG by Engine Type” on page 37
- “Find the Relationship between Hwy and City MPG by Engine Type” on page 37
Get an Overall Picture of Combined Miles per Gallon

1. Select **Help > Sample Data Library** and open Hybrid Fuel Economy.jmp.
2. Select **Graph > Graph Builder**.
3. Select Comb MPG (combined miles per gallon) and drag it to the Y zone.

**Figure 3.4 Initial Graph of Combined MPG**

Because markers are assigned to rows in the data table, points are represented by those markers. The value of Comb MPG for each row is plotted at its value on the vertical axis. To avoid over-plotting points that correspond to observations with the same Comb MPG values, JMP automatically jitters the points.

You can get a cleaner picture of the distribution by plotting a histogram.

4. Click the Histogram icon.
   
   You want the histogram to be vertical, so you need to move Comb MPG to the X zone.
5. Hover over Comb MPG in the Y axis. The cursor turns into a hand. Select and drag Comb MPG into the X zone.
6. Click the Caption Box icon to show the mean Comb MPG on the graph.
Figure 3.5  Histogram of Combined MPG

The histogram shows that Comb MPG can range widely, from about 10 to 45. However, a lot of vehicles get mileage between 15 and 30. The mean MPG is 23.3286.

Plot Mileage Stratified by Engine and Driving Type

1. Click Start Over.
2. Select City MPG, Hwy MPG, and Comb MPG.
3. Hover over the Y zone, hold down the Shift key and click in the Y zone.
   This creates separate Y axes for City MPG, Hwy MPG, and Comb MPG.
Figure 3.6  MPG Variables with Separate Y Zone Axes

In the legend at right, markers are colored according to the driving type.

**Tip:** To change the color assigned to a driving type, right-click the marker in the legend.

4. Drag Engine to the Group X zone.
5. Click the Box Plot icon 📈.
The box plots show the distributions in a very compact form. You can see that all three types of MPG values are substantially lower for the gas vehicles than for the hybrids in the study. From the horizontal lines in the centers of the two City MPG box plots, you can estimate that the median difference is about five miles per gallon. However, you can use the Caption element to be sure.

6. Click the Caption Box icon.

7. In the Caption Box options at the left of the plot, select **Median** from the Summary Statistic list for Comb MPG, Hwy MPG, and City MPG.
The median city MPG for gas engines is 17 and for hybrid engines is 22.

**Find the Relationship between Hwy and City MPG by Engine Type**

1. Click **Start Over**.
2. Select City MPG and drag it into the X zone.
3. Select Hwy MPG and drag it into the Y zone.
4. Select Engine and drag it into the Overlay zone.
Figure 3.9 Hwy and City MPG by Engine Type

A Smoother appears for each type of engine, Gas, and Hybrid.

**Tip**: To change the line properties (color, width, and so on), right-click a line in the legend.

5. Click the Line of Fit icon.

For each engine type, the smoother is removed and a least squares line, together with confidence bands for the predicted mean, is added.

**Tip**: To add the $y = x$ line, right-click in the graph and select Customize > + > Templates > Y Function. Replace _function_of_x_ with $y = x$ and click OK.

6. Drag a rectangle around the “o” marker with the smallest value of City MPG and check the number of rows selected in the Rows panel of the data table.

You see that two rows are represented by this marker. You can check that over-plotting happens for other markers as well. When there is over-plotting of observations, namely when several observations are represented by a single point on a plot, density contour plots can help you see the density of points.

7. Drag the Contour icon into the graph.

Dragging the Contour icon into the graph retains the Line of Fit for each engine type.
The contours indicate that for both engine types, there are more vehicles in the study with lower MPG values than higher MPG values.

**Move or Remove Variables in Zones**

There are several ways that you can move a variable into a zone:

- To move a variable from one zone to another, click and drag it from the old zone into the new zone.
- To replace a variable in a zone, drag the new variable over the old one.
- To switch a variable from one zone to another, right-click the variable in the zone that you want to move and select **Swap**. Then, select the variable that you want to switch places with.
- To merge variables on the same axis, see “**Merge Variables on a Common Axis**” on page 40.

To remove a variable, drag it into empty space, or right-click the name of the variable in the zone and select **Remove**.
Work with Axes

- "Merge Variables on a Common Axis"
- "Create Separate Axes in the X and Y Zones"
- "Create a Second Y Axis"
- "Create Nested Axes for Character Variables"
- "Order the Levels of a Categorical Variable"

Merge Variables on a Common Axis

Merging variables places both variables on the same axis and creates a single graph for both variables. Elements in the plot are colored by the variables, and a legend appears to the right of the plot. When points are plotted, they are randomly jittered for each value or category defined by the combination of the axes.

- If you are starting with an empty zone, highlight multiple variables from the list and drag them into the zone at the same time.
- If you already have variables in the zone and want to add more, drag the new variables to the inner side of the zone, in the graph area, until a symmetric polygonal shape appears.

Figure 3.11 New Variable Merged with Existing Variable
Results Based on Data and Modeling Type

- If only variables with continuous modeling types are merged, their values are plotted against a common axis.
- If variables with categorical (nominal or ordinal) modeling types are merged with a continuous variable, the values of all variables are plotted against a common axis.

Before you can merge a variable with the character data type with numeric variables, the levels of the character variable have to be assigned numeric values. Integer values are assigned based on the Value Order column property or the default value ordering. These integer values range from 0 (highest level in value ordering) to the number of levels minus one (lowest value in value ordering). These integer values are then plotted against the common axis.

- If only variables with categorical modeling types are merged, then separate, nested, axes are constructed for each variable. See “Create Nested Axes for Character Variables” on page 45.

Create Separate Axes in the X and Y Zones

To quickly plot multiple variables against separate axes in the X zone:

1. Select the columns in the Variables list.
2. Click Shift and then click the X zone.

If you want more control over where the variables appear, drag them individually. Drag additional variables above, below, or between existing variables in the X zone.
Figure 3.12  Dragging a Variable to the Right of the Existing Variable

A single polygonal shape indicates when your variable is in the appropriate target zone.

To quickly plot multiple variables against separate axes in the Y zone:

1. Select the columns in the Variables list.
2. Click **Shift** and then click the **Y** zone.

If you want more control over where the variables appear, drag them individually. Drag additional variables above, below, or between existing variables in the Y zone.
Figure 3.13 Dragging a Variable above the Existing Variable

A single polygonal shape indicates when your variable is in the appropriate target zone.

Create a Second Y Axis

If you have two or more Y variables on the same axis, you can reflect the scaling of a second set of variables by creating a second Y axis. This can be useful when two variables measure the same underlying quantities, but have different scales. In general, it is unwise to use a second Y axis in any other situation. See Few (2008).

To create a second Y axis:

1. Right-click one of the Y variable names in the Y zone and select Move Right.
2. Select the variable or variables that you want to move to the new axis.
   The new axis is scaled according to the values of the specified variable, and the selected variable is plotted against this axis.
3. Repeat the process to plot additional variables against the new axis.
   The new axis adjusts to accommodate the values of the additional variables.
Change the Graph for a Second Y Axis

When you click an element type, it applies only to the variables on the left Y axis. To apply an element to the variables on the right Y axis, right-click and change the second element, which corresponds to the right axis.

Example of Creating a Second Y Axis

The CrimeData.jmp sample data table contains data on various types of crime for the 50 US states yearly, from 1973 to 2010. The Total column sums the number of incidents, and the Total Rate column gives a population-adjusted rate. You want to show these two variables on a single chart.

1. Select Help > Sample Data Library and open CrimeData.jmp.
2. Select Graph > Graph Builder.
3. Select Total Rate and Total and drag them to the Y zone.
4. Select Year and drag it to the X zone.

Figure 3.14 Total Rate and Total Merged

The Total Rate values are all between 0 and 1, and they are barely visible. Calculate yearly means and then use a second Y axis to make these values visible.

5. In the options panel for Points, select Mean next to Summary Statistic.
6. Click the Line element.
7. Right-click the variable names in the Y zone and select **Move Right > Total Rate**.

**Figure 3.15 Second Y Axis Added**

An axis for Total Rate is added on the right, and the axes rescale to show both sets of values. You can now see relationships between the two measures. For example, both measures began to decrease in 1991.

8. (Optional) Click **Done**.

**Create Nested Axes for Character Variables**

If you merge variables that all have categorical modeling types, then an individual axis is constructed for each variable. The outermost axis corresponds to the first variable selected, the next to the second, and so on.

To nest the axes in a specific order, drag the variables to the zone individually. First, drag the variable for the innermost axis to the zone. Then drag the variable for the next axis to the outside of the preceding variable and drop the variable once a trapezoid shape appears.

The following example illustrates nested axes.
After changes are made to improve a measurement process, a measurement systems analysis study is conducted to study repeatability and reproducibility with Part, Operator, and Instrument as factors. Each of three operators measures each of eight parts with four instruments. Of particular interest is the consistency of the instruments. The measured quantity is called new Y.

1. Select Help > Sample Data Library and open Variability Data/3 Factors Crossed.jmp.
2. Select Graph > Graph Builder.
3. Select new Y and drag it to the Y zone.
4. Select Part and drag it to the X zone.
   The plot shows variation in the values that are measured for each of the eight parts. There are systematic differences among the parts, which is to be expected. For example, measurements for parts 7 and 8 are lower than those for parts 1 through 6.
5. Drag Operator to the Color zone.
   The new Y values are colored by Operator, using the legend at the right of the graph. It appears that Janet might be measuring higher values than the other two operators on most parts. But the Operator effect is not easy to visualize, so you create a separate Operator axis.
6. Select Operator and drag it beneath Part in the X zone.
   The label Operator/Part appears, indicating that Part is associated with the topmost axis, and Operator is associated with the lower axis.
Figure 3.16 Drag Operator to Add a Second Axis

Now it is easier to see that Janet tends to obtain higher measurements for the same parts than do Bob and Frank. But what about the effect of Instrument?

7. Select Instrument and drag it beneath Operator/Part in the X zone.

The label Instrument/Operator/Part appears, indicating that a third axis for Instrument has been added beneath the Operator axis.
It is clear that Instrument 2 leads to much more consistent measurements than the other three instruments. For Instrument 2, there is comparatively little variation between or within operators.

8. Select Instrument and drag it to the **Color** zone.
Now the new Y values are colored by Instrument, and it is easy to see Instrument differences.

By nesting the axes for the three factors in study, you are able to obtain a visual understanding of the variation attributable to the factors.

**Order the Levels of a Categorical Variable**

JMP orders the levels of a categorical variable according to the following rules:

- Numeric, nominal data are sorted numerically.
  - White space around numbers is compared: “vt 1” is sorted before “vt1”.
- Character data that are only digits (numbers) are sorted numerically.
- Character data are sorted alphabetically, with the following exceptions:
  - Months and days of the week are in chronological order.
  - Ratings are sorted from low to high:
    - **Low to high**: Very Low, Low, Medium Low, Medium, Medium High, High, Very High
    - **Agreement**: Strongly Disagree, Disagree, Neutral, Indifferent, Agree, Strongly Agree
    - **Bad or good**: Failing, Unacceptable, Very Poor, Poor, Bad, Acceptable, Average, Good, Better, Very Good, Excellent, Best
– Character data that have a character prefix and a numeric suffix are sorted first by prefix and then by suffix. For example, lots 1 through 12 are ordered “lot1”, “lot2”, “lot3”, ..., “lot10”, “lot11”, and “lot12”.

– If the numeric suffix starts with a “0”, it does not follow numeric ordering by suffix. (“lot1” is ordered after “lot02”).

**Note:** The preceding rules apply only to graphs with categorical axes.

To change the order of the levels of a categorical variable on a graph axis, click and hold a level on the axis to enter edit mode. In the edit mode, denoted by boxes around each label, you can drag one or more labels (using shift-click for multiple selection) to rearrange them. As you rearrange labels, the value order column property is updated. You can also edit labels, which updates the value label column property. Press Esc to exit the edit mode.

You can also order the levels of a categorical (nominal or ordinal) variable on axes using the Value Order column property, which takes precedence over all other ordering rules. To change the ordering, you can do one of the following:

- Use the Value Order column property to ensure that values are ordered as you intend. For more information about the Value Order column property, see *Using JMP*.
- Use the values of a numeric variable already in the graph. In Graph Builder, right-click the categorical axis and select **Order By**.
- Use the values of an arbitrary numeric variable. In Graph Builder, drag the numeric variable next to the categorical variable in the zone until a trapezoid appears and then drop the variable. The axis label changes to <categorical variable> ordered by <numeric variable>. See “Example of Ordering the Levels of a Categorical Variable Using a Numeric Variable” on page 51.

Change the order of the levels or the statistic:

1. Right-click the axis label and select **Order By**.
2. Select one of the ascending or descending options or **other** to select a numerical column.

You can order by a variable’s Order Statistic (these options are prefixed by the variable’s name) or by the number of observations in each level of the categorical variable (Count).

3. The default ordering statistic is the mean. To use another statistic, right-click the axis label and select **Order Statistic**.

**Note:** If you try to order the values of a numeric variable using another numeric variable, JMP merges the variables. See “Merge Variables on a Common Axis” on page 40.
Example of Ordering the Levels of a Categorical Variable Using a Numeric Variable

To order a nominal or ordinal variable by a numeric variable, consider data about vehicle types. You want to see the vehicle types arranged in a meaningful order.

1. Select Help > Sample Data Library and open Cars.jmp.
2. Select Graph > Graph Builder.
3. Select Size and drag it into the X zone.

   This variable represents the type of the vehicle. Eight levels are listed alphabetically on the X axis: compact (comp), heavy (hev), lightweight (lt), medium (med), mini, multi-purpose (mpv), pick-up truck (pu), and van. Since the levels are listed alphabetically, they are not ordered in a meaningful way. For example, heavy comes before mini and lightweight. You want to order the levels by Wt (weight).

4. Select Wt and drag it to the middle of the X axis. Drop it just above the X axis. Before you drop the variable, a blue quadrilateral appears.

\[ \text{Figure 3.19 Merging Wt and Size} \]

The levels of Size are now arranged in increasing order according to the average Wt of all vehicles in the levels. Notice that mini and lt (lightweight) are now ordered before hev (heavy). The axis label is updated, signifying that an ordering variable is in use.

Next, verify that Size is actually ordered by Wt.

5. Select Wt and drag it to the Y zone.
6. Select Mean from the Summary Statistic list.
**Figure 3.20** Example of Size Ordered by Wt, Ascending

You can see that the average Wt increases from left to right.

Change the order from ascending to descending.

7. Right-click in the X zone and select **Order By > Wt, descending**.

   Now the levels of Size are arranged in decreasing order of mean Wt. You want to see whether the right femur load (R Leg) decreases with vehicle weight.

8. Right-click Wt in the Y zone and select **Remove**.

9. Select **R Leg** and drag it to the Y zone.

10. Select **None** from the Summary Statistic list.

   This selection replaces the means with points for all the individual observations.

11. Click the Smoother element 🌤️.
**Figure 3.21** Example of R Leg Ordered by Wt, Descending

R Leg seems unrelated to the weight classes.

The default ordering statistic is the mean. To use another statistic, right-click in the X zone, select **Order Statistic** and change it to the statistic that you want.

---

**Element Types and Options**

You can change how your data appear by clicking an element type icon, such as a bar chart, line, or histogram.

**Figure 3.22** Element Type Icons

---

**Note:** Supported element types vary depending on the variable type and zones that are selected. Element types that are not applicable appear dimmed.

For each element that you add to a graph, an outline appears in the Properties area at left. This is where you specify and change properties for each element type.
You can also right-click in any graph to change the element, or customize elements in the graph.

**Select Multiple Elements at Once**

To select and overlay multiple elements, hold down the Shift key and click the elements. Alternatively, you can drag the elements into the graph one at a time.
Labels for Points

In most graphs that display points, when you hover over a point, a label appears showing information about the corresponding row. Hover over the label and right-click for more options. You can pin the label to the graph, copy the contents, or close to remove the label. You can also pin the label by clicking the pin icon in the upper right of the label. See Using JMP.

Hidden and Excluded Rows

Hide and exclude are two different row states:

- The goal of a hidden row is to impact visibility but not analytical results.
- The goal of an excluded row is to impact the analytical result.

For graphs, an analytical value is usually part of the appearance. Therefore, excluding rows typically impacts the graph appearance and any analytical result included as part of the graph. Hiding a row typically impacts only the graph appearance.

For example, consider a graph with points and a line of fit:

- If rows are hidden, those rows are included in the calculations to obtain the line of fit but they are not plotted.
- If rows are excluded, those rows are excluded from both the calculations and the display.

In the two scenarios, the number of points that appear is the same, but the line of fit is different.

When graphing groups, if all rows in a group are hidden, then the visual for that group is also hidden.

Points

The Points element shows data values as points.

Figure 3.25 Points Options

Summary Statistic Changes the statistic being plotted. The statistic is calculated using the variable on the Response Axis. None is the default setting, indicating that the data values themselves are plotted.
Error Interval  Adds or removes specified error interval in the graph.

Interval Style  Draws error bars or error bands for the selected error interval.

Jitter  Jitter adds random noise to values to reduce over-plotting. Choose from the following types of jitter:

   None  No adjustments are made.

   Auto  Adds various types of jitter when categorical variables are involved. No jitter is added when you have only continuous variables.

Random Uniform  Random offset with uniform distribution.

Random Normal  Random offset with Gaussian distribution.

Packed  Places markers tightly to preserve any non-jittered dimensions.

Centered Grid  Similar to Packed, but adjusts the non-jittered dimensions to fall into a grid.

Positive Grid  Similar to Center Grid, but in the positive direction.

Density Random  For one-dimensional jitter, this option places markers randomly within the bounds of a violin plot. For two-dimensional jitter, this option places markers randomly within an oval.

You can also customize jitter by right-clicking and selecting Customize > Marker.

Tip:  To create a dot plot, select the Positive Grid option. You can move the dot plot to start at the bottom by changing the Y-axis values to 0-1. You can also resize the markers to a larger value, such as 20, to adjust the binning of the dots.

Jitter Limit  Controls the spread or amount of overlap.

Variables  Shows or hides graph elements for variables, or re-orders the display of variables.

Note:  These options do not apply to variables in the Group X, Group Y, Wrap, or Page zones.

Check boxes are followed by the zone designation and the name of the variable. Use check boxes to do the following:

–  Show or hide the elements corresponding to a variable in a zone.

–  Add or remove the effect of applying the Color, Size, Shape, or Freq variable to the variable in the zone.
**Tip:** If you have multiple graphs, you can color or size each graph by different variables. Drag a second variable to the **Color** or **Size** zone, and drop it in a corner. In the Variables option, select the specific color or size variable to apply to each graph.

Use arrows to re-order the display if there are multiple variables in a zone. Highlight a variable name and click an arrow to reposition it.

For an example using Variables, see “Example of an Area and Line Chart” on page 124 in the “Graph Builder Examples” chapter.

**Red Triangle Options for Points**

**Response Axis**  Changes the axis that is associated with the response variable to X (horizontal), Y (vertical), or automatically determines the response direction.

**Set Shape Expression**  Enables the use of a JSL expression to define a marker shape.

**Set Shape Column**  Sets a column to use as the marker shape.

**Smoother**

The **Smoother** element shows a smooth curve through the data.

**Tip:** To label a smoother, right-click on the smoother element in the legend.

**Figure 3.26 Smoother Options**

<table>
<thead>
<tr>
<th>Method</th>
<th>Specifies the method used for generating the smooth fit. Options include Spline, Local Kernel, Savitzky-Golay, Moving Average, and Moving Box.</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Lambda</strong></td>
<td>(Available for Spline.) Enables you to adjust the value of lambda. The default value is 0.05. For more information about lambda, see Basic Analysis.</td>
</tr>
<tr>
<td><strong>Degree</strong></td>
<td>(Available for Savitzky-Golay.) Specifies the degree of the smoother.</td>
</tr>
<tr>
<td><strong>Local Width</strong></td>
<td>(Not available for Spline.) Enables you to control the smoother fit in terms of a local to a global fit. Use the red triangle Local Region option for further control.</td>
</tr>
<tr>
<td><strong>Trim</strong></td>
<td>Enables you to trim the sections of the smoother that are based on incomplete or imbalanced data ranges. The slider is scaled from 0 to 1. At 1, all of the incomplete or</td>
</tr>
</tbody>
</table>
imbalanced regions are trimmed with the exception of the spline where 1 corresponds to the penultimate edge knots.

**Confidence of Fit**  Shows or hides the bootstrap confidence region for each fit.

**Variables**  Shows or hides graph elements for variables, or re-orders the display of variables.

**Note:** These options do not apply to variables in the Group X, Group Y, Wrap, or Page zones.

Check boxes are followed by the zone designation and the name of the variable. Use check boxes to do the following:

- Show or hide the elements corresponding to a variable in a zone.
- Add or remove the effect of applying the Color, Size, Shape, or Freq variable to the variable in the zone.

**Tip:** If you have multiple graphs, you can color or size each graph by different variables. Drag a second variable to the **Color** or **Size** zone, and drop it in a corner. In the Variables option, select the specific color or size variable to apply to each graph.

Use arrows to re-order the display if there are multiple variables in a zone. Highlight a variable name and click an arrow to reposition it.

For an example using Variables, see “Example of an Area and Line Chart” on page 124 in the “Graph Builder Examples” chapter.

**Red Triangle Options for Smoother**

**Response Axis**  Changes the axis that is associated with the response variable to X (horizontal), Y (vertical), or Auto (the Y axis for Smoother).

**Local Region**  Specifies options for controlling the region used for the local width option.

**Local Weighting**  Specifies weighting options.

**Adapt to Axis Scale**  For log and other axis transformations, applies computations on the transformed coordinates.

**Save Formula**  Saves fit formulas and upper and lower confidence intervals for a single variable to the data table.

**Line of Fit**

The **Line of Fit** element shows a linear regression line with confidence intervals for the fit.
Tip: To label a line of fit, right-click on the line element in the legend.

Figure 3.27  Line of Fit Options

Fit  Specifies the type of fit:
- **Polynomial**  A simple linear regression.
- **Robust Cauchy**  A linear regression assuming Cauchy distributed residuals, to de-emphasize outliers.
- **Time Series**  Smoothing for equally spaced X values with optimal seasonality. Includes options for a forecast model and the number of seasonal and forecast periods. The smoothing model is selected from a subset of state space smoothing models defined by Hyndman et al. (2008). See *Predictive and Specialized Modeling*.

Degree  Specifies the polynomial degree of the linear regression fit, which can be linear, quadratic, or cubic.

Confidence  Shows or hides confidence intervals for the predicted value (Fit) or for individual values (Prediction). Both types of intervals are fixed at 95% confidence.

Statistics  Shows various selections on the graph. You can show the root mean square error (RMSE), R-square, the equation of the regression line, and the F Test value.

Variables  Shows or hides graph elements for variables, or re-orders the display of variables.

Note: These options do not apply to variables in the Group X, Group Y, Wrap, or Page zones.

Check boxes are followed by the zone designation and the name of the variable. Use check boxes to do the following:
- Show or hide the elements corresponding to a variable in a zone.
- Add or remove the effect of applying the Color, Size, Shape, or Freq variable to the variable in the zone.
Tip: If you have multiple graphs, you can color or size each graph by different variables. Drag a second variable to the Color or Size zone, and drop it in a corner. In the Variables option, select the specific color or size variable to apply to each graph.

Use arrows to re-order the display if there are multiple variables in a zone. Highlight a variable name and click an arrow to reposition it.

For an example using Variables, see “Example of an Area and Line Chart” on page 124 in the “Graph Builder Examples” chapter.

Red Triangle Options for Line of Fit

Response Axis  Specifies the axis for the variable that is used as the response in the calculation of the linear regression line. Because standard least squares typically uses the Y (vertical) axis as the response axis, the Auto setting defaults to the Y axis.

Adapt to Axis Scale  For log and other axis transformations, applies computations on the transformed coordinates.

Save Formula  Saves fit formulas and upper and lower confidence intervals for a single variable to the data table.

Ellipse

The Ellipse element 🎨 shows a bivariate normal density ellipse.

Figure 3.28  Ellipse Options

Coverage  Specifies the coverage percentage (99%, 95%, 90%, or 50%) for the density ellipse.

Correlation  Shows the Pearson correlation coefficient for the X and Y variables on the graph.

Mean Point  Shows the mean on the graph.

Variables  Shows or hides graph elements for variables, or re-orders the display of variables.

Note: These options do not apply to variables in the Group X, Group Y, Wrap, or Page zones.

Check boxes are followed by the zone designation and the name of the variable. Use check boxes to do the following:
– Show or hide the elements corresponding to a variable in a zone.
– Add or remove the effect of applying the Color, Size, Shape, or Freq variable to the variable in the zone.

**Tip:** If you have multiple graphs, you can color or size each graph by different variables. Drag a second variable to the Color or Size zone, and drop it in a corner. In the Variables option, select the specific color or size variable to apply to each graph.

Use arrows to re-order the display if there are multiple variables in a zone. Highlight a variable name and click an arrow to reposition it.

For an example using Variables, see “Example of an Area and Line Chart” on page 124 in the “Graph Builder Examples” chapter.

**Red Triangle Option for Ellipse**

**Adapt to Axis Scale**  For log and other axis transformations, applies computations on the transformed coordinates.

### Contour

The **Contour** element shows regions of density (or value contours when used with a Color variable). Density contours are useful when you have a scatterplot with many points where the mass of points makes it difficult to see patterns in density. Multiple contour types are available. The default is a smooth bivariate nonparametric density surface that is fit to reflect the density of the data points. The nonparametric density surface estimates the bivariate probability density function at each point, providing a continuous analog of a bivariate histogram.

- For two continuous variables, four contours are plotted by default. These contours are 100%, 75%, 50%, and 25% density contours. You can specify the number of contour levels to display. Alternatively, you can select a Bagplot or High Density Region (HDR) contours.
- For only one continuous variable, a **violin** plot appears instead of a contour plot. A violin plot illustrates the density of the data by plotting symmetric kernel densities around a common vertical axis. The kernel density estimates the probability density function at each point, providing a continuous analog of the histogram. The violin plot is similar to a box plot with symmetric kernel densities replacing the box and whiskers. Alternatively, you can select High Density Region (HDR) contours.
- If you add a Color variable to a contour plot, the plot shows **value contours** that reflect the levels of the Color variable. The value contours are computed using Delaunay triangulation. You can select an option (Transform) to show a plot where the X and Y ranges have been normalized.
Contour Options

**Figure 3.29** Contour Options for a Contour Plot or a Violin Plot

- **Fill**  (Not available for Bagplots.) Fills in the contours.

- **Line**   (Not available for Bagplots.) Adds lines around the contours.

- **Number of Levels**   (Available for Nonpar Density.) For density contours, specifies the number of contours that appear. The number can be between 1 and 1000, the default is 4 contours.

- **Boundary**   (Available only when you have a Color variable.) Adds a line around the outside boundary of the contour.

- **Alpha**   (Available only when you have a Color variable.) Controls the hull of value contours. Increasing alpha can eliminate some of the long, skinny, or large triangles where interpolation might be undesirable.

- **Smoothness**   (Not available for Bagplots.) Smooths the boundaries of the contour plots. The smoothness value is normalized between -1 and 1. This value can be interpreted as a smoothing kernel radius. The original data are interpolated to a grid, and then a Gaussian smoother is applied.

- **Transform**   (Available only when you have a Color variable.) Transforms the triangulation to use a normalized scale for X and Y by selecting Range Normalized. This causes both the X and Y values to be scaled to [0,1] before computing the Delaunay triangulation. This option might be desirable in cases where the X and Y units are very different. In these cases, if points are stretched in one dimension and not the other, Delaunay triangulation tries to minimize long, skinny triangles, which can obscure some features.

- **Contour Type**   Enables selection of contour types

  - **Nonpar Density**   (Available only for bivariate plots.) A smooth bivariate nonparametric density surface.
Bagplot  Draws a Bagplot, also known as a bivariate box plot. A Bagplot consists of two polygons, a set of outlier points, and a median point. All computations are based on first computing the Tukey depth (bivariate depth) of each point in the data. The median point is the average of all points at maximum depth, which is plotted as an asterisk. The inner polygon is the bag, which contains at most 50% of the data points. Not shown in the plot is the fence, which is the bag polygon inflated three times relative to the median point. The outer polygon is the convex hull of all points contained within the fence. This is referred to as the loop. Points that lie outside the fence are designated outliers, and are shown as points on the plot. For more information about Bagplots, see Rousseeuw (1999).

HDR  Draws highest density region rectangles for univariate and contours for bivariate data. The lighter shaded region represents the 99% probability region; the darker shaded region represents the 50% probability region. (Note that the regions can be noncontiguous.) The density mode within the 50% probability region is represented by a line (univariate data) or an asterisk (bivariate data). If you remove points from the plot, the points that remain represent outliers relative to the 99% probability region. You can adjust the smoothness of the regions using the Smoothness option.

The HDR regions are based on a nonparametric density estimated by applying a Gaussian kernel to the data after the points have been interpolated to a grid. For more information about highest density regions, see Hyndman (1996).

Violin  (Available only for univariate plots.) Draws a violin plot of the density of the data by plotting symmetric kernel densities around a common vertical axis.

Jitter  Turns jitter on or off. Jitter adds random noise to data, and can help reduce over-plotting. For descriptions of the specific jitter options, see “Points” on page 55.

Outliers  (Available for Bagplot and HDR contours.) Plots outliers.

Violin Scaling  For multiple violin plots, choose a scaling option. Equal area or width means that the areas or maximum width of the violins are the same. Weighted area means that the areas of the violins are proportional to the number of observations in each violin.

Variables  Shows or hides graph elements for variables, or re-orders the display of variables.

**Note:** These options do not apply to variables in the Group X, Group Y, Wrap, or Page zones.

Check boxes are followed by the zone designation and the name of the variable. Use check boxes to do the following:

- Show or hide the elements corresponding to a variable in a zone.
- Add or remove the effect of applying the Color, Size, Shape, or Freq variable to the variable in the zone.
**Tip:** If you have multiple graphs, you can color or size each graph by different variables. Drag a second variable to the **Color** or **Size** zone, and drop it in a corner. In the Variables option, select the specific color or size variable to apply to each graph.

Use arrows to re-order the display if there are multiple variables in a zone. Highlight a variable name and click an arrow to reposition it.

For an example using Variables, see “Example of an Area and Line Chart” on page 124 in the “Graph Builder Examples” chapter.

**Red Triangle Options for Contour**

- **Adapt to Axis Scale** For log and other axis transformations, applies computations on the transformed coordinates.

- **Contour Placement** (Available with grouping variables.) Enables you to align or offset the contours.

**Line**

The **Line** element uses line segments to connect summary statistic values (or raw values) of the variable plotted on the Response Axis across the values or categories of another variable.

For an example that combines a line chart with an area plot to emphasize a line, see “Example of an Area and Line Chart” on page 124 in the “Graph Builder Examples” chapter.

**Notes:**

- If any of the rows used in calculating a point on the plot are hidden and not excluded, the point is not shown, but the position that it would occupy remains. The line segment connects the adjoining points.
- To label a line, right-click on the line element in the legend.

**Figure 3.30** Line Options
**Row order**  Connects points with line segments in the order of their row numbers.

**Connection**  Changes the connection type to a line, curve, step, centered step, horizontal, or vertical line. If you select a curve, you can also change the smoothness.

**Smoothness**  Changes the smoothness of a Curve connection. To use this option, select Curve for the Connection type.

**Summary Statistic**  Specifies the statistic that is plotted. The statistic is computed for observations at each distinct value of the variable in the X zone (or the Y zone, if X is specified as the Response Axis).

**Stack**  (Available for multiple Y variables.) Accumulates, or stacks, the Y values. Use to build an area chart.

**Fill**  Specify how to fill the area below or between the lines.

**Error Interval**  Adds or removes specified error interval in the graph.

**Interval Style**  Draws error bars or error bands for the selected error interval.

**Missing Factors**  Provides options for connections when all values are missing for a setting of the variable on the X axis:

- **Skip**  Skips over the missing factor value, connecting the previous factor to the next factor.

- **Treat as Missing**  Skips over the missing factor value, connecting the previous factor to the next factor. Draws the connection in the style specified for Missing Values.

- **Treat as zero**  Treats the missing factor values as zero.

**Missing Values**  Provides options for connections when all values are missing for a setting of the variable on the Response axis:

- **Connect Through**  Connects the points adjacent to the missing values with the connector type used for the remaining points.

- **Connect Faded**  Connects the points adjacent to the missing values with a faded connection.

- **Connect Dashed**  Connects the points adjacent to the missing values with a dashed connection.

- **No Connection**  Shows no connection between the points adjacent to the missing values.

**Variables**  Shows or hides graph elements for variables, or re-orders the display of variables.
Note: These options do not apply to variables in the Group X, Group Y, Wrap, or Page zones.

Check boxes are followed by the zone designation and the name of the variable. Use check boxes to do the following:

- Show or hide the elements corresponding to a variable in a zone.
- Add or remove the effect of applying the Color, Size, Shape, or Freq variable to the variable in the zone.

Tip: If you have multiple graphs, you can color or size each graph by different variables. Drag a second variable to the Color or Size zone, and drop it in a corner. In the Variables option, select the specific color or size variable to apply to each graph.

Use arrows to re-order the display if there are multiple variables in a zone. Highlight a variable name and click an arrow to reposition it.

For an example using Variables, see “Example of an Area and Line Chart” on page 124 in the “Graph Builder Examples” chapter.

Red Triangle Options for Line

Response Axis  Specifies the axis for the variable that is used as the response in plotting the line segments. The Auto setting is the Y axis.

Save Formula  Saves fit formulas and upper and lower confidence intervals for a single variable to the data table.

Bar

The Bar element shows a bar chart of summary statistic values of one or more variables across the values or categories of one or more stratifying variables. The graph can display a single variable or multiple variables of any type arranged in the X and Y zones.

- If you add a single categorical variable, then each bar shows the count of observations in the corresponding level of the variable.
- If you add two variables, with one in each zone, each bar represents the value of the specified summary statistic for the variable on the specified Response Axis. There is a bar for each value or level of the stratifying variable.
- If you add multiple variables in each zone, multiple bars are plotted for each value or combination of levels of the stratifying variables.
Response Axis Variables with Character Data Type

If the variable on the Response Axis has the Character data type, then this variable is assigned numeric values:

- Integer values are assigned based on the Value Order column property or the default value ordering.
- These integer values range from 0 (highest level in value ordering) to the number of levels minus one (lowest value in value ordering).
- These integer values are used in calculating the Summary Statistic.

Note: If any of the rows used in constructing a bar on the plot are hidden and not excluded, the bar is not shown, but the position that it would occupy remains.

For an example of a graph that uses the bar element, see “Example of an Overlaid Histogram and Ridgeline Chart” on page 143 in the “Graph Builder Examples” chapter and “Example of a Packed Bar Chart” on page 141 in the “Graph Builder Examples” chapter.

Figure 3.31 Bar Options

Bar Style You can change the appearance of the bars that describe the levels of the stratifying variable. Many bar styles are applicable only when there are merged variables on the response axis, or if an overlay variable is present. For bar style descriptions, see Table 3.1. To change bar widths and space, right-click in the graph and select Customize > Bar.

Packed Bar Style Options

Packed Primaries Specifies the number of primary bars.

Packed Placement Specifies where the secondary bars are stacked. Options include the following:

- **First Stack**—Start on the top row and fill it before moving to the next row.
- **Smallest Stack**—Place each bar at the stack that is currently the smallest.
- **Separate Stack**—Make a stack called Other where all secondary bars appear.
Packed Ordering  
Specifies the order in which secondary bars are placed. Can be by size. The biggest bars appear first or by label, which is in natural order and usually alphabetical.

Packed Coloring  
Specifies how the secondary bars are colored. Options include the following:

- **Bar color**—Applies the same color as the primary bar color.
- **Faded bar color**—Applies a faded version of the primary bar color.
- **Grays**—Applies random shades of light gray.

Packed Labeling  
Controls the percentage of secondary bars that are labeled.

Packed Primary Labels  
Specifies where primary labels should be placed, either inside bars or on the axis.

Summary Statistic  
Specifies the statistic that is used as bar labels and controls the response axis scale. Available statistics depend on the type of bar chart used.

Error Interval  
Adds or removes error intervals in the graph when applicable, otherwise it is not available. To customize error bars, right-click in the graph and select Customize > Error Bar.

Label  
Adds or removes labels in the bar chart. You can label by value, percent of total value, or by row. When **Label by Value** is selected the values are determined by the summary statistic setting. Click and drag to reposition a label.

Label Format  
(Available for value and percent labels.) Enables you to set the format for the cell labels.

Variables  
Shows or hides graph elements for variables, or re-orders the display of variables.

**Note:** These options do not apply to variables in the Group X, Group Y, Wrap, or Page zones.

Check boxes are followed by the zone designation and the name of the variable. Use check boxes to do the following:

- Show or hide the elements corresponding to a variable in a zone.
- Add or remove the effect of applying the Color, Size, Shape, or Freq variable to the variable in the zone.

**Tip:** If you have multiple graphs, you can color or size each graph by different variables. Drag a second variable to the **Color** or **Size** zone, and drop it in a corner. In the Variables option, select the specific color or size variable to apply to each graph.
Use arrows to re-order the display if there are multiple variables in a zone. Highlight a variable name and click an arrow to reposition it.

For an example using Variables, see “Example of an Area and Line Chart” on page 124 in the “Graph Builder Examples” chapter.

**Red Triangle Options for Bar**

**Response Axis**  Specifies the axis for the variable that is used as the response in plotting the bars. This option is available only when each axis contains at least one variable with a Continuous modeling type. If only one variable is Continuous, its axis is the response axis. The Auto setting is the Y axis.

**Save Formula**  Saves fit formulas and upper and lower confidence intervals for a single variable to the data table.

**Overlap**  Specifies the amount of overlap (Auto, None, Half, Full) between multiple bars.

### Table 3.1  Bar Styles and Descriptions

<td>Stacked</td>
<td>When you have two or more merged variables on the response axis, a single bar is plotted for each level of the stratifying variables. Each bar stacks the bars for each of the merged variables. The part of the bar corresponding to each merged variable is colored and a legend appears.</td>
</tr>
<tr>
<td>Bullet</td>
<td>When you have two or more merged variables on the response axis, a narrow bar is plotted within a wider and taller bar. The widths of the bars depend on the order of the variables. The part of the bar corresponding to each merged variable is colored and a legend appears. If you have only a single variable, this style plots narrow bars.</td>
</tr>
</tbody>
</table>
Table 3.1 Bar Styles and Descriptions (Continued)

<table>
<thead>
<tr>
<th>Bar Style</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Nested</td>
<td>When you have two or more merged variables on the response axis, the bars for each variable are nested within each other. The narrowest bar corresponds to the first variable listed in the legend, the next narrowest to the second, and so on. <strong>Tip:</strong> You can change the legend order using the arrows in the Variables panel.</td>
</tr>
</tbody>
</table>

Range When you have two or more merged variables on the response axis, a rectangle and a line are plotted for each level of the stratifying variables. For each level of the stratifying variables:

- The values of the summary statistic are calculated for each of the merged variables.
- A rectangle is plotted with bounds equal to the summary statistic values for the first two of variables, as indicated in the legend.
- Lines are plotted at the values of the summary statistic for the other variables.
**Table 3.1 Bar Styles and Descriptions (Continued)**

<th>Bar Style</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Two-way interval</td>
<td>This style is for two-dimensional bar charts with bars in each direction.</td>
</tr>
</tbody>
</table>

- - -

| Single | For each level of the stratifying variables, a bar is plotted. When you have two or more merged variables on the response axis, the bar represents the value of the summary statistic for the first variable in the legend and lines are shown for the values of the summary statistic for the remaining variables. |

**Tip:** You can change the legend order using the arrows in the Variables panel.
When you have two or more merged variables on the response axis, line segments are plotted at the levels of the stratifying variables. For each level of the stratifying variables:

- The values of the summary statistic are calculated for each of the merged variables.
- A line segment connecting the summary statistic values for two of the variables, as indicated in the legend.
- Bars are plotted at right angles to the line segment at the remaining values of the summary statistic.

Table 3.1 Bar Styles and Descriptions (Continued)

<table>
<thead>
<tr>
<th>Bar Style</th>
<th>Description</th>
</tr>
</thead>
</table>
| Stock     | When you have two or more merged variables on the response axis, line segments are plotted at the levels of the stratifying variables. For each level of the stratifying variables:  
- The values of the summary statistic are calculated for each of the merged variables.  
- A line segment connecting the summary statistic values for two of the variables, as indicated in the legend.  
- Bars are plotted at right angles to the line segment at the remaining values of the summary statistic. |
Table 3.1 Bar Styles and Descriptions (Continued)

<table>
<thead>
<tr>
<th>Bar Style</th>
<th>Description</th>
</tr>
</thead>
</table>
| Box Plot  | When you have two or more merged variables on the response axis, box plots are shown for the levels of the stratifying variables. For each level of the stratifying variables:  
  • The values of the summary statistic are calculated for each of the merged variables.  
  • An outlier box plot is constructed for these values. |
| Needle    | When you have two or more merged variables on the response axis, needle-shaped bars are plotted side-by-side for each of the merged variables. The bars are colored and a legend appears. This style is useful when you have many levels of the stratifying variables. |
When you have two or more merged variables on the response axis, bars are plotted at the levels of the stratifying variables. For each level of the stratifying variables:

- The values of the summary statistic are calculated for each of the merged variables.
- A bar is plotted at each of these values.

This style is useful when you have many merged variables.

This bar style shows the top categories as a bar chart and stacks the other categories as bars with an approximately rectangular fill. The top categories are the focus and the other bars provide context.

This style is useful when you have many categories and skewed response data.
Area

Note: You can also create an area plot using the Line element.

The Area element shows a contiguous area that represents the area beneath summary statistic values of a variable across the values or categories of another variable. The Area element can be considered a continuous representation of the Bar element.

- Both variables might be nominal or ordinal. The summary statistic represents the count of observations in a level of the variable on the axis that is not specified as the Response Axis.
- One of the variables might be continuous and the other nominal or ordinal. The summary statistic represents the value of the specified summary statistic for the continuous variable for the corresponding level of the categorical variable.
- If both variables are continuous, the summary statistic is computed for the continuous variable on the axis that is specified as the Response Axis.

Note: The plot is not affected in any way if rows are hidden and not excluded.

For an example of a graph that uses the Area element, see “Example of an Area and Line Chart” on page 124 in the “Graph Builder Examples” chapter.

Figure 3.32 Area Options

Area Style Changes how the area is displayed when there are merged variables on the response axis. For area style descriptions, see Table 3.2.

Row order Connects points with line segments in the order of their row numbers.

Connection Changes the connection type to a line, curve, step, centered step, horizontal, or vertical line. If you select a curve, you can also change the smoothness.

Summary Statistic Specifies the statistic that is plotted. The statistic is computed for observations at each distinct value of the variable in the X zone (or the Y zone, if X is specified as the Response Axis).
**Error Interval**  Adds or removes specified error interval in the graph.

**Interval Style**  Draws error bars or error bands for the selected error interval.

**Missing Factors**  Provides options for connections when all values are missing for a setting of the variable on the X axis:

- **Skip**  Skips over the missing factor value, connecting the previous factor to the next factor.
- **Treat as Missing**  Skips over the missing factor value, connecting the previous factor to the next factor. Draws the connection in the style specified for Missing Values.
- **Treat as zero**  Treats the missing factor values as zero.

**Missing Values**  Provides options for connections when all values are missing for a setting of the variable on the Response axis:

- **Connect Through**  Connects the points adjacent to the missing values with the connector type used for the remaining points.
- **Connect Faded**  Connects the points adjacent to the missing values with a faded connection.
- **Connect Dashed**  Connects the points adjacent to the missing values with a dashed connection.
- **No Connection**  Shows no connection between the points adjacent to the missing values.

**Variables**  Shows or hides graph elements for variables, or re-orders the display of variables.

---

**Note:** These options do not apply to variables in the Group X, Group Y, Wrap, or Page zones.

Check boxes are followed by the zone designation and the name of the variable. Use check boxes to do the following:
- Show or hide the elements corresponding to a variable in a zone.
- Add or remove the effect of applying the Color, Size, Shape, or Freq variable to the variable in the zone.

**Tip:** If you have multiple graphs, you can color or size each graph by different variables. Drag a second variable to the **Color** or **Size** zone, and drop it in a corner. In the Variables option, select the specific color or size variable to apply to each graph.

Use arrows to re-order the display if there are multiple variables in a zone. Highlight a variable name and click an arrow to reposition it.
For an example using Variables, see “Example of an Area and Line Chart” on page 124 in the “Graph Builder Examples” chapter.

Red Triangle Options for Area

**Response Axis**  Specifies the axis for the variable that is used as the response in plotting the areas. Available only when both variables have a Continuous modeling type. If only one variable is Continuous, its axis is the response axis. The Auto setting is the Y axis.

**Save Formula**  Saves fit formulas and upper and lower confidence intervals for a single variable to the data table.

<table>
<thead>
<tr>
<th>Area Style</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Stacked</td>
<td>Shows areas that correspond to summary statistics for each of the merged variables. The plots are colored and a legend appears in the Legend zone.</td>
</tr>
<tr>
<td>Overlaid</td>
<td>Shows the area plots for the merged variables superimposed over each other. The plots are colored and a legend appears in the Legend zone.</td>
</tr>
</tbody>
</table>
The Box Plot element shows outlier or quantile box plots. A box plot provides a compact view of a distribution of values. The box plot element is useful when variables have a Numeric data type. For more information about outlier and quantile box plots, see Basic Analysis.

- If one of the variables is continuous and the other is nominal or ordinal, box plots are constructed for values of the continuous variable. There is a box plot for each level of the categorical variable.
- If both variables are continuous, box plots are constructed for values of the continuous variable on the axis specified as the Response Axis. There is a box plot for each level of the other continuous variable.

<td>Stacked Range</td>
<td>Shows the areas corresponding to the difference in the summary statistic after the variables are stacked.</td>
</tr>
</tbody>
</table>
For an example of a graph using box plots, see “Example of Features in Graph Builder” on page 32.

**Figure 3.33  Box Plot Options**

![Box Plot Options](image)

**Jitter**  Turns jitter on or off. Jitter adds random noise to data, and can help reduce over-plotting.

**Outliers**  Shows or hides values that extend beyond the whiskers.

**Box Type**  Specifies whether the box plot is an outlier box plot or a quantile box plot.

**Box Style**  Changes the style the box plot. For box style descriptions, see Table 3.3.

**5 Number Summary**  Adds statistics like the median, maximum, minimum, and quantiles 1 and 3 to the graph.

**Width Proportion**  Adjusts the width of the box plots.

**Variables**  Shows or hides graph elements for variables, or re-orders the display of variables.

**Note:** These options do not apply to variables in the Group X, Group Y, Wrap, or Page zones.

Check boxes are followed by the zone designation and the name of the variable. Use check boxes to do the following:

- Show or hide the elements corresponding to a variable in a zone.
- Add or remove the effect of applying the Color, Size, Shape, or Freq variable to the variable in the zone.

**Tip:** If you have multiple graphs, you can color or size each graph by different variables. Drag a second variable to the **Color** or **Size** zone, and drop it in a corner. In the Variables option, select the specific color or size variable to apply to each graph.

Use arrows to re-order the display if there are multiple variables in a zone. Highlight a variable name and click an arrow to reposition it.

For an example using Variables, see “Example of an Area and Line Chart” on page 124 in the “Graph Builder Examples” chapter.
Red Triangle Options for Box Plots

**Confidence Diamond**  Shows or hides a confidence diamond about the mean. The diamond covers the 95th confidence interval for the mean.

**Notched**  Displays a box plot that is notched at the median where the notches span:

\[
\text{median} \pm (1.58 \times \text{IQR})/(\sqrt{n})
\]

**Fences**  Shows or hides vertical lines, or fences, at the end of the box plot whiskers.

**Shortest Half**  Shows or hides a bracket that indicates the location of the shortest interval that contains 50% of the data.

**Shortest Half Color**  Enables you to select a color for the shortest half bracket.

**Response Axis**  (Available only when the X and Y axes variables both have a continuous modeling type.) Specifies the axis for the variable that is used as the response in constructing the box plots. Available only when both variables have a continuous modeling type. If only one variable is continuous, its axis is the response axis. The Auto setting is the Y axis.

**Box Placement**  (Available with grouping variables.) Enables you to align or offset the box plots.

**Tip:** When you have a categorical grouping variable for your box plot, right-click on the categorical axis and select **Size By > Count** to draw box plots that are proportional to the number of observations in each category.
### Table 3.3 Box Styles and Descriptions

<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Thin</td>
<td>The box defined by the quartiles is not shown. It is discernible due to the whiskers. The median is denoted by a point.</td>
</tr>
</tbody>
</table>

**Histogram**

The Histogram element shows a variable’s distribution using binning. For more information about histograms, see *Basic Analysis*.

**Note:** The bars of the histogram align with the tick marks on the axis for the zone containing the variable. If you customize the axis, the histogram adjusts to match the new tick marks.

You can change the primary direction of the graph to X (horizontal), Y (vertical), or Auto using the Response Axis option.

- If both variables are nominal or ordinal, the histogram shows the count of observations in a level of the variable on the axis that is not specified as the Response Axis.
- If one of the variables is continuous and the other is nominal or ordinal, the plot shows a histogram for the continuous variable for each level of the categorical variable.
- If the same variable is specified for both X and Y, then the Y role is ignored and a single histogram appears.
- If both variables are continuous, then the variable on the X axis is treated as discrete. You might need to rescale the X axis to view the graph clearly. For an alternative visual, use a scatterplot with the Contour element.
**Tip:** You can overlay histograms with transparent color so that you can see the individual histograms. To do this, assign the variable of interest as X or Y. Assign your overlay variable to the **Overlay** zone. Then, click the **Histogram** element icon. See “Example of an Overlaid Histogram and Ridgeline Chart” on page 143 in the “Graph Builder Examples” chapter.

**Figure 3.34  Histogram Options**

![Histogram Options](image)

**Response Scale**  Specifies the scale for the response axis. The options are count, percent, or fill. Fill has no response axis label, fills the display space, and scales multiple histograms independently.

**Overlap**  (Available with a categorical response.) Adjusts the amount of histogram overlap between vertical categories.

**Histogram Style**  Specifies the histogram style.

- **Bar**  Default traditional histogram bars with a height based on the number or percent of observations that fall within each bar or bin.

- **Polygon**  Connects the peaks of each histogram bar to construct a polygon representation of the distribution of the data.

- **Kernel Density**  Density curve with a smoother control.

- **Shadowgram**  Overlays histograms with different bin widths.

**Means and Std Devs**  Shows the means and standard deviations for the levels of the variables in the X or Y zone.

**t Test for Mean At**  Performs a t test for the specified mean.

**Confid Percent**  Specifies the confidence interval for the mean.

**Counts**  Displays counts on the histogram bars.

**Percents**  Displays percents on the histogram bars.

**Variables**  Shows or hides graph elements for variables, or re-orders the display of variables.
**Note:** These options do not apply to variables in the Group X, Group Y, Wrap, or Page zones.

Check boxes are followed by the zone designation and the name of the variable. Use check boxes to do the following:

- Show or hide the elements corresponding to a variable in a zone.
- Add or remove the effect of applying the Color, Size, Shape, or Freq variable to the variable in the zone.

**Tip:** If you have multiple graphs, you can color or size each graph by different variables. Drag a second variable to the **Color** or **Size** zone, and drop it in a corner. In the Variables option, select the specific color or size variable to apply to each graph.

Use arrows to re-order the display if there are multiple variables in a zone. Highlight a variable name and click an arrow to reposition it.

For an example using Variables, see “Example of an Area and Line Chart” on page 124 in the “Graph Builder Examples” chapter.

### Red Triangle Option for Histogram

**Response Axis**  
Specifies the axis for the variable that is used as the response in constructing the histograms. Available only when both variables have a Continuous modeling type. If only one variable is Continuous, the other axis is the response axis.

### Heatmap

The **Heatmap** element shows the counts or average values for groups of observations using a color intensity scale. If you plot a single variable as either Y or X, your plot appears as bars. If you plot a cross tabulation of two variables Y and X, your plot shows rectangles.

- For a categorical variable, the levels define the groups of observations.
- For a continuous variable, Graph Builder constructs non-overlapping intervals of values. These intervals define the groups of observations.

**Note:** If all of the rows used in constructing a bar or rectangle on the plot are hidden and not excluded, the rectangle is not shown, but the position that it would occupy remains.

When you create a heatmap, an intensity legend appears in the Legend area. See “Discrete or Continuous Legend Items” on page 115. The intensity legend shows counts or average values:

- If no Color variable is assigned, the counts in each bar or rectangle define the scale for the intensity legend.
• If a Color variable is assigned, the average of that variable for the observations in each bar or rectangle define the scale for the intensity legend.

**Tip:** Hover over a cell to see labels. Click a cell to select the corresponding rows.

To color or size a heatmap by two variables, drag the first variable into the Color or Size zone and then drag the second variable into the top or bottom corner of the zone.

**Figure 3.35 Heatmap Options**

- **Bin Shape** (Available for continuous variables). Specifies the shape of the bin.
- **Hex Bin Radius** (Available for hexagonal bins.) Enables you to adjust the radius of the bin.
- **Label** Specifies labels for the heatmap. You can label by value, percent of total, or by row.
- **Max Label Size** Enables you to adjust the size of the label.
- **Cell Outline** (Available when a size variable is used.) Enables you to add outlines for the original bin sizes. This highlights the size scaling on the bins.
- **Label Format** (Available for value and percent labels.) Enables you to set the format for the cell labels.
- **Variables** Shows or hides graph elements for variables, or re-orders the display of variables.

**Note:** These options do not apply to variables in the Group X, Group Y, Wrap, or Page zones.

Check boxes are followed by the zone designation and the name of the variable. Use check boxes to do the following:

- Show or hide the elements corresponding to a variable in a zone.
- Add or remove the effect of applying the Color, Size, Shape, or Freq variable to the variable in the zone.

**Tip:** If you have multiple graphs, you can color or size each graph by different variables. Drag a second variable to the **Color** or **Size** zone, and drop it in a corner. In the Variables option, select the specific color or size variable to apply to each graph.
Use arrows to re-order the display if there are multiple variables in a zone. Highlight a variable name and click an arrow to reposition it.

For an example using Variables, see “Example of an Area and Line Chart” on page 124 in the “Graph Builder Examples” chapter.

Use a Heatmap to Apply Background Colors

You can also use the heatmap to control the background color when you have plot elements that use the Wrap, Group X, or Group Y zones. To do so:

1. Select the variable for the background color and drag it to the **Color** zone.
2. Select the Heatmap element.
3. Construct the plot elements.

In the Heatmap panel, under Variables, deselect all check boxes except the one for Color.

**Pie**

The **Pie** element plots summary statistics for groups of observations, representing their values as the size of the slices or rings on a pie chart.

**Note:** If any of the rows used in constructing a slice of the pie chart are hidden and not excluded, the slice is not shown, but the position that it would occupy remains.

- For a single variable, the slice sizes the number of observations in each category.
- For two variables, the variable in the Y zone is used to size the slices according to the selected Summary Statistic. A legend appears in the Legend zone showing the values of the variable in the X zone.

**Figure 3.36  Pie Options**

![Pie Options](image)

When you add an Overlay variable, a ring chart is constructed for each level of the Overlay variable. The outer ring represents the smallest value in the value ordering, and the inner ring represents the largest value.

**Pie Style**  Changes the appearance of the pie chart. For pie style descriptions, see Table 3.4.

**Summary Statistic**  Changes the statistic that is plotted.
**Label**  Adds or removes labels in the pie chart.

**Label Format** (Available for value and percent labels.) Enables you to set the format for the cell labels.

**Variables**  Shows or hides graph elements for variables, or re-orders the display of variables.

**Note:** These options do not apply to variables in the Group X, Group Y, Wrap, or Page zones.

Check boxes are followed by the zone designation and the name of the variable. Use check boxes to do the following:

- Show or hide the elements corresponding to a variable in a zone.
- Add or remove the effect of applying the Color, Size, Shape, or Freq variable to the variable in the zone.

**Tip:** If you have multiple graphs, you can color or size each graph by different variables. Drag a second variable to the **Color** or **Size** zone, and drop it in a corner. In the Variables option, select the specific color or size variable to apply to each graph.

Use arrows to re-order the display if there are multiple variables in a zone. Highlight a variable name and click an arrow to reposition it.

For an example using Variables, see “Example of an Area and Line Chart” on page 124 in the “Graph Builder Examples” chapter.

**Table 3.4** Pie Style Descriptions

<table>
<thead>
<tr>
<th>Pie Style</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Pie</td>
<td>Traditional pie chart with each slice sized by the Summary Statistic.</td>
</tr>

Table 3.4  Pie Style Descriptions (Continued)

<table>
<thead>
<tr>
<th>Pie Style</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Ring</td>
<td>Each variable or level of a stratifying variable is represented by a concentric ring. The sections are sized by the Summary Statistic. Ring charts can help you visualize hierarchical data, using concentric rings.</td>
</tr>
<tr>
<td>Coxcomb</td>
<td>The central angles for all slices are equal. The size of each slice is determined by the Summary Statistic. Also known as an exploded pie chart, a coxcomb chart can help you see smaller areas.</td>
</tr>
</tbody>
</table>

Treemap

The Treemap element shows the levels or values of a variable as rectangles within a rectangular display. The rectangle sizes represent summary statistic values of the variable in the Size zone across the levels or values of one or more X variables.

To construct a treemap that shows summary values across the levels of two or more X variables, merge the variables in the X zone. The rectangles are sized to represent the values of the summary statistic without leaving unused space in the overall rectangular layout.
By default, the data table order is used when ordering the tiles in the treemap using the Split layout. Alternatively, you can specify one or two continuous variables as Y variables for ordering:

- If one Y variable is specified, it orders both the X and Y axes.
- If two Y variables are specified, the first orders the X axis and the second orders the Y axis.

If the Squarify layout is specified, then the order of the tiles is determined by the size, and ordering variables are ignored.

**Note:** The plot is not affected in any way if rows are hidden and not excluded.

**Figure 3.37 Treemap Options**

**Summary Statistic**  
Specifies the summary statistic, corresponding to the variable in the Y zone, that is used to size the rectangles.

**Layout**  
Arranges rectangles to the extent possible by the value ordering of the X variable or by the size of the rectangle.

**Split**  
Arranges the rectangles according to the value ordering of the levels or values of the X variable. Split is the default setting.

**Squarify**  
Arranges the rectangles according to the values of the summary statistic, sorted in descending order. This places the largest rectangles in the top left corner of the plot and the smallest in the bottom right corner.
**Mixed**  Applies only when you have two or more X variables. It applies Split to the outermost variable and Squarify to the other variables. It follows that the large groupings are ordered according to their value ordering, whereas the inscribed rectangles are ordered according to the summary statistic values.

**Group Labels**  (Available when you have more than one X variable.) Shows or hides the additional group labels above each category or floating in the center of each category.

**Tip:** To filter data in a group, click a group label.

**Label Transparency**  (Available with floating group labels.) Specifies the transparency of the floating group labels.

**Show Group Name**  Adds the variable title to the group labels.

**Tile Labels**  Shows or hides the following labels:

- **Category Value**  The values of the X variable.
- **Category Name**  The name of the X variable.
- **Color Value**  The values of the Color variable.
- **Color Name**  The name of the Color variable.
- **Size Value**  The values of the Size variable, or the Y variable if no Size variable exists (Size Value).
- **Size Name**  The name of the Size variable, or the Y variable if no Size variable exists (Size Name).

**Tip:** Hover over a rectangle to see details.

**Max Label Size**  Increases or decreases the size of the labels.

**Label Threshold**  Removes labels based on the size of the rectangle. By default, all labels are shown. Move the slider to the right to remove labels for progressively larger rectangles.

**Label Justification**  Places the label in the center, left, or right.

**Color Label Format**  (Available when a color variable is used.) Enables you to set the format for the cell labels based on the color variable.

**Size Label Format**  (Available when Size Value is selected.) Enables you to set the format for the cell labels based on the size value variable.

**Show Frames**  Shows or hides the borders around the rectangles.
**Tip:** Use the treemap option in the right-click customize menu to adjust frame color, style, and thickness.

**Implicit Color**  Shows or hides the color. If no variable is specified in the Color zone, all rectangles have the same color.

**Variables**  Shows or hides graph elements for variables, or re-orders the display of variables.

**Note:** These options do not apply to variables in the Group X, Group Y, Wrap, or Page zones.

Check boxes are followed by the zone designation and the name of the variable. Use check boxes to do the following:

- Show or hide the elements corresponding to a variable in a zone.
- Add or remove the effect of applying the Color, Size, Shape, or Freq variable to the variable in the zone.

**Tip:** If you have multiple graphs, you can color or size each graph by different variables. Drag a second variable to the **Color** or **Size** zone, and drop it in a corner. In the Variables option, select the specific color or size variable to apply to each graph.

Use arrows to re-order the display if there are multiple variables in a zone. Highlight a variable name and click an arrow to reposition it.

For an example using Variables, see “Example of an Area and Line Chart” on page 124 in the “Graph Builder Examples” chapter.

**Mosaic**

The **Mosaic** element uses rectangle sizes to represent the proportion of observations in categories for one variable across categories of another variable. Although variables can be categorical or continuous, they are treated as categorical. For more information about mosaic plots, see *Basic Analysis*.

The default Response Axis is the Y axis. This means that, for each level of the X variable, vertical stacked bars show the proportion of values in each level of the Y variable. You can change the primary direction of the graph to X (horizontal).

**Note:** The plot is not affected in any way if rows are hidden and not excluded.
Figure 3.38  Mosaic Options

**Cell Labeling**  Add labels to cells based on counts, percents, values, or row.

**Label Format**  (Available for percent or value labels.) Enables you to set the format for the cell labels.

**Chi-square Test**  Performs a Pearson chi-square test and shows results in a label on the graph. This option appears if each side has 2 or more levels.

**Variables**  Shows or hides graph elements for variables, or re-orders the display of variables.

**Note:** These options do not apply to variables in the Group X, Group Y, Wrap, or Page zones.

Check boxes are followed by the zone designation and the name of the variable. Use check boxes to do the following:

- Show or hide the elements corresponding to a variable in a zone.
- Add or remove the effect of applying the Color, Size, Shape, or Freq variable to the variable in the zone.

**Tip:** If you have multiple graphs, you can color or size each graph by different variables. Drag a second variable to the **Color** or **Size** zone, and drop it in a corner. In the Variables option, select the specific color or size variable to apply to each graph.

Use arrows to re-order the display if there are multiple variables in a zone. Highlight a variable name and click an arrow to reposition it.

For an example using Variables, see “Example of an Area and Line Chart” on page 124 in the “Graph Builder Examples” chapter.

**Red Triangle Option for Mosaic**

**Response Axis**  Changes the axis that is associated with the response variable to X (horizontal), Y (vertical), or Auto (the Y axis for Mosaic). The variable on the Response Axis is used to calculate the proportion of observations in each level of the variable on the other axis.
Caption Box

The Caption Box element displays summary statistics on the plot. The summary statistic corresponds to the variable that corresponds to the axis that you specify as the Response Axis in the Caption Box options.

Summary Statistic for Categorical Variables

For a categorical variable, the Summary Statistic that appears is calculated by assigning numerical values to the levels of the categorical variable. The levels are placed in the order defined by their value ordering. They are assigned integer values ranging from 0 to the number of levels minus one.

Note: When using categorical values in zones associated with summarization roles like Y and Color, summary statistics are calculated based on numerical values assigned to the variable levels. (The integer values range from 0 to the number of levels minus one.) The final result is then mapped back as a level to a corresponding categorical value or value range. This approach allows the use of ordinal variables in summarization, but might not lead to clear results for nominal variables.

For an example illustrating the Caption Box element, see “Example of Features in Graph Builder” on page 32.

Figure 3.39 Caption Box Options

Summary Statistic  Specifies the summary statistic to be displayed for the variable defined by the Response Axis setting. The default Summary Statistic is the Mean. For more information about how summary statistics are computed for categorical variables, see “Summary Statistic for Categorical Variables” on page 95.

X Position  Specifies the horizontal position of the caption.

Y Position  Specifies the vertical position of the caption.

Per Factor  Shows a caption for each X, or each Y if horizontal.

Number Format  Enables you to set the format of the summary statistic.

Variables  Shows or hides graph elements for variables, or re-orders the display of variables.
**Note:** These options do not apply to variables in the Group X, Group Y, Wrap, or Page zones.

Check boxes are followed by the zone designation and the name of the variable. Use check boxes to do the following:

- Show or hide the elements corresponding to a variable in a zone.
- Add or remove the effect of applying the Color, Size, Shape, or Freq variable to the variable in the zone.

**Tip:** If you have multiple graphs, you can color or size each graph by different variables. Drag a second variable to the **Color** or **Size** zone, and drop it in a corner. In the Variables option, select the specific color or size variable to apply to each graph.

Use arrows to re-order the display if there are multiple variables in a zone. Highlight a variable name and click an arrow to reposition it.

For an example using Variables, see “Example of an Area and Line Chart” on page 124 in the “Graph Builder Examples” chapter.

**Red Triangle Option for Caption Box**

**Response Axis**  Specifies the axis for the variable whose summary statistic is displayed. The Y axis is the default. Notice that this axis can differ from the Response Axis specified to define the plot.

**Formula**

The **Formula** element shows the graphs of a function, its inverse, or a parametric curve. The function or functions are defined by column formulas.

- \( y = f(x) \):
  - To plot a function of a single argument across the values of its single argument, drag the column that contains the formula to the Y zone and the column that contains the values of its single argument to the X zone.
  - Make sure that the Response Axis is set to Auto or Y.
- \( y = f^{-1}(x) \):
  - To plot the inverse of a function of a single argument for a column of values, drag the column that contains the formula to the X zone. Drag the column that contains the values of interest to the Y zone.
  - Set the Response Axis to X.
- \( x = f(t) \) and \( y = g(t) \): To plot the parametric curve defined by two functions, drag one to the X zone and the other to the Y zone.
**Note:** Because the Formula element plots the values of a function, the plot is not affected in any way if rows are hidden and not excluded.

**Figure 3.40** Formula Option

Variables  Shows or hides graph elements for variables, or re-orders the display of variables.

**Note:** These options do not apply to variables in the Group X, Group Y, Wrap, or Page zones.

Check boxes are followed by the zone designation and the name of the variable. Use check boxes to do the following:

- Show or hide the elements corresponding to a variable in a zone.
- Add or remove the effect of applying the Color, Size, Shape, or Freq variable to the variable in the zone.

**Tip:** If you have multiple graphs, you can color or size each graph by different variables. Drag a second variable to the **Color** or **Size** zone, and drop it in a corner. In the Variables option, select the specific color or size variable to apply to each graph.

Use arrows to re-order the display if there are multiple variables in a zone. Highlight a variable name and click an arrow to reposition it.

For an example using Variables, see “Example of an Area and Line Chart” on page 124 in the “Graph Builder Examples” chapter.

**Red Triangle Option for Formula**

**Response Axis**  Specifies the axis for the formula variable.

**Map Shapes**

The Map Shapes element shows areas defined by the variable in the Map Shape zone.

When a column in your data table contains the names of geographical regions (such as countries, states, provinces, counties), you can assign the column to the Map Shape zone. When a variable is dropped in the Map Shape zone, Graph Builder searches for internal maps that correspond to the values in the column. If it finds an appropriate map, it draws the map in the graph area.
Alternatively, you can define the Map Role column property for the column of interest. This property tells JMP how to connect the values in the column with map shape data. It is especially useful when you create custom maps. See “Custom Map Files” on page 261 in the “Maps” chapter.

If you have a variable in the Map Shape zone, the X and Y zones disappear. You can add information from other variables using Color and Size.

- To color the map shapes by the values of a summary statistic, drag the column of interest to the Color zone. The categorical or continuous color theme selected in your Preferences is applied to each shape.
- To size the map shapes by the values of a summary statistic, drag the column of interest to the Size zone. This scales the map shapes according to the summary statistic value of the size variable, minimizing distortion.

See the “Maps” chapter on page 251. For examples, see “Examples of Creating Maps” on page 275 in the “Maps” chapter, or run the associated scripts in these sample data tables: PopulationByMSA.jmp or SAT.jmp.

Figure 3.41 Map Shapes Options

Summary Statistic  Changes the statistic that is plotted as the Color or Size variable.

Show Missing Shapes  Shows or hides missing data from the map.

Variables  Shows or hides graph elements for variables, or re-orders the display of variables.

Note: These options do not apply to variables in the Group X, Group Y, Wrap, or Page zones.

Check boxes are followed by the zone designation and the name of the variable. Use check boxes to do the following:
- Show or hide the elements corresponding to a variable in a zone.
- Add or remove the effect of applying the Color, Size, Shape, or Freq variable to the variable in the zone.

Tip: If you have multiple graphs, you can color or size each graph by different variables. Drag a second variable to the Color or Size zone, and drop it in a corner. In the Variables option, select the specific color or size variable to apply to each graph.

Use arrows to re-order the display if there are multiple variables in a zone. Highlight a variable name and click an arrow to reposition it.
For an example using Variables, see “Example of an Area and Line Chart” on page 124 in the “Graph Builder Examples” chapter.

Parallel

The **Parallel** element connects the values in a row across two or more variables. Drag two or more variables together to either the X or Y zone. The variable names appear as axis labels in the zone to which they were dragged.

- Values for each continuous variable are plotted along lines (axes) parallel to the other axis.
- Levels of categorical variables are represented by intervals on lines (axes) parallel to the other axis. The sizes of the intervals are proportional to the number of observations in each level of the categorical variable.
- The values (for continuous variables) or bands (for categorical variables) are joined with continuous curves.

When all variables are categorical, there is a band for every combination of levels of the categorical variables. The bands split as they move from left to right. In the first interval corresponding to a categorical variable, there is a band for every level of that categorical variable. In the last interval corresponding to categorical variables, there is a band for every possible combination of the categorical variables.

**Figure 3.42** Example of Categorical Bands Using Titanic.jmp
In Figure 3.42, the band containing all second-class passengers is selected. The parallel plot shows that most were adults, there were more males than females, and slightly fewer survived than did not survive.

The values or levels of the variables are connected with lines or curves using the Curve Lines option.

- To color the curves by the values of a variable, drag the column of interest to the **Color** zone. The categorical or continuous color theme selected in your Preferences is shown in the Legend zone.
- To size the curves by the values of a variable, drag the column of interest to the **Size** zone.
- To change the direction of a variable’s axis, click the arrow at the top of the vertical line denoting the variable’s axis.
- To move a variable and its axis, click and drag the axis.

**Tip:** Hover over a curve to see a label giving information about the corresponding row.

Figure 3.43 shows a parallel plot for six variables in the Cities.jmp data table. The variable POP is used both as a Color and Size variable. The curve for Los Angeles is labeled.

**Figure 3.43** Parallel Plot for Pollution Data in Cities.jmp
**Tips:**

- You can add a line element to a parallel plot to show a summary relationship across the parallel plot.
- You can add reference lines for specification limits. For information, see *Using JMP*.

**Scaling**

By default, the scales for the values of the variables are adjusted so that the minimum and maximum values are plotted at the same level. For example, in Figure 3.43, the values of each of the variables have an identical vertical spread. Each vertical line is labeled by the minimum and maximum values of the variables.

In Figure 3.43, the scales for CO and PM10 differ greatly from the scales of the other variables. When your variables are measured on very different scales, this scaling enables you to see differences clearly.

**Figure 3.44  Parallel Options**

![Parallel Options](image)

**Curve Lines** Adjusts the amount of curvature of the curves that connect points. Place the slider all the way to the left for lines. As you move the slider to the right, the degree of curvature increases.

**Combine Sets** (Applicable only if you have three or more categorical factors.) For categorical variables, when Combine Sets is not selected, bands split as they move from left to right. In the last interval that corresponds to a categorical variable, there is a band for every possible combination of the categorical variables. Selecting the Combine Sets option causes the bands not to split. Each interval that follows a categorical variable shows a band for each level of that variable.

**Axes Labels** Removes the axis labels from the display.

**Variables** Shows or hides graph elements for variables, or re-orders the display of variables.

**Note:** These options do not apply to variables in the Group X, Group Y, Wrap, or Page zones.

Check boxes are followed by the zone designation and the name of the variable. Use check boxes to do the following:

- Show or hide the elements corresponding to a variable in a zone.
Add or remove the effect of applying the Color, Size, Shape, or Freq variable to the variable in the zone.

**Tip:** If you have multiple graphs, you can color or size each graph by different variables. Drag a second variable to the **Color** or **Size** zone, and drop it in a corner. In the Variables option, select the specific color or size variable to apply to each graph.

Use arrows to re-order the display if there are multiple variables in a zone. Highlight a variable name and click an arrow to reposition it.

For an example using Variables, see “Example of an Area and Line Chart” on page 124 in the “Graph Builder Examples” chapter.

---

**Graph Zones**

The main element in the Graph Builder window is the graph area. The graph area contains zones, and you drag and drop variables from the Variables box into the zones.

**Tip:** If you drop variables into the center of the graph, JMP guesses which drop zone to put them into, based on whether the variables are continuous, ordinal, or nominal.

There are two types of zones into which you can drag variables:

- **Data zones** include **X**, **Y**, **Map Shape**, **Freq**, **Color**, **Size**, and **Interval**. The **X**, **Y**, and **Map Shape** zones are positional, and influence the types of graph elements that are available. The **Freq**, **Color**, **Size**, and **Interval** zones modify certain graph elements.

- **Grouping zones** partition the data into subsets that repeat the graph for each possible subset. Grouping zones include **Group X**, **Group Y**, **Wrap**, **Overlay**, and **Page**.

The following zones are available in Graph Builder:

<table>
<thead>
<tr>
<th>Zone</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>X and Y</td>
<td>Constructs plots that are based on the values, levels, or categories of the variables that you drop into these zones. Use the X zone for a horizontal layout and the Y zone for a vertical layout.</td>
</tr>
</tbody>
</table>
Group X and Group Y | Stratifies your data by the levels of the nominal or ordinal variable and constructs a plot for each level. Group X produces a horizontal display, and Group Y produces a vertical display.

The type of variable that you put in Group X or Y also determines aspects of the display:

- Adding a continuous variable creates non-overlapping interval subgroups and plots for the values in each interval.
- Adding a categorical variable creates plots for each level of the categorical variable.

You can add multiple variables to Group X or Group Y:

- To add a variable *above* a variable in one of the Group zones, drag it to the left of that variable in the Group X zone or above that variable in the Group Y zone.
- To add a variable *below* a variable in one of the zones, drag it to the right of that variable in the Group X zone or below that variable in the Group Y zone.

To stratify by the levels of two variables, drag a variable into both Group X and Group Y. To change the number of levels that appear, right-click in the axis border and select Levels in View. For a description of all options, see “Options for Axes, Variable Labels, or Graph Titles” on page 111.

<table>
<thead>
<tr>
<th>Table 3.5 Graph Builder Zones (Continued)</th>
<th></th>
</tr>
</thead>
</table>
| Group X and Group Y                    | Stratifies your data by the levels of the nominal or ordinal variable and constructs a plot for each level. Group X produces a horizontal display, and Group Y produces a vertical display. The type of variable that you put in Group X or Y also determines aspects of the display:

- Adding a continuous variable creates non-overlapping interval subgroups and plots for the values in each interval.
- Adding a categorical variable creates plots for each level of the categorical variable.

You can add multiple variables to Group X or Group Y:

- To add a variable *above* a variable in one of the Group zones, drag it to the left of that variable in the Group X zone or above that variable in the Group Y zone.
- To add a variable *below* a variable in one of the zones, drag it to the right of that variable in the Group X zone or below that variable in the Group Y zone.

To stratify by the levels of two variables, drag a variable into both Group X and Group Y. To change the number of levels that appear, right-click in the axis border and select Levels in View. For a description of all options, see “Options for Axes, Variable Labels, or Graph Titles” on page 111. |
### Table 3.5 Graph Builder Zones (Continued)

<table>
<thead>
<tr>
<th>Zone</th>
<th>Description</th>
</tr>
</thead>
</table>
| Map Shape  | Adds a map. Your variable must contain geographic place names, such as countries, regions, states, or provinces, or you must provide information in a custom shape file. Note the following:  
  - If you drag and drop columns labeled Latitude and Longitude, JMP automatically assigns them to the Y and X roles (respectively).  
  - When you drop a variable into the Map Shape zone, the X and Y zones disappear.  
  - The Map Shape element can be used with the Points element to place points within the shape.  
  For more information about creating map shapes, see “Red Triangle Option for Formula” on page 97 and “Graph Builder” on page 255 in the “Maps” chapter. |
| Wrap       | Creates rows of plots for the levels of a categorical variable or for the interval subgroups of a continuous variable. Use Wrap when your stratifying variable has many levels. To change the number of levels that appear, right-click in the axis border and select Levels in View. For a description of all options, see “Grouping Zones Options” on page 110.  
  **Note:** Once a variable is placed here, no variable can be placed in Group X. |
| Overlay    | Subgroups and colors the plot elements according to the levels of the Overlay variable.  
  - Adding a nominal or ordinal variable stratifies and colors the plot elements by the levels of the variable.  
  - Adding a continuous variable creates interval subgroups. The plot elements are stratified and colored according to the subgroups.  
  A legend appears to the right of the plot. Right-click on legend items for customization options. |
| Color   | Adds color to points, map shapes, and other objects.  
|         | • Adding a nominal or ordinal variable colors the plot elements by the variable's levels.  
|         | • Adding a continuous variable colors the plot elements according to an intensity scale.  
|         | A legend appears to the right of the plot. Right-click in the legend to change colors or to customize the intensity scale.  
|         | **Tip:** Once you have added a variable in the Color zone, you can show or hide color using the Variables option in the element properties panel.  
| Size    | Sizes graph elements by a summarizing statistic or other size variable.  
|         | A legend appears to the right of the plot. Right-click on legend items for customization options.  
| Interval| Add interval variables to draw custom error bars.  
|         | • A single interval variable is treated as a delta to compute upper and lower ends of the interval.  
|         | • Two interval variables are treated as lower and upper values for the interval.  
| Freq    | Add a frequency or weight variable. When all values are integer values, the Freq variable is treated as a frequency, otherwise it is treated as a weight. A footer note indicates how the variable is treated. The Freq variable affects summary statistics.  

**Table 3.5 Graph Builder Zones (Continued)**
Table 3.5 Graph Builder Zones (Continued)

<table>
<thead>
<tr>
<th>Zone</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Page</td>
<td>Drop a By group variable to the Page zone to show each level of the group on a separate graph. By default, the Page zone is limited to 200 pages.</td>
</tr>
<tr>
<td></td>
<td>The first 200 categories are displayed. Adjust this limit in the Graph Builder preferences.</td>
</tr>
<tr>
<td></td>
<td>For more information about the legend, see “Legend Options” on page 113.</td>
</tr>
<tr>
<td></td>
<td><strong>Tips:</strong></td>
</tr>
<tr>
<td></td>
<td>• Once you click Page, you can select the red triangle menu option Link Page Axes. Use this option to link or unlink graph axis scales across levels of the By group variable in the Page zone.</td>
</tr>
<tr>
<td></td>
<td>• To copy select individual plots with the selection tool, first save the graph builder output to a journal (Edit &gt; Journal).</td>
</tr>
</tbody>
</table>

For more information about the legend, see “Legend Options” on page 113.

**Note:** When you use categorical values in zones associated with summarization roles like Y and Color, summary statistics are calculated based on numerical values assigned to the variable levels (integer values ranging from 0 to the number of levels minus one). The final result is then mapped back as a level to a corresponding categorical value or value range. This approach allows the use of ordinal variables in summarization, but might not lead to clear results for nominal variables.

**Categorical and Continuous Variables in Group X or Y Zones**

When a categorical variable is added to the Group X or Group Y zone, a partition is created for each level of the variable.

When a continuous variable is added to a grouping zone, Graph Builder uses quantiles of the data to divide the variable into five groups. To change the number of groups:

1. Right-click the grouping variable label and select **Number of Levels**.
2. Type in the number of levels that you want to display.
3. Click **OK**.
Move Group X and Group Y Labels

Grouping variable labels can be relocated to another position on the graph. The Group X labels can be either on the top or the bottom of the graph. The Group Y labels can be either on the right or the left of the graph.

- To relocate a Group X label, right-click the variable in the Group X zone and select X Group Edge > Top or Bottom.
- To relocate a Group Y label, right-click the variable in the Group Y zone and select Y Group Edge > Left or Right.

Red Triangle Options

The red triangle menu for Graph Builder contains these options:

**Show Control Panel**  Shows or hides the platform buttons, the Select Columns box, and the drop zone borders.

**Show**

**Title**  Shows or hides the graph title. Right-click to change the alignment or the span of the title.

**Subtitle**  Shows or hides the graph subtitle. Right-click to change the alignment or the span of the subtitle.

**Legend**  Shows or hides the legend.

**Footer**  Shows or hides the footer, which contains informative messages such as missing map shapes, error bar notes, frequency notes, and WHERE clauses.

**X Axis**  Shows or hides the X axis.

**Y Axis**  Shows or hides the Y axis.

**X Axis Title**  Shows or hides the X-axis title.

**Y Axis Title**  Shows or hides the Y-axis title.

**Legend Position**  Sets the position of the legend. The legend appears on the right by default. Putting the legend at the bottom places it in the center below the graph. The legend items then appear horizontally instead of vertically. Or, you can put the legend inside the graph, on the left or right.

**Legend Settings**  Opens a window where you can modify legend settings, such as the title, font, and title position.
**Color Settings**  Contains the following options:

- **Continuous Color Theme**  Selects the color theme for continuous variables.
- **Categorical Color Theme**  Selects the color theme for categorical variables.

*Note:* For more information about color themes, see *Using JMP*.

- **Lighten large fills**  Automatically lightens colors for elements that fill large areas, such as pie, treemap, and mosaic plots.
- **Use row colors for levels**  When every level has a unique color, initialize legend levels with row colors.

**Lock Scales**  Prevents axis scales and gradient legend scales from automatically adjusting in response to data or filtering changes.

**Error Bar Offset**  Adjust the offset for overlaid error bars.

**Link Page Axes**  Links or unlinks graph axis scales across levels of the By group variable in the Page zone.

**Fit to Window**  Specifies whether the graph is resized as you resize the JMP window. The default setting is Auto, which is usually set to On except when the window is shared with other content or if there is a Page variable. To always fit the graph inside the window, keep the setting at On. You can also maintain the aspect ratio. To prevent the graph from resizing, change the setting to Off.

**Sampling**  Uses a random sample of the data to speed up graph drawing. If the sample size is zero, or greater than or equal to the number of rows in the data table, then sampling is turned off.

**Graph Spacing**  Sets the amount of space between graph panels.

**Include Missing Categories**  Enables a graph to collect and display missing values for categorical variables.

**Set Alpha Level**  Enables you to set the Alpha level for graphs and statistics that use an alpha value for confidence intervals.

**Launch Analysis**  Launches the Fit Model platform with the variables on the graph placed into roles. It launches the Distribution platform when only one variable is placed.

**Make into Data Table**  Creates a new data table that contains the results from the graph.

See *Using JMP* for more information about the following options:

**Local Data Filter**  Shows or hides the local data filter that enables you to filter the data used in a specific report.
**Graph Builder Buttons**

The Graph Builder window contains these buttons:

- **Recall**  Populates the Graph Builder window with the last graph that you created. This button changes into the Undo button once you perform an action.

- **Dialog**  Opens the Graph Builder launch window. This button changes into the Start Over button once you perform an action. You can add a By variable in the Graph Builder launch window.

- **Done**  Hides the buttons, Columns list, and all drop zone outlines. Equivalent to deselecting the Show Control Panel option.

  Use this presentation-friendly format for pasting into other applications. To copy the graph, select **Edit > Copy**. To restore the window to the interactive mode, click the Graph Builder red triangle and select **Show Control Panel**.

- **Undo**  Reverses the last change made to the window.

- **Start Over**  Returns the window to the default condition, removing all data and graph elements from the window, and all variables from the drop zones.

**Right-Click Menus**

- “Graph Options”
- “Grouping Zones Options”
- “Options for Columns in the Variables Panel”
- “Options for Axes, Variable Labels, or Graph Titles”
- “Options for the Dividing Line between Multiple Graphs”
- “Legend Options”
For multiple graphs (created with grouping zones or the Wrap zone), note the following:

- Generally, any options that you apply to one graph element apply to all graphs, across all grouping and wrap variables.
- To apply an option to only one graph, right-click in that graph area and select the option from the Graph menu.
- To apply an option to all of your multiple graphs simultaneously, first hold down the Ctrl key and right-click and then select the option from the Graph menu.

**Graph Options**

Right-clicking in a graph shows the following:

1. Element types that appear in the plot (such as Points, Line, and so on). Sub-menues provide options that are specific to each element type, and general options. Alternatively, you can change element-specific options in each element’s properties panel, below the Variables panel.
2. The Add option, where you can select other elements to add to the graph. Alternatively, you can add more elements to the graph by dragging the desired element icons.
3. The Rows, Graph, Customize, and Edit menus. For descriptions of these options, see *Using JMP*.

**Tip:** Select **Rows > Name Selection in Column** to create a new column to name and label selected points in a graph.

**Grouping Zones Options**

Right-clicking in the X Group, Y Group, Wrap, Color, Size, and Overlay zones can show the following options:

**Levels in View**  Changes the number of levels of the grouping variable that are visible. Use the arrow buttons to scroll forward and backward.

**Number of Levels**  Changes the number of levels. See “Categorical and Continuous Variables in Group X or Y Zones” on page 106.

**Order By**  Orders the levels of a variable. See “Order the Levels of a Categorical Variable” on page 49.

**Show Title**  Shows or hides the variable title.

**Title Orientation**  Changes the orientation of the variable text to horizontal or vertical.

**Level Orientation**  Changes the orientation of the level values to horizontal or vertical.
**Levels per Row**  Changes the number of columns included in the graph. Use with a **Wrap** variable.

**Color**  Changes the background color of the grouping zone.

**X or Y Group Edge**  Moves the grouping variable labels. See “Move Group X and Group Y Labels” on page 107.

**Summary Statistic**  Applies color and or size variables based on a summary statistic. Available only for a summarized Y response.

**Swap**  Swaps the position of two variables. See “Move or Remove Variables in Zones” on page 39.

**Remove**  Removes a variable.

### Options for Columns in the Variables Panel

Right-clicking on a column in the Variables panel shows options that depend on the column’s modeling type. For more information about these menus, see *Using JMP*.

### Options for Axes, Variable Labels, or Graph Titles

Right-clicking on axes, variable labels, or graph titles shows options that are specific to Graph Builder and general options. Select **Show Properties** from the right-click menu to access the properties panel for additional customizations. The following options are specific to Graph Builder:

**Alignment**  Changes the graph title alignment.

**Span**  Changes the width of the graph title span.

**Combine Scales**  Combines scales when you have multiple variables in the same zone. Auto does the following:

- If there are 4 or more variables on one axis and no variables on the other axis, elements that support parallel mode are combined as parallel scales. If all variables are continuous and overlapping, Parallel Merged is used.
- If all variables are categorical, use Nested.

In addition, consider the following:

- Merged creates one scale that covers all variables.
- Nested creates a nested scale with one level per variable.
– Parallel Merged is for parallel coordinates with a shared scale. You can use this option with the following elements: Points, Contour (Violin), Histogram, Box Plot and Parallel.

– Parallel Independent is for parallel coordinates with independent scales. You can use this option with the following elements: Points, Contour (Violin), Histogram, Box Plot and Parallel.

**Date/Time Bin**  (Appears only for a date or time axis variable.) Enables you to select a level of granularity to bin the data. For example, you might choose to bin at a high level, by year, or at a low level, by second.

**Date/Time Wrap**  (Appears only for a date or time axis variable.) Enables you to select a cyclic period for your date data.

**Swap**  Switches a variable from one zone to another. Select the variable that you want to switch places with.

**Remove**  Removes the variable from the zone.

**Move Right**  (Appears only if you have more than one variable in the Y zone.) Creates a second Y axis (on the right) for the variable that you select.

**Order By**  (Appears only if you have categorical variables in the X or Y zone.) Orders the levels of a categorical variable. See “Order the Levels of a Categorical Variable” on page 49.

**Note:** Select Other to indicate a continuous variable as the ordering variable.

**Order Statistic**  Enables you to select a statistic to use for the ordering.

**Save Value Order**  (Available once an ordering has been defined.) Saves the defined order to the Value Order column property.

**Note:** You can edit value ordering from Graph Builder. Right-click on an axis and select Edit Value Order.

**Size By**  (Available for a categorical axis.) Enables you to size your box plots by the count of observations within a group or by a numerical column.

**Size Statistic**  (Available when the Size By option indicates a numerical column as the sizing variable.) Enables you to select a statistic to use for the sizing.

For descriptions of the general options below the line, see *Using JMP*.

**Tip:** For additional axis customizations, such as tick line thickness or color, select Show Properties from the right-click menu.
Options for the Dividing Line between Multiple Graphs

This menu appears only if you have two or more graphs in the graph area. Right-click the line that separates graphs. Options appear that change the formatting of the line, such as color, transparency, spacing, and borders.

**Tip:** If the line between the graphs is too thin, you can resize it. Click the Graph Builder red triangle, select **Graph Spacing**, and enter a larger value.

Legend Options

A legend consists of elements, such as lines, fill colors, and gradients. Right-click on legend elements for customization properties. These properties include color and labeling options when available. Additional legend settings are found in the Legend Settings window.

To change legend settings or revert to initial settings, right-click to the right of the legend or on the title (if applicable). To undo recent changes to the legend, click Undo.

**Tip:** When you have both an overlay and a color variable, the color variable levels are shown by rounded color icons in the legend.

**Legend Settings**  Change certain aspects of the graphics elements (line, bars, and so on) such as color, fill, transparency, and gradient. You can also add a title to the legend. See “Legend Settings Window” on page 113.

**Revert Legend**  Returns the legend to its initial settings.

**Move the Legend**

To move the position of the legend, click and drag to the desired location. The location can be a hotspot corresponding to the locations accessible from the Graph Builder red triangle menu or the legend or it can be any other location within the graph.

To use the menu options, click the Graph Builder red triangle and select **Legend Position**. To make the legend vertical or horizontal, change the Item Direction in the Legend Settings window.

**Legend Settings Window**

Change aspects of the legend through the Legend Settings window.
**Figure 3.45** Example of the Legend Settings Window Using Hybrid Fuel Economy.jmp

- **Title**  The name of the legend.

- **Check boxes**  Shows or hides items in the legend. JMP hides items that appear to be redundant, but you can make them appear by selecting them. If your legend has a large number of entries, some might be hidden in the Graph Builder window to ensure sufficient space for the graph. However, all of the entries appear here, so you can select the ones that you want to show. To select or deselect all entries, right-click and select **Toggle** check box.

- **Up and down arrows**  Changes the order of items in the legend.

- **Color Theme**  Select a different color theme. For more information about color themes, see *Using JMP*.

- **Title Position**  Places the legend title on top or to the left of the items in the legend.

- **Item Direction**  Displays the legend horizontally or vertically.

- **Item Wrap**  Sets the legend to be \( n \) items tall (if vertical) or \( n \) items wide (if horizontal).

- **Font**  Changes the font type, style, and size.

- **Preview**  Shows your changes to the legend.

- **OK**  Commits your changes to the legend.

- **Cancel**  Cancels your changes to the legend.

- **Help**  Opens the online Help.
Discrete or Continuous Legend Items

Legends can list discrete values or show a scale of continuous values:

- Discrete legends can contain the levels of a categorical variable, or a list of variables.
- Continuous legends describe a color intensity scale for a range of numerical values.

Right-click an item in either legend to see the following options:

**Line Color**  (Discrete legends only.) Changes the color of the element associated with the item.

**Marker**  Changes the type of marker associated with the item.

**Marker Size**  Changes the size of the marker associated with the item.

**Pattern or Style**  Changes the fill or pattern of the element associated with the item.

**Line Width**  Changes the width of the line associated with the item.

**Fill Color**  Assigns a color to the item.

**Color by Theme**  Colors multiple contours by levels in a color theme. This option sets line colors and fill colors for density contours.

**Transparency**  Changes the marker or label transparency. Enter the level of transparency to draw markers (points) on the graph. The degrees of opacity ranges from 0 (clear) to 1 (opaque).

**Gradient**  (Continuous legends only.) Changes the gradient settings. See “Gradient Settings” on page 116.

**Density Gradient**  (Contour element only.) Changes the gradient colors:

- **Fade to White**  The highest density contour uses the fill color, and colors fade to white at lower densities.
- **Fade to Gray**  The highest density contour uses the fill color, and colors fade to gray at lower densities.
- **Full Color**  Density contours use a predefined or customized color theme with full color control.

**Gradient Transparency**  (Contour element only.) Changes the transparency of the gradient:

- **None**  Density contours use one transparency level for all levels.
- **Linear**  Density contours get gradually more transparent at lower densities.

**Revert**  Restores default settings.
Gradient Settings

You can change various aspects of the gradient legend in the Gradient Settings window.

Figure 3.46 Gradient Settings Window

To format the labels in the legend, use the menu, Width and Dec boxes, and the **Use thousands separator (,)** check box in the top left of the window.

**Color Theme**  Change the color theme or define a custom color theme. For more information about color options, see *Using JMP*.

**Lightness Range**  Set the range of intensities for the gradient coloring.

**Number of Labels**  Specify the number of labels for your legend. The value of zero provides the default number of labels.

**Show Missing Color**  Specifies whether to show missing color in the legend. Auto shows the color only when there are missing values, Off never shows the color, On always shows the color.

**Scale Type**  Sets the scale for the gradient coloring. Look below the Maximum option for a description of the scale type.

- **Linear**  The scale is piecewise linear between the Minimum and Center values and between the Center and Maximum values. This is the default scaling.

- **Quantile**  The scale is piecewise linear for quantiles of the variable represented by the legend.
**Standard Deviation**  The legend range is divided into offsets from the mean determined by standard deviation increments. The scale is piecewise linear between these offset settings. The number of offsets is determined by the Number of Labels.

**Log**  The scale is linear for the logarithm of the values represented by the legend.

**Log Offset**  The scale is linear for the offset of the base 10 logarithm of the values represented by the legend.

**Range Type**  Sets the range of the legend values.

**Default**  Unless you specify values for the Minimum and Maximum, the minimum and maximum values include the range of the data and are chosen to be appropriately rounded values.

**Exact Data Range**  The minimum and maximum values are the exact minimum and maximum values for the data, or they are the values that you specify as Minimum and Maximum.

**Middle 90%**  The minimum and maximum values are the $5^{th}$ and $95^{th}$ quantiles, or they are the values that you specify as Minimum and Maximum. This option is resistant to outliers.

**Minimum, Center, Maximum**  Specify the smallest, middle, and largest values to use for your legend scaling.

**Note:** These values can override the Range Type values.

**Horizontal**  Changes the orientation of the legend to horizontal.

**Reverse Colors**  Reverses the colors in the color scheme.

**Reverse Scale**  Reverses the scale for the color theme.

**Discrete Colors**  Changes the color scheme from a continuous gradient to a stepped gradient with discrete colors.

**Show Labels**  Shows or hides labels for the legend.
Graph Builder provides you with a variety of ways to visualize and explore your data. This chapter provides detailed examples of data exploration using bar charts, histograms, area plots, maps, and other types of plots.

Example of an Ordered Bar Chart

Data
This example uses data from college graduates in 2012. The table contains counts of degrees for graduates in 15 fields of study. Each degree is subdivided by the graduate’s job type. There are categorical columns for degree, degree type, and job type (where type is STEM or non-STEM related). The continuous column Number contains the number of graduates from each unique combination of degree and job type.

Note: These data come from the U.S. Census Bureau (2012).

Techniques
This example uses color, a local data filter, and sorting options.

Goal
The goal of this example is to visualize the percentage of graduates who are employed in STEM-related jobs, based on their degree type.

1. Select Help > Sample Data Library and open STEM Jobs.jmp.
2. Select Graph > Graph Builder.
3. Select Degree and drag it to the X zone.
4. Select Percent and drag it to the Y zone.
5. Click the Bar element .
6. Click the Graph Builder red triangle and select Local Data Filter. In the Local Data Filter, perform these steps:
   a. Click Job Type and then click .
   b. Click STEM.

Figure 4.2 Selections in the Local Data Filter

7. In the Graph Builder column list, select Degree Type and drag it to the Color zone.
8. In the legend, change the bar colors according to degree type:
   - Right-click **STEM** and change the fill color to purple.
   - Right-click **Non-STEM** and change the fill color to yellow.

9. In the Graph Builder column list, select **Percent** and drag it above the X axis. See Figure 4.4.
Figure 4.4 Ordering Degree by Percent

This orders the degree by percent in ascending order. However, you want it to be in descending order.

10. Right-click the X axis and select **Order By > Percent, descending**.

11. Click the graph title and type Graduates Employed in STEM Jobs and press Enter.

12. Click **Done**.
This graph displays the percent of graduates employed in STEM jobs by their degree type. Nearly 50% of Engineering and CompMath graduates are employed in STEM jobs, as compared to less than 2% of Education graduates.

**Example of an Area and Line Chart**

**Data**
This example uses data based on website traffic. It includes hourly measurements and historical range information.

**Techniques**
This example uses Recode to improve data labels, multiple graph elements (area and line), and legend customization. It also shows how to remove variables from a graphing element when multiple variables are plotted on a single axis.

**Goal**
The goal of this example is to display trend lines for website traffic within an overall range.

1. Select **Help > Sample Data Library** and open Bands.jmp.
2. Select the Hour column, and then select Cols > Recode.

3. In the Recode window, make these changes:
   a. Click the red triangle and select First Word.
      Notice that the New Values include only the first hour.
   b. Under New Values, click 12am and enter midnight. Click 12pm and enter noon.

Figure 4.6 Completed Recode Window

4. Select Graph > Graph Builder.

5. Select Hour 2 and drag it to the X zone.

   Note: The ordering of the X axis is logical, going from midnight to 11pm. This is because the Hour column has a value ordering column property that was copied to the Hour 2 column when you created it with Recode.

6. Select Average, Today, Last Week, Lo, and Hi and drag them to the Y zone.
7. Click the Area element.

8. In the Area properties panel, make these selections:
   a. Change the Area Style to **Range**.
   b. Open Variables and deselect **Average**, **Today**, and **Last Week**.

   Now the area element is applied only to the **Lo** and **Hi** variables.

**Figure 4.7** Completed Area Properties Panel

---

9. Hold down the Shift key and click the Line element.

   **Tip:** Holding down the Shift key and clicking adds additional elements to the graph, without replacing any existing elements.

10. In the Line properties panel, open Variables and deselect **Lo** and **Hi**.

    Now the line element is applied only to the **Avg**, **Today**, and **Last Week** **Y** variables.
11. Customize the graph elements using the legend:
   a. In the legend at right, double-click **Lo..Hi**.
   b. In the Legend Settings window, double-click **Lo..Hi** and rename it to **Typical**.
   c. Highlight **Today** and **Last Week**, and click the up arrow to move them up one, so that the order is: **Typical**, **Today**, **Last Week**, and **Average**. Click **OK**.
Example of an Area and Line Chart

12. Right-click the X axis > Axis Settings. For Label Orientation, click Horizontal, and then click OK.

13. Change the titles of the axes and graph:
   a. Click the Y-axis title and enter Volume of web traffic.
   b. Click the X-axis title and enter Time of day.
   c. Click the graph title and enter Current and Historical Website Traffic Based on Time of Day.

14. Click Done.

Figure 4.10 Completed Area and Line Graph

Tip: If an item in the legend is still highlighted, click it to deselect it.

The graph shows that the afternoon website traffic fell to unusually low levels today. The red trend line that represents today’s traffic peaks at 1pm and then falls to outside of the gray band that represents the range of expected daily traffic for this website by about 3pm.
Example of a Map Chart

Data
This example uses data from 2017 of commodity acres planted in states within the US that grow corn, wheat, and soybeans.

Note: These data come from the United States Department of Agriculture (2017).

Techniques
This example uses map shapes and legend customization.

Goal
The goal of this example is to show the median number of commodity acres that have been planted per state.

1. Select Help > Sample Data Library and open Corn Wheat Soybean Production.jmp.
2. Select Graph > Graph Builder.
3. Select State and drag it to the Map Shape zone.

Note: JMP recognizes US State names as map shapes. For more information, see “Map Shape” on page 255.

4. Select Commodity Acres Planted and drag it to the Color zone.
5. In the Map Shapes properties panel, change the Summary Statistic to Median.
6. Customize the graph elements in the legend:
   a. In the legend color bar, right-click and select **Gradient**.
   b. Next to Width, enter **12**.
   c. Next to Color Theme, click the color bar. Under Sequential, click the 2nd option (white to blue) and then click **OK**.
   d. From the Scale Type list, choose **Quantile**.
e. Click OK.

7. Click the title above the graph and type **State Colored by Median Commodity Acres Planted**.

8. Right-click in the graph and select **Hover Label > Bar**.

   This adds a bar chart hover graph. When you hover over a state, you can see the proportions of the commodities grown in that state in a bar chart.

   **Note:** For more information about Hover Labels, see the Using JMP book.

9. Click Done.

10. Hover over a state (in this case, Mississippi).
**Figure 4.13** Completed Map Colored by Median Commodity Acres Planted

The coloring on the map highlights the states with the highest number of acres of wheat, corn, and soybeans. The dark blue states are known as America’s Breadbasket. The hover graphs enable you to explore the proportions of the three crops grown in a state. This example shows that in Mississippi, soybeans are the prominent crop.

**Tip:** To see other examples using Graph Builder, run the additional scripts in the Corn Wheat Soybean Production.jmp data table.

---

**Example of a Butterfly Chart**

**Data**

This example uses summarized survey responses to 20 questions all using the same 5-point Likert scale.

**Techniques**

This example uses a bar chart with variable ordering and color customizations.
1. Select Help > Sample Data Library and open Likert Survey.jmp.

Notice the following about this data:

– The data has a row for each question and columns with the counts of responders for each different response.

– The order of the survey questions in the question column is not sequential. When you use this column in Graph Builder, JMP orders the rows sequentially.

– Formula columns are included in the table to create negative counts for negative responses. The neutral counts are split so that half contribute to a negative column and half contribute to a positive column.

2. Select Graph > Graph Builder.

3. Select question and drag it to the Y zone.

4. Select agree, strongly agree, -strongly disagree, -disagree, -neutral, and +neutral and drag them to the X zone.

5. Click the Bar element.

6. In the Bar properties panel, do the following:

   – Change the Bar Style to Stacked.
   
   – Open Variables, and then highlight a variable and use the arrow icons to move them into this order, from top to bottom: -neutral, -disagree, -strongly disagree, +neutral, agree, strongly agree.

Figure 4.14 Completed Bar Properties Panel

7. Click the Graph Builder red triangle and select Legend Position > Bottom.

8. Click Done.
Figure 4.15 Graph Prior to Legend Customizations

Customize the Legend Colors and Ordering

1. Right-click on each color in the legend and change the Fill Color:
   - Light gray for +neutral and -neutral
   - Light pink for -disagree
   - Red for -strongly disagree
   - Light green for agree
   - Dark green for strongly agree

2. Hover over any item in the legend. The cursor should appear as a hand. Double-click to open the Legend Settings window.

3. Highlight a variable and use the arrow icons to change the order from top to bottom:
   - strongly disagree, -disagree, -neutral, +neutral, agree, strongly agree.

4. Double-click +neutral and rename it to neutral.

5. Deselect the box next to -neutral so that it no longer appears in the legend, because it is a duplicate.

Figure 4.16 Completed Legend Settings

7. Click **OK**.

8. Change the titles of the X axis and graph:
   a. Click the graph title and enter Agreement vs. Question.
   b. Click the X-axis title and enter agreement.

9. Double-click in the Y axis and select the **Reverse Order** box, and then click **OK**.

10. Double-click in the X axis and select the **Major Grid Lines** box, and then click **OK**.

    The grid lines help you visually judge the differences between question results.

Figure 4.17 Final Likert Scale Graph

**Tip:** If an item in the legend is still highlighted, click it to deselect it.
This graph provides a visual summary of 20 survey questions, ignoring the non-responses. Note that the non-responses are less than 1% of the total responders for any question. Therefore, leaving them out of the visualization does not impact the conclusions. Question 19 has the most positive responses, and Question 11 has the least favorable responses.

## Example of a Scatterplot

<table>
<thead>
<tr>
<th>Data</th>
<th>This example uses data from 442 diabetic patients. The data includes baseline clinical and laboratory data as well as a binary measure of diabetes disease progression obtained one year after each patient’s initial visit. This measure classifies disease progression as Low or High.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Techniques</td>
<td>This example uses two scatterplots with a shared X axis, axis customization, and annotation.</td>
</tr>
<tr>
<td>Goal</td>
<td>The goal of this example is to compare and understand the predicted probabilities of High disease progression from two classification models.</td>
</tr>
</tbody>
</table>

## Run the Classification Models

You want to construct a classification model to predict the disease progression based on clinical and laboratory variables. You will build two different classification models, save prediction formulas, and compare their predicted classifications.

1. Select Help > Sample Data Library and open Diabetes.jmp.
2. Click the green triangle next to the Decision Tree of Y Binary script to build a decision tree prediction model.
3. Click the Partition for Y Binary red triangle and select Save Columns > Save Prediction Formula. You can close this window.
   - This saves the probability formulas to the data table.
4. In the data table, right-click the Prob(Y Binary= = High) column and select Column Info.
5. Change the column name to Partition Prob High and click OK.
6. Click the green triangle next to the Neural of Y Binary script to build a neural net prediction model.
7. Click the Model NTanH(3) red triangle and select Save Profile Formulas. You can close this window.
   - This saves the probability formulas to the data table.
8. In the data table, right-click the Probability(Y Binary=High) column and select Column Info.
9. Change the column name to Neural Prob High and click OK.

Create the Initial Graph

You will compare the model predicted probabilities of a patient having a High disease progression.

1. Select Graph > Graph Builder.
2. Select Partition Prob High and drag it to the X zone.
3. Select Neural Prob High and drag it to the X zone, to the right of Partition Prob High. This creates a second X axis.

Figure 4.18 Drag Neural Prob High to the Right of Partition Prob High

4. Select Y Binary and drag it to the Overlay zone.
5. Click the Graph Builder red triangle and select Graph Spacing.
6. Type 6 next to Graph Spacing and click OK.
   This increases the spacing between the two X axes.
Customize the Graph

In both modeling platforms, the default threshold value is 0.50. This means that if a patient has a predicted probability greater than 0.50 of “High”, the model predicts their classification as “High”. Use reference lines to show the threshold value in the graph.

1. Right-click the Partition Prob High X axis and select **Axis Settings**.
2. In the Scale section, click the box next to **Reverse Order**.
3. In the Tick/Bin Increment section, set **# Minor Ticks** to 2.
4. In the Reference Lines section, type 0.50 in the boxes next to **Value** and **Label**.
5. In the box next to Line Style, enter 3. The 3 indicates the thickness of the reference line.
6. Click **Add**.
Figure 4.20  X Axis Settings

7. Click OK.
9. Click Done.

Annotate the Graph

1. In the main menu, click Tools > Line. Draw a horizontal line to the left of the reference line in the Partition Prob High graph.
Figure 4.21  Line Drawn to the Left of the Partition Prob High Reference Line

2. Right-click the line and select **Point to**.
   The arrow should be pointing away from the reference line.

3. In the main menu, click **Tools > Annotate** and click on the graph above the arrow.

4. Type **Classified as “High”** in the text box. See Figure 4.22.

5. Repeat step 1 through step 4 in the Neural Prob High graph.
The graph shows that the distribution of the predicted probabilities differs between the two models. The partition model has five predicted score levels while the neural model scores are dispersed across the score range. For both models, there is a cluster of blue data points on the far right of each plot. These are low subjects that both models classify correctly as they fall to the right of the threshold.

**Example of a Packed Bar Chart**

<table>
<thead>
<tr>
<th>Data</th>
<th>This example uses data from the National Oceanic and Atmospheric Administration on the economic impact of weather and climate events in the U.S. during the years 1980 to 2018.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Techniques</td>
<td>This example uses a packed bar chart with 10 primary categories.</td>
</tr>
<tr>
<td>Goal</td>
<td>The goal of this example is to create a packed bar chart showing the events that had the greatest economic impact.</td>
</tr>
</tbody>
</table>

1. Select Help > Sample Data Library and open Billion Dollar Events.jmp.
2. Select Graph > Graph Builder.
3. Select Unique Event and drag it to the Y zone.
4. Select Cost and drag it to the $X$ zone.

5. Select the Bar element

6. In the Bar options panel:
   a. For the Bar Style, select Packed.
   b. Change Packed Primaries to 10.
   c. Move the Packed Labeling slider to the left until it is about halfway.

**Figure 4.23** Weather Events With Large Economic Impacts in a Packed Bar Chart

The top 10 categories appear as a bar chart with blue bars. These are the “Packed Primaries” that you set to 10 in the options. Secondary categories are labeled and in gray. You can hover over any bar for more details.

In this graph, you can clearly see that Katrina in 2005 had the largest financial impact of any storm that hit the US between 1980 and 2018. The 2017 hurricanes, Harvey and Maria, also had large financial impacts.
Example of an Overlaid Histogram and Ridgeline Chart

Data
This example uses data from 442 diabetic patients. The data include baseline clinical and laboratory data as well as a binary measure of diabetes disease progression obtained one year after each patient’s initial visit. This measure classifies disease progression as Low or High.

Techniques
This example uses overlaid histograms and a ridgeline chart.

Goal
The goal of this example is to explore the distribution of a continuous variable grouped by categories. Specifically, you are interested in exploring how the distribution of HDL varies by gender and then by disease progression.

1. Select Help > Sample Data Library and open Diabetes.jmp.
2. Select Graph > Graph Builder.
3. Select HDL and drag it to the X zone.
4. Select Gender and drag it to the Overlay zone.
5. Click the Histogram element icon.
6. In the Histogram properties panel, from the Histogram Style list, select Kernel Density.
7. Hover over the Y axis near the top of the scale until the cursor turns into a horizontal hand. Click and drag until the maximum value is about 85.
Figure 4.24 Overlaid HDL Histograms by Gender

The histograms indicate that HDL levels are higher in males (blue) than females (pink). The blue distribution falls to the right, or higher on the HDL scale, than the pink distribution. Now change the graph to view the differences in gender in a ridgeline plot.

8. Select Gender and drag it to the Y zone.

9. In the Histogram properties panel, move the Overlap slider to overlap the histograms (until the slider is about 3/4 up).

10. Click Done.

11. Double-click in the legend. In the Legend Settings window, double-click 1 and type male. Double-click 2 and type female.

12. Click OK.

**Tip:** If an item in the legend is still highlighted, click it to deselect it.
Chapter 4
Essential Graphing

Graph Builder Examples
Example of a Bullet Bar Chart

Figure 4.25  Ridgeline Chart of HDL by Gender and Diabetes Level

The ridgeline chart shows the gender distributions offsets.

Example of a Bullet Bar Chart

<table>
<thead>
<tr>
<th>Data</th>
<th>This example uses fabricated sales data for four products.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Techniques</td>
<td>This example uses a bullet chart.</td>
</tr>
<tr>
<td>Goal</td>
<td>The goal of this example is to display actual units sold compared to a minimum and target number of units.</td>
</tr>
</tbody>
</table>

1. Select Help > Sample Data Library and open Bullet Measures.jmp.
2. Select Graph > Graph Builder.
3. Select Actual, Target, and Minimum and drag them to the X zone.
4. Select Product and drag it to the Y zone.
5. Click the Bar element icon.
6. In the Bar properties panel, perform these actions:
   - From the Bar Style list, select Bullet.
– Open Variables, and then highlight Minimum and click the Up arrow once.
7. Click the Graph Builder red triangle and select Legend Position > Bottom.
8. Right-click on a color in the legend and change the Fill Color:
   – No change to Actual
   – Change Minimum to dark gray
   – Change Target to light gray
9. Right-click in the Y axis > Order By > Target, ascending.
10. Change the titles of the X axis and graph:
    a. Click the graph title and enter Sales Data vs. Products.
    b. Click the X-axis title and enter Units.
11. Click Done.

**Figure 4.26** Bullet Chart of Actual, Target, and Minimum Units Sold

The products are ordered by the target number of units as shown by the light gray bars. Products A and D have actual sales that are above their targets; the blue bars extend beyond the light gray target bars. Sales for Product C are on target. Sales for Product B are below target but above the minimum number of units.
Example of a Forecast Plot

<table>
<thead>
<tr>
<th>Data</th>
<th>This example uses maximum monthly temperature data from the US city of Raleigh, NC that were recorded from 1980 to 1990.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Techniques</td>
<td>This example uses a time series line of fit.</td>
</tr>
<tr>
<td>Goal</td>
<td>The goal of this example is to forecast the maximum monthly temperature for the following year.</td>
</tr>
</tbody>
</table>

2. Select Graph > Graph Builder.
3. Select Month/Year and drag it to the X zone.
4. Select Temperature and drag it to the Y zone.
5. Click the Line of Fit element icon .
6. In the Line of Fit properties panel, do these actions:
   - From the Fit list, select Time Series.
   - In the box next to Seasonal Period, type 12.
   - In the box next to Forecast Periods, type 12.
     This forecasts 12 months out. Since the data ends at 1990, it forecasts through 1991.
7. Right-click the X axis and select Axis Settings.
   - Under Tick/Bin Increment, change the Increment to 1.
   - Under Tick/Bin Increment, change the Label Row Nesting to 2.
   - Under Axis Label Rows, on the Label Row 1 tab, select Labels for the minor tick marks.
   - Click OK.
8. (Optional) To save the predicted forecast values and the lower and upper points of the forecast interval as new columns in the data table, click the Line of Fit red triangle and select Save Formula.
9. Click Done.
**Figure 4.27** Forecast Plot of Maximum Monthly Temperature

The graph shows the data points used to estimate the time series function that extends through the forecast period. Note the following about this graph:

- The solid blue line represents the forecast model. The shaded blue area is the 95% confidence interval around the predicted values.
- The forecast period covers 1991, which is 12 months past the last data point. The forecast period is the right most portion of the plot that has no data points.
- The peak forecast high for 1991 is in July with an estimated value of 90°F. This estimate has a confidence interval of about 83°F to 96°F represented by the limits of the blue region above and below the estimate.
- The text at the top indicates the type of model that was fit, the parameter values for that model, and information about missing values. To remove this text from your graph, deselect the Forecast Model option in the Line of Fit properties panel.
A bubble plot is a scatterplot that represents its points as circles, or bubbles. Bubble plots can be dynamic (animated over time) or static (fixed bubbles that do not move). Use bubble plots to:

- dynamically animate bubbles using a time variable, to see patterns and movement across time
- use size and color to clearly distinguish between different variables
- aggregate data (rows) into a single bubble, simplifying the bubble plot

Because you can see up to five dimensions at once (x position, y position, size, color, and time), bubble plots can produce dramatic visualizations and readily show patterns and trends.

Note: Dynamic bubble plots were pioneered by Hans Rosling, Professor of International Health, Karolinska Institutet, and the people involved in the Gapminder.org project.

Example of a Dynamic Bubble Plot

This example uses the PopAgeGroup.jmp sample data table, which contains population data for countries and regions around the world. Examine the relationship between the proportion of younger and older people in the sample populations.

1. Select Help > Sample Data Library and open PopAgeGroup.jmp.
2. Select Graph > Bubble Plot.
   
   The launch window appears.

   **Figure 5.2** The Bubble Plot Launch Window

3. Select Portion60+ and click Y.
   
   The portion of the population that are 60 years or older becomes the y coordinate.

4. Select Portion 0-19 and click X.
   
   The portion of the population that are 0-19 years becomes the x coordinate.

5. Select Country and click ID.
   
   All the rows for each country are aggregated into a single bubble.

6. Select Year and click Time.
   
   The bubble plot shows a unique plot for each year’s data.

7. Select Pop and click Sizes.
   
   The sizes of the bubbles reflect the overall population values.

8. Select Region and click Coloring.
   
   Bubbles for different regions are assigned different colors. See the Region legend in Figure 5.3. The colors shown in the plot are JMP default colors.

9. Click OK.
The report window appears.

**Figure 5.3** The Bubble Plot Report Window

![Bubble Plot Report Window](image)

10. Click the play button to see the animated, dynamic report. Alternatively, you can click the previous button to move forward by one year.

11. (Optional) To view a legend that identifies each color with its region, click the Bubble Plot red triangle and select **Legend**.

As time progresses, you can see that the portion of the population that is 0-19 years decreases, and the portion of the population that is 60 years or more increases.
Launch the Bubble Plot Platform

Launch the Bubble Plot platform by selecting **Graph > Bubble Plot**.

Figure 5.4 The Bubble Plot Launch Window

- **Y, X**  The Y and X columns become the $y$ and $x$ coordinates of the bubbles in the plot. These values can be continuous or categorical (nominal or ordinal).

- **ID**  ID variables identify rows that should be aggregated and shown as a single bubble. The default coordinates of each bubble are the averaged $x$ and $y$ values, and the default size of each bubble is the sum of the sizes of all aggregated members. See “Specifying Two ID Variables” on page 154.

- **Time**  Maintains separate coordinates, sizes, and colors for each unique time period. The bubble plot shows these values for a single time period. For example, if the Time column contains years, the bubble plot is updated to show data by each year. See “Specifying a Time Variable” on page 154.

- **Freq**  Weights computations when aggregating bubbles using an ID variable.

  **Note:** Negative frequency values are ignored.

- **Sizes**  Controls the size of the bubbles. The area of the bubbles is proportional to the **Size** value. There is a minimum bubble size, to keep bubbles visible, even if the size value is
zero. If **Size** is left blank, the default bubble size is proportional to the number of rows in that combination of **Time** and **ID**.

**Coloring**  Colors the bubbles according to the selected variable. If the selected variable is categorical (nominal or ordinal), each category is assigned a unique color. If the selected variable is continuous, a gradient of colors is used. You can set a preference for a color theme by selecting File > Preferences > Graphs and making a selection in the Color Themes panel.

**By**  Place a column here to produce a separate bubble plot for each level of the variable.

After you click **OK**, the Bubble Plot report window appears.

### Specifying Two ID Variables

Specifying a second **ID** variable provides a hierarchy of categories, but the bubbles are not split by the second category until they are selected and split interactively. In the launch window, if you specify a second **ID** variable, **Split** and **Combine** buttons appear in the report window.

For example, you might specify a country as the first **ID** variable, resulting in a separate aggregated bubble for each country. A second **ID** variable, perhaps designating regions within each country, would further split each country when the interactive **Split** button under the graph is pressed.

### Specifying a Time Variable

Maintains separate coordinates, sizes, and colors for each unique time period. The bubble plot shows these values for a single time period. For example, if the **Time** column contains years, the bubble plot is updated to show data by each year.

To move the time label on the plot, click and drag the label.

If data is missing within a time period, the value is linearly interpolated. If data is missing for the first or last time period, the value is not estimated, but left as missing.

### Related Information

- “Control Animation for Dynamic Bubble Plots” on page 155
- “Example of Specifying Only a Time Variable” on page 161
Interact with the Bubble Plot

Note: If all of the rows used in constructing a bubble plot shape are hidden and not excluded, the corresponding bubble plot shape is not shown in the bubble plot. If rows are excluded in the data table, the bubble plot is constructed without the excluded rows.

Use the Bubble Plot platform in one of two modes:

- **Static mode**, where the bubbles are fixed and do not animate over time (no **Time** variable is specified). See “Example of a Static Bubble Plot” on page 165.
- **Dynamic mode**, where the bubbles are animated over time (a **Time** variable is specified). See “Example of a Dynamic Bubble Plot” on page 151.

You interact with both static and dynamic bubble plots in different ways.

**Control Animation for Dynamic Bubble Plots**

Use sliders and buttons to control the animation of dynamic bubble plots.

**Figure 5.5** Animation Controls

<table>
<thead>
<tr>
<th>Slider or Button</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>&lt;Time variable&gt;</code></td>
<td>Controls which time values appear in the bubble plot. You manually drag the slider to see a progression of time. Click and drag on the time variable in the bubble plot to move its position. Appears only if you specified a variable for <strong>Time</strong>.</td>
</tr>
<tr>
<td>Speed</td>
<td>Adjusts the speed of the animation.</td>
</tr>
<tr>
<td></td>
<td>Appears only if you specified a variable for <strong>Time</strong>.</td>
</tr>
<tr>
<td>Bubble Size</td>
<td>Adjusts the size of the bubbles. The bubbles maintain their relative size, but their absolute size can be adjusted.</td>
</tr>
<tr>
<td></td>
<td>Appears on all bubble plots.</td>
</tr>
</tbody>
</table>
Interact with the Bubble Plot

**Select Bubbles**

Click a bubble to select it. Note the following:

- Visually, selected bubbles become darker or brighter, and non-selected bubbles are more transparent.
- If the bubble was not filled initially, selection fills it.
- If no bubbles are selected, all of the bubbles are semi-transparent.

---

**Table 5.1 Descriptions of the Animation Controls (Continued)**

<table>
<thead>
<tr>
<th>Slider or Button</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;left&gt;</td>
<td>Adjusts the time value by one unit and shows the previous time value. &lt;right&gt; &lt;left&gt;Appears only if you specified a variable for Time. &lt;right&gt;</td>
</tr>
<tr>
<td>&lt;left&gt; &lt;right&gt;</td>
<td>Press Play to animate the bubble plot. Moves through all of the time values in order, and loops back to the beginning when the last time period is reached. Press Pause to stop the animation. &lt;left&gt;Appears only if you specified a variable for Time. &lt;right&gt;</td>
</tr>
<tr>
<td>&lt;left&gt;</td>
<td>Adjusts the time value by one unit and shows the next time value. &lt;left&gt;Appears only if you specified a variable for Time. &lt;right&gt;</td>
</tr>
<tr>
<td>&lt;left&gt;</td>
<td>Records the animation (Windows only). &lt;right&gt;</td>
</tr>
<tr>
<td>&lt;left&gt;</td>
<td>Saves the animation as an animated GIF file (Windows only). &lt;right&gt;</td>
</tr>
<tr>
<td><strong>Split</strong></td>
<td>Separates the bubble represented by the first, larger ID variable into its smaller constituent parts, which are defined by the second, smaller ID column. Select the bubble and click Split. &lt;left&gt;Appears only if you specified two ID variables. &lt;right&gt;</td>
</tr>
<tr>
<td><strong>Combine</strong></td>
<td>Reverses the action of the Split button by recombining the smaller bubbles back into their original bubble. Select any of the smaller bubbles in the group and click Combine. &lt;left&gt;Appears only if you specified two ID variables. &lt;right&gt;</td>
</tr>
</tbody>
</table>
When you select a bubble, all of the rows in the data table that correspond to the selected bubble are highlighted. Note the following:

- If the bubble is an aggregate based on an ID column, all of the rows for that ID are highlighted. Otherwise, the one row represented by that bubble is highlighted.
- If you specify an ID and a Time variable, selecting a bubble highlights all of the rows for that ID, across all of the Time levels.

If you select a row from the data table, it is selected in the associated bubble plot. Note the following:

- If you have not specified a Time variable, selecting one row from the data table highlights the corresponding bubble in the plot.
- If you have specified a Time variable, selecting one row from the data table highlights the corresponding bubble for only that time period in the dynamic bubble plot.

Use the Brush Tool

Use the brush tool to temporarily select bubbles and obtain more information about the selected bubbles. When you select bubbles with the brush tool, the corresponding rows are highlighted in the associated data table.

Note: For a more granular examination of the highlighted rows, use the Tables > Subset command or the Row Editor. See Using JMP.

Bubble Plot Platform Options

The Bubble Plot red triangle menu provides the following options:

Draw  Applies a fill or outline.
   - Filled  Fills all of the bubbles.
   - Outlined  Outlines all of the bubbles.
   - Filled and Outlined  Fills and outlines all of the bubbles.

Set Shape  Change the shape of the bubble.

You can create a custom shape using JSL. The Custom option opens the custom shape. If no custom shape has been created, the Custom option uses the default circle shape. For more information about creating custom shapes, see the Scripting Guide.
**Orient Shapes**  Orient the shapes as they move in particular directions over time, following the shape of the data.

This option appears only if you have specified a variable for **Time**.

**Trail Bubbles**  Shows the past history of bubbles as a semi-transparent trail. See “Example of Specifying Only a Time Variable” on page 161.

Note the following:
- This option appears only if you have specified a variable for **Time**.
- If you do not want to see the bubble labels, select the **Label > None** option.

**Trail Lines**  Shows the past history of bubbles as connected line segments. See “Example of Specifying Only a Time Variable” on page 161.

Note the following:
- This option appears only if you have specified a variable for **Time**.
- If you do not want to see the bubble labels, select the **Label > None** option.

**Label**  Changes the labels on the plot.

- **None**  Labels none of the bubbles in the plot.
- **All**  Labels all of the bubbles in the plot.
- **Selected**  Labels bubbles only when you select them.

**Note:** Click and drag on a label to move it.

**Color Theme**  Change the colors representing the high, middle, and low values of the color variable.

This option appears only if you have specified a variable for **Coloring**.

**Revert Color Theme**  Reverts back to the original color theme.

This option appears only if you have applied a color theme.

**Legend**  Shows a legend that describes the colors in the bubble plot.

This option appears only if you have specified a variable for **Coloring**.

**Selectable Across Gaps**  If a bubble is selected, this option keeps the bubble selected during time periods where data is missing. Otherwise, the bubble is not selected during time periods where data is missing.

**Show Roles**  Shows the variables that are used in the bubble plot. You can change and delete the variables. See “Show Roles” on page 160.
Split All  Splits all bubbles into their constituent parts. Unlike the Split button, the bubbles do not have to be selected.

This option appears only if you have specified two ID variables.

Combine All  Combines all constituent bubbles within a group into their larger bubble. Unlike the Combine button, the bubbles do not have to be selected.

This option appears only if you have specified two ID variables.

Show Time Annotation  In bubble plots that contain a time variable, the Show Time Annotation option shows or hides the time that is displayed on the bubble plot.

Lock Scales  Prevents axis scales and gradient legend scales from automatically adjusting in response to data or filtering changes.

Fit to Window  Determines whether the plot is resized as you resize the JMP window. The default setting is Auto, which bases the scaling on the contents of the plot. For example, a plot with By variables does not stretch to fit the resized window; the plot extends beyond the viewing area. Change the setting to On to always fit the plot inside the window. Change the setting to Off to prevent the plot from resizing.

Aggregation Options  Alters how the X, Y, and Sizes roles are computed. By default, the values are calculated using means for X and Y, and sums for Sizes.

X as Sum or Y as Sum  Computes the X and Y values using sums.

Size as Sum  Deselecting this option computes Size values using means.

Color as Sum  Computes the sum of the data values and maps to a color. This option appears only for continuous variables.

See Using JMP for more information about the following options:

Local Data Filter  Shows or hides the local data filter that enables you to filter the data used in a specific report.

Redo  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

Save Script  Contains options that enable you to save a script that reproduces the report to several destinations.

Save By-Group Script  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.
Show Roles

Using the **Show Roles** option in the red triangle menu, you can make changes to your existing variables without having to relaunch the platform and start your analysis over.

Follow the instructions in "Example of a Dynamic Bubble Plot" on page 151 to produce the report window shown in Figure 5.6. (The colors are the JMP default colors.)

**Figure 5.6** Example of Bubble Plot with Show Roles Selected

![Bubble Plot with Show Roles Selected](image)

**Change the Variable Assigned to a Role**

To change the variable assigned to a role, click a blue underlined role name. For example, perform these steps to change the **Coloring** variable in Figure 5.6:

1. Click the **Coloring** link.
   
   The Select column for Coloring window appears.

2. Click **Country**.

3. Click **OK**.

   Country now replaces **Region** as the **Coloring** variable in the bubble plot.
Remove a Variable

To remove an existing variable from the bubble plot, make sure that nothing is selected in the Select column for <Role> window, and click OK. For example, perform these steps to remove the Sizes variable (Pop) in Figure 5.6:

1. Click the Sizes link.
   The Select column for Sizes window appears.
2. Ensure that nothing is selected. If a variable is selected, deselect it by holding down the Ctrl key and clicking on the variable.
3. Click OK.
   The Sizes role now appears with an empty box.

**Note:** The X and Y variables can be changed only and cannot be removed.

Add a Variable

Once you have removed an existing variable from the bubble plot, there are two ways to add a new variable:

- Click the blue underlined role name. See “Change the Variable Assigned to a Role” on page 160.
- In the data table, click the variable in the column panel, and drag it into the empty role box.

Additional Examples of the Bubble Plot Platform

- “Example of Specifying Only a Time Variable”
- “Example of Specifying Only ID Variables and Splitting a Bubble”
- “Example of a Static Bubble Plot”
- “Example of a Bubble Plot with a Categorical Y Variable”

Example of Specifying Only a Time Variable

For dynamic bubble plots, you might specify only a Time variable and no ID variable. The resulting bubble plot contains a single moving bubble that tracks the series as the Time value changes.

1. Select Help > Sample Data Library and open PopAgeGroup.jmp.
2. Select **Graph > Bubble Plot**.
3. Select Portion60+ and click **Y**.
4. Select Portion 0-19 and click **X**.
5. Select Year and click **Time**.
6. Click **OK**.

**Figure 5.7** The Initial Report Window with a Time Variable

7. Click the bubble to select it.
   All rows in the data table are also highlighted.
8. Click the Bubble Plot red triangle and select **Trail Bubbles > All** and **Trail Lines > All**.
9. Click the play button.
   The bubble plot animates, showing a trail for the single bubble.
Example of Specifying Only ID Variables and Splitting a Bubble

For static bubble plots, you might specify one or two ID variables and no Time variable. The resulting bubble plot contains a bubble at each ID value. Note that although this bubble plot is static, you can perform splitting on bubbles.

1. Select Help > Sample Data Library and open PopAgeGroup.jmp.
2. Select Graph > Bubble Plot.
3. Select Portion60+ and click Y.
4. Select Portion 0-19 and click X.
5. Select Region and Country and click ID.
6. Select Region and click Coloring.
7. Click OK.

The initial report window appears. (Figure 5.9 uses the default JMP colors.)
Split the bubble representing the region of North America into countries.

8. Click the bubble representing North America (hover over a bubble to see its label, or use the legend to find the color of North America.)

9. Click **Split**.

You see that the North America bubble has split into three bubbles, representing the countries within the region of North America (the United States of America, Canada, and Mexico).
**Example of a Static Bubble Plot**

This example uses the `SATByYear.jmp` sample data table, which contains SAT verbal and math test scores for a selection of the US population in 2004.

1. Select **Help > Sample Data Library** and open `SATByYear.jmp`.
2. Select **Graph > Bubble Plot**.
3. Select SAT Verbal and click **Y**.
4. Select SAT Math and click **X**.
5. Select State and click **ID**.
6. Select % Taking (2004) and click **Sizes**.
7. Click **OK**.

The report window appears. (Figure 5.11 uses the default JMP colors.)
You draw the following conclusions:

- Higher verbal scores appear to be associated with higher math scores, since the two track very closely in the bubble plot. This signifies a correlation between verbal and math scores.

- The larger bubbles represent the US states that have a high percentage of individuals taking the SAT test in 2004. These larger bubbles are all grouped together in the lower left of the graph. This shows that when a state has a high percentage of individuals taking the test, both the math and verbal scores are low.

Instead of grouping the bubbles primarily by state, group the bubbles primarily by region:

1. Click the Bubble Plot red triangle and select **Show Roles**.
2. Click the **ID** link.
3. Select **Region** and click **OK**.
   Region is now the primary **ID** variable.
4. Click the **ID2** link.
5. Select **State** and click **OK**.
   State is now the secondary **ID** variable.
Figure 5.12  Example of Bubble Plot Grouped by Region and State

6. Click the bubble that represents the Southwest region (hover over a bubble or click it to see its label).

7. Click **Split**.
   
   Now the bubbles are split by the secondary **ID** variable, which is **State**. You now see each state within the Southwest region.
Figure 5.13  Example of Southwest Region Split by State

You see that there is significant variation between the scores from the Southwest states.

8. Click **Combine** to combine the southwest states again.

9. To do a comparison, click the New England bubble (hover over a bubble or click it to see its label).

10. Click **Split**.
Figure 5.14  Example of New England Region Split by State

You see that the New England states do not have as much variation as the Southwest states.

Example of a Bubble Plot with a Categorical Y Variable

All of the examples shown so far use continuous Y variables. If you use a categorical (nominal or ordinal) Y variable, the bubble plot appears differently.

This example uses the blsPriceData.jmp sample data table, which shows the price of commodities over several years. Because the value of the US dollar changes over time, a column named Price/Price2000 shows the ratio of a commodity’s price at any given time to the price in the year 2000.

1. Select Help > Sample Data Library and open blsPriceData.jmp.
2. Select Graph > Bubble Plot.
3. Select Series and click Y.
4. Select Price/Price2000 and click X.
5. Select date and click Time.
6. Click OK.

The report window appears. (Figure 5.15 uses the JMP default colors.)
This produces a bubble plot that, when animated by clicking the play button, shows the price bubbles moving side to side according to their price ratio.

**Figure 5.15** Static Example of Animated Bubbles

For easier readability, add grid lines:

7. Double-click the categorical axis.

8. In the Y Axis Settings window, select **Show Grid**.

9. Click **OK**.

To animate the bubble plot, click the play button. The price bubbles move side to side, according to their price ratio.
Using the Scatterplot Matrix platform, you can assess the relationships between multiple variables simultaneously. A scatterplot matrix is an ordered collection of bivariate graphs. For further analysis, you can customize the scatterplots with density ellipses for all of your data, or for only groups of your data.

**Figure 6.1** Example of a Scatterplot Matrix
Contents

Example of a Scatterplot Matrix ........................................................................... 173

  Change the Matrix Format .............................................................................. 176
The Scatterplot Matrix Window ......................................................................... 177
Scatterplot Matrix Platform Options .................................................................. 177
Example Using a Grouping Variable ................................................................... 179
  Create a Grouping Variable ............................................................................ 180
Example of a Scatterplot Matrix

This example shows you how to create a scatterplot matrix.

1. Select Help > Sample Data Library and open Students.jmp.
2. Select Graph > Scatterplot Matrix.
3. Select age, sex, height, and weight and click Y, Columns.
4. Click OK.

Figure 6.2 Example of a Scatterplot Matrix

In this example, you can see that the graph for weight versus height is different from the graph for sex versus age. If you turn off jitter by clicking on the red triangle menu and selecting Points Jittered, the difference becomes even more pronounced.
The weight versus height graph shows continuous data, and the sex versus age graph shows categorical data.

Launch the Scatterplot Matrix Platform

Launch the Scatterplot Matrix platform by selecting **Graph > Scatterplot Matrix**.

**Figure 6.4** The Scatterplot Matrix Launch Window

**Y, Columns, X** Specify columns for Y and X.

- If you assign variables to the **Y, Columns** role only, they appear on both the horizontal and vertical axes.
- If you assign variables to both the **Y, Columns** and **X** role, then the **Y, Columns** variables appear on the vertical axis. The **X** variables appear on the horizontal axis. This
approach enables you to produce rectangular matrices, or matrices that have different, yet overlapping, sets of variables forming the axes of the matrix.

**Group**  If you assign a variable to the **Group** role, you can add shaded density ellipses for each level of the **Group** variable. See “Example Using a Grouping Variable” on page 179.

**By**  This option produces a separate scatterplot matrix for each level of the **By** variable. If two **By** variables are assigned, a separate graph for each possible combination of the levels of both **By** variables is produced.

**Matrix Format**  The **Matrix Format** can be one of three arrangements: **Upper Triangular**, **Lower Triangular**, or **Square**. See “Change the Matrix Format” on page 176.

After you click **OK**, the Scatterplot Matrix window appears. See “The Scatterplot Matrix Window” on page 177.
Change the Matrix Format

The Matrix Format can be one of three arrangements: **Upper Triangular, Lower Triangular, or Square**.

**Figure 6.5** Examples of Matrix Formats

---

**Lower Triangular**

**Upper Triangular**

**Square**
The Scatterplot Matrix Window

The Scatterplot Matrix window shows an ordered grouping of bivariate graphs. In each graph, you can examine the relationships between each pair of variables.

Follow the instructions in “Example of a Scatterplot Matrix” on page 173 to produce the plot shown in Figure 6.6.

Note: For information about additional options, see “Scatterplot Matrix Platform Options” on page 177.

Figure 6.6  Example of a Scatterplot Matrix Window

Replace variables in the plot by dragging and dropping a variable, in one of two ways: swap existing variables by dragging and dropping a variable from one axis to the other axis; or, click a variable in the Columns panel of the associated data table and drag it onto an axis. This feature is not available for matrices in the Square format.

Scatterplot Matrix Platform Options

The Scatterplot Matrix red triangle menu provides the following options:

Show Points  Shows or hides the points in the scatterplots.

Points Jittered  Turns the jittering of the points in the scatterplot on or off. This option is available when at least one variable is either ordinal or nominal.
**Fit Line**  Fits a simple regression line and its mean confidence interval to the scatterplots.

**Density Ellipses**  Shows or hides the outline and area of the density ellipses. See “Example Using a Grouping Variable” on page 179.

**Shaded Ellipses**  Colors the area within each ellipse. See “Example Using a Grouping Variable” on page 179.

**Ellipses Coverage**  Enables you to select an $\alpha$-level for the ellipses to cover.

**Ellipses Transparency**  Enables you to select the transparency of the shaded ellipses, where 0 is completely transparent and 1 is completely opaque.

**Ellipses Color**  Enables you to select a color for the outline and the area within an ellipse.

**Nonpar Density**  Shows or hides the nonparametric density, which represents the areas where the data points are the most dense. The nonparametric density estimation is helpful when you have a lot of points and the density of the points is difficult to see.

There are two quantile density contours. One contour includes 50% of the smoothed density, and the other contour includes 90% of the smoothed density. Since the percentage is based on the smoothed density, the percentage may not agree with the actual proportion of points within a contour.

**Group By**  In the Group By window, you can perform the following actions:

- If you did not select a **Group** variable in the launch window, you can add one now.
- If you did select a **Group** variable in the launch window, you can remove the existing **Group** variable, or you can replace the **Group** variable.

See “Example Using a Grouping Variable” on page 179.

**Lock Scales**  Prevents axis scales and gradient legend scales from automatically adjusting in response to data or filtering changes.

See *Using JMP* for more information about the following options:

**Local Data Filter**  Shows or hides the local data filter that enables you to filter the data used in a specific report.

**Redo**  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

**Save Script**  Contains options that enable you to save a script that reproduces the report to several destinations.

**Save By-Group Script**  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.
Example Using a Grouping Variable

This example shows you how to create a scatterplot matrix using a grouping variable.

1. Select Help > Sample Data Library and open Iris.jmp.
2. Select Graph > Scatterplot Matrix.
4. Select Species and click Group.
5. Click OK.

**Figure 6.7** Initial Example Using a Grouping Variable

Make the groupings stand out by adding ellipses and shading:

6. Click the Scatterplot Matrix red triangle and select *Density Ellipses > Density Ellipses*.
7. Click the Scatterplot Matrix red triangle and select *Density Ellipses > Shaded Ellipses*.
Create a Grouping Variable

If your data does not already have a grouping variable, you can create one using the Cluster platform. Using the Iris.jmp data, assume that the Species column does not exist. You know that the data comes from three species of Iris flowers, so you want to create three clusters within a group.

1. Using the Iris.jmp sample data table, select **Analyze > Clustering > Hierarchical Cluster**.
2. Select Sepal length, Sepal width, Petal length, and Petal width and click **Y, Columns**.
3. Click **OK**.
4. Click the Hierarchical Clustering red triangle and select **Number of Clusters**.
5. Type 3 to represent the three different Iris species.
6. Click **OK**.
7. Click the Hierarchical Clustering red triangle and select **Save Clusters**.
8. Close the Hierarchical Cluster report window, and go back to the Iris.jmp data table.
   
   You can see that a Cluster column has been added to the Iris.jmp data table.
9. Perform the Scatterplot Matrix analysis. Follow the instructions in the section “Example Using a Grouping Variable” on page 179, but use Cluster as the grouping variable.
Figure 6.9  Example of a Scatterplot Matrix Using a Cluster Variable
Using parallel plots, you can visualize each cell in a data table. Parallel plots draw connected line segments that represent each row in a data table. Parallel plots were initially developed by Inselberg (1985) and later popularized by Wegman (1990).

Figure 7.1  Example of a Parallel Plot
Contents
Example of a Parallel Plot ................................................................. 185
Launch the Parallel Plot Platform .................................................... 187
The Parallel Plot .............................................................................. 188
  Interpreting Parallel Plots .............................................................. 188
Parallel Plot Platform Options ......................................................... 190
Additional Examples of the Parallel Plot Platform ......................... 191
  Examine Iris Measurements .......................................................... 191
  Examine Student Measurements ................................................... 192
Example of a Parallel Plot

This example uses the Dogs.jmp sample data table, which contains histamine level measurements for 16 dogs that were given two different drugs. The histamine levels were taken at zero, one, three, and five minutes. Examine the variation in the histamine levels for each drug.

1. Select **Help > Sample Data Library** and open Dogs.jmp.
   To see the differences by drug, color the parallel plot lines by drug:

2. Select **Rows > Color or Mark by Column**.

3. Select **drug**.
   If the selection shown in your Colors menu is **JMP Default**, morphine is assigned the color red and trimeth is assigned the color blue.

4. Click **OK**.

Create the parallel plot:

5. Select **Graph > Parallel Plot**.

6. Select **hist0**, **hist1**, **hist3**, and **hist5** and click **Y, Response**.

7. Click **OK**.
   The report window appears.

**Figure 7.2** Parallel Plot of Histamine Variables

Each connected line segment represents a single observation. Click a line segment to see which observation (or row) it corresponds to in the data table.

For further exploration, isolate the trimeth values:
8. Select **Rows > Data Filter**.

9. Select *drug* and click Add (+).

10. Select *trimeth*.

Only the *trimeth* values are highlighted in the parallel plot.

**Figure 7.3 Trimeth Values Highlighted**

You observe the following about the histamine levels for dogs given *trimeth*:

- For most of the dogs, the histamine levels had a sharp drop at one minute.
- For four of the dogs, the histamine levels remained high, or rose higher. You might investigate this finding further, to determine why the histamine levels were different for these dogs.
Launch the Parallel Plot Platform

Launch the Parallel Plot platform by selecting Graph > Parallel Plot.

Figure 7.4  The Parallel Plot Launch Window

Y, Response  Variables appear on the horizontal axis of the parallel plot. These values are plotted and connected in the parallel plot.

X, Grouping  Produces a separate parallel plot for each level of the variable.

By  Identifies a column that creates a report consisting of separate analyses for each level of the specified variable.

Scale Uniformly  Represents all variables on the same scale, adding a y-axis to the plot. Without this option, each variable is on a different scale.

To allow for proper comparisons, select this option if your variables are measured on the same scale.

Center at zero  Centers the parallel plot (not the variables) at zero.

After you click OK, the Parallel plot appears. See “The Parallel Plot” on page 188.
The Parallel Plot

To produce the plot shown in Figure 7.5, follow the instructions in “Example of a Parallel Plot” on page 185.

**Figure 7.5** The Parallel Plot Report

A parallel plot is one of the few types of coordinate plots that show any number of variables in one plot. However, the relationships between variables might be evident only in the following circumstances:

- when the variables are side by side
- if you assign a color to a level of a variable to track groups
- if you select lines to track groups

**Tip:** You can add reference lines for specification limits. For information, see *Using JMP.*

Interpreting Parallel Plots

To help you interpret parallel plots, compare the parallel plot with a scatterplot. In each of the following figures, the parallel plot appears on the left, and the scatterplot appears on the right.

**Strong Positive Correlation**

The following relationship shows a strong positive correlation. Notice the coherence of the lines in the parallel plot.
**Figure 7.6** Strong Positive Correlation

![Strong Positive Correlation](image)

**Strong Negative Correlation**

A strong negative correlation, by contrast, shows a narrow neck in the parallel plot.

**Figure 7.7** Strong Negative Correlation

![Strong Negative Correlation](image)

**Collinear Groups**

Now, consider a case that encompasses both situations: two groups, both strongly collinear. One has a positive slope, the other has a negative slope. In Figure 7.8, the positively sloped group is highlighted.

**Figure 7.8** Collinear Groups: Parallel Plot and Scatterplot

![Collinear Groups](image)
**Single Outlier**

Finally, consider the case of a single outlier. The parallel plot shows a general coherence among the lines, with a noticeable exception.

**Figure 7.9** Single Outlier: Parallel Plot and Scatterplot

![Single Outlier: Parallel Plot and Scatterplot](image)

**Related Information**
- “Additional Examples of the Parallel Plot Platform” on page 191

---

**Parallel Plot Platform Options**

The Parallel Plot red triangle menu provides the following options:

- **Show Reversing Checkboxes** Reverses the scale for one or more variables.

See *Using JMP* for more information about the following options:

- **Local Data Filter** Shows or hides the local data filter that enables you to filter the data used in a specific report.

- **Redo** Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

- **Save Script** Contains options that enable you to save a script that reproduces the report to several destinations.

- **Save By-Group Script** Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.

For more information about the context menu options that appear when you right-click a parallel plot, see *Using JMP*. 
Additional Examples of the Parallel Plot Platform

- “Examine Iris Measurements”
- “Examine Student Measurements”

Examine Iris Measurements

The following example uses the Fisher’s Iris data set (Mardia, Kent, and Bibby 1979). The Iris.jmp sample data table contains measurements of the sepal length and width and petal length and width in centimeters for three species of Iris flowers: setosa, versicolor, and virginica. To find characteristics that differentiate the three species, examine these measurements.

Examine Three Species in One Parallel Plot

1. Select Help > Sample Data Library and open Iris.jmp.
2. Select Graph > Parallel Plot.
4. Select the Scale Uniformly check box.
5. Click OK.

The report window appears.

Figure 7.10 Three Species in One Parallel Plot

In this parallel plot, the three species are all represented in the same plot. The colors correspond to the three species:

- Blue corresponds to virginica.
- Green corresponds to versicolor.
- Red corresponds to setosa.
From the parallel plot, you observe the following:

- For sepal width, the setosa values appear to be higher than the virginica and versicolor values.
- For petal width, the setosa values appear to be lower than the virginica and versicolor values.

Examine Three Species in Different Parallel Plots

1. From the iris.jmp sample data table, select Graph > Parallel Plot.
2. Select Sepal length, Sepal width, Petal length, and Petal width and click Y, Response.
3. Select Species and click X, Grouping.
4. Click OK.

The report window appears.

Figure 7.11  Three Species in Different Parallel Plots

Each species is represented in a separate parallel plot.

Examine Student Measurements

The following example uses the Big Class.jmp sample data table, which contains data on age, sex, height, and weight for 40 students. Examine the relationships between different variables.

1. Select Help > Sample Data Library and open Big Class.jmp.
2. Select Graph > Parallel Plot.
4. Select age and click X, Grouping.
5. Select sex and click By.
6. Select the Scale Uniformly check box.
7. Click OK.
Figure 7.12 Height and Weight by Sex, Grouped by Age

You observe the following:

- Among the 13-year-old females, one female’s weight is lower than the other females in her age group. If you click the line representing the lower weight, the respective individual (Susan) is highlighted in the data table.

- Among the 14-year-old females, one female’s weight is higher than the other females in her age group. If you click the line representing the higher weight, the respective individual (Leslie) is highlighted in the data table.
Using cell plots, you can visualize each cell in a data table. Cell plots are direct representations of a data table, since they draw a rectangular array of cells where each cell corresponds to a data table entry. Cell plots were popularized by genomics applications to browse large numbers of values for gene expression levels.

Figure 8.1 Example of a Cell Plot
Contents

Example of a Cell Plot................................................................. 197

Additional Example of the Cell Plot Platform............................... 201
Example of a Cell Plot

Learn how to create and analyze a cell plot in JMP. This example uses the Dogs.jmp sample data table, which contains histamine level measurements for 16 dogs that were given two different drugs. The histamine levels were taken at zero, one, three, and five minutes. Examine the variation in the histamine levels for each drug.

1. Select Help > Sample Data Library and open Dogs.jmp.
2. Select the third row from the bottom (row 14).
3. Select Graph > Cell Plot.
4. Select drug, hist0, hist1, hist3, and hist5 and click Y, Response.
5. Click OK.

The report window appears.

Figure 8.2 Dogs.jmp cell plot

Notice the following:

- There are two types of drugs, represented by two distinct colors.
- Histamine levels are assigned colors from a gradient of blue to red.
- Any missing values are delineated by an X.
- The third row from the bottom is selected, and black lines appear next to the cells.
Launch the Cell Plot Platform

Launch the Cell Plot platform by selecting Graph > Cell Plot.

**Figure 8.3 The Cell Plot Launch Window**

- **Y, Response** Variables appear on the horizontal axis of the cell plot. Each cell represents a value.
- **X, Grouping** Produces a separate cell plot for each level of the variable.
- **Label** Labels each row by the specified variable. See “Additional Example of the Cell Plot Platform” on page 201.
- **By** Identifies a column that creates a report consisting of separate analyses for each level of the variable.
- **Scale Uniformly** Represents all variables on the same scale. Without this option, each variable is on a different scale.
- **Center at zero** Centers the cell plot at zero.

After you click **OK**, the Cell Plot window appears. See “The Cell Plot” on page 198.

**The Cell Plot**

The cell plot appears with a one-to-one correspondence of a colored cell representing each data table entry. Colors are assigned to each cell based on the range and type of values found in the column.

**Note:** Any rows that are excluded in the data table are also hidden in the cell plot.
Note: To produce the plot shown in Figure 8.4, follow the instructions in “Example of a Cell Plot” on page 197.

Note the following information about cell plots:

- Nominal variables use a distinct color for each level. You can customize nominal and ordinal colors using the **Value Colors** property of data columns, available through the **Column Info** command.
- Continuous variables are assigned a gradient of colors to show the smooth range of values in the variable.
- Ordinal variables are scaled like continuous variables in order.
- When some outliers are present, the scale uses all but the extreme categories for the 90% middle of the distribution, so that the outliers do not overly influence the scale.

- “Additional Example of the Cell Plot Platform” on page 201

---

**Cell Plot Platform Options**

The Cell Plot red triangle menu provides the following options:

- **Legend**  Shows or hides a legend.
- **Arrange Plots**  Specifies how many plots to put on the same row before starting the next row of plots.
  
  This option is available only if you specify an **X, Grouping** variable.

See *Using JMP* for more information about the following options:
**Local Data Filter**  Shows or hides the local data filter that enables you to filter the data used in a specific report.

**Redo**  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

**Save Script**  Contains options that enable you to save a script that reproduces the report to several destinations.

**Save By-Group Script**  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.

### Right-Click Menu for Cell Plots

Right-click the cell plot to find the following options:

**Graph Type**  Determines the appearance of the graph. See “Change the Graph Type” on page 201.

**Color Theme**  Shows a list of color themes that affect continuous variables in color maps. The default color theme is **Blue to Gray to Red** (corresponding to small values to middle values to large values). Use **White to Black** to create a gray-scale plot.

**Note:** To see custom colors, you must first create them. Select **File > Preferences > Graphs.** In the Color Themes area, click the type of color theme that you want to create, click **New,** and then change the colors. See *Using JMP* for more information about creating custom color themes.

**Sort Ascending**  Sorts the rows of the plot from lowest to highest by the values of a column. To sort, right-click in the plot under a column and select **Sort Ascending.** The entire plot is rearranged to accommodate the sorting. See “Additional Example of the Cell Plot Platform” on page 201.

**Sort Descending**  Sorts the rows of the plot from highest to lowest by the values of a column. To sort, right-click in the plot under a column and select **Sort Descending.** The entire plot is rearranged to accommodate the sorting.

**No Separator Lines**  Draws or removes lines separating the columns.

**Note:** For more information about the pop-up options that appear when you right-click labels, see *Using JMP.*
Chapter 8
Essential Graphing

Cell Plots

Additional Example of the Cell Plot Platform
Change the Graph Type

Use the Graph Type option to change the appearance of the cell plot.

Figure 8.5 Graph Types

Additional Example of the Cell Plot Platform

This example uses the SAT jmp sample data table, which contains SAT test scores (divided into verbal and mathematics portions) for all 50 United States.

1. Select Help > Sample Data Library and open SAT jmp.
2. Select Graph > Cell Plot.
3. Select all of the Verbal scores for all of the years, and click Y, Response.
4. Select all of the Math scores for all of the years, and click Y, Response.
5. Select State and click Label.
6. Click OK.
   The report window appears.
7. Right-click the plot under 2004 Verbal (the top left cell) and select Sort Ascending.
   This sorts the cell plot by the verbal scores for 2004.
Figure 8.6  Cell Plot for SAT Scores

You notice the following:

- Hawaii has the lowest verbal scores for 2004, and South Dakota has the highest verbal scores for 2004.
- There is a contrast between Hawaii’s math and verbal scores. Hawaii has average math scores (represented by gray color values) but low verbal scores (represented by blue color values). Hawaii appears to be an outlier, since it has a strikingly different pattern for its math scores and its verbal scores.
- There is very little contrast between North Dakota’s math and verbal scores. North Dakota’s math and verbal scores are generally high (represented by red color values).

For a description of color themes, see “Right-Click Menu for Cell Plots” on page 200.
The Scatterplot 3D platform shows the values of numeric columns in the associated data table in a rotatable, three-dimensional view. Up to three columns that you select from the associated data table are displayed at one time.

To help visualize variation in higher dimensions, the 3D scatterplot can show a biplot representation of the points and variables when you request principal components. The most prominent directions of data are displayed on the 3D scatterplot report.

**Figure 9.1** Example of a 3D Scatterplot
Contents

Example of a 3D Scatterplot ................................................................. 205

  Example of a Grouped Nonparametric Density Contour ...................... 221
Example of a 3D Scatterplot

This example uses the Iris.jmp sample data table, which includes measurements of sepal length, sepal width, petal length, and petal width for three species of iris.

1. Open the Iris.jmp sample data table.
2. Select Graph > Scatterplot 3D.
4. Select Petal width and click Weight.
5. Click OK.

Figure 9.2 Example of an Initial 3D Scatterplot

Now you can spin the 3D scatterplot to see the relationships between the variables. In this example, the data points are formatted in blue, red, and green. You might want to spin the scatterplot to see more clearly the relationships between the red and green points.
Launch the Scatterplot 3D Platform

Launch the Scatterplot 3D platform by selecting Graph > Scatterplot 3D.

**Figure 9.3** The Scatterplot 3D Launch Window

**Y, Columns** Select the variables to plot on the 3D scatterplot. The order in which you select the variables determines where the data points appear on the axes:

- The first variable appears on the x axis.
- The second variable appears on the y axis.
- The third variable appears on the z axis.

You can assign the remaining variables interactively through the drop-down menus below the scatterplot.

**Weight** Use the Weight variable to:

- Assign a weight (importance or influence) to the data
- Visualize a fourth variable that sizes the points

**Note:** Red triangle options account for the Weight variable. If you do not want this variable accounted for in your analyses, remove it from the launch window.

When you specify a Weight variable, JMP draws the points as balls. The balls are scaled so that their volume represents the weight value. You click and drag the Circle Size slider below the scatterplot to resize the balls.

**Freq** Identifies the data table column whose variables assign a frequency to each row. This option is useful when a frequency is assigned to each row in summarized data.

**Coloring** Colors the points according to the selected variable. If the selected variable is categorical (nominal or ordinal), each category is colored distinctly. If the selected variable is continuous, a gradient of colors is used.
**By**  Produces a separate 3D scatterplot for each By variable value. When two By variables are assigned, a separate graph is produced for each combination of both By variables.

After you click **OK**, the Scatterplot 3D report window appears. See “The Scatterplot 3D Report” on page 207.

---

### The Scatterplot 3D Report

To produce the 3D scatterplot shown in Figure 9.4, follow the instructions in “Example of a 3D Scatterplot” on page 205.

The Scatterplot 3D report shows a three-dimensional spinnable view of your data. See Figure 9.4. In the launch window, you select the variables and then create the report. The variables are displayed on the 3D scatterplots’ x, y, and z axes. Up to three variables can be displayed at a time.

**Note:** The Crosshairs tool is not supported in 3D scatterplots.
Figure 9.4  Example of Information Displayed on the Scatterplot 3D Report

Note: Any rows that are excluded in the data table are also hidden in the 3D scatterplot.

Plot source  The plot source box indicates the source of the data in the plot.

Circle Size slider  Click and drag the Circle Size slider to resize the balls while maintaining their relative sizes.

Note: The Circle Size slider appears only if you have specified a Weight variable.

Axis controls  Select which variable appears on each axis. Choose the Other option to add a new variable.

Next Axis Set  Cycles through the axis controls for any hidden variables. See “Change Variables on the Axes” on page 210.
Note: The Next Axis Set button appears only if your analysis contains more than three variables.

After you create a 3D scatterplot, you can add features such as displaying ellipses around specific data points, showing separate principal components, rotating components, connecting points, and more. See “Scatterplot 3D Platform Options” on page 211.

You can also assign colors and symbols (or markers) to data points either on the 3D scatterplot itself or in the associated data table. See “Assign Colors and Markers to Data Points” on page 211 and “Assign Colors and Markers in the Data Table” on page 211.

Spin the 3D Scatterplot

You spin the 3D scatterplot report in four ways:

- Click and drag an empty area on the 3D scatterplot. The 3D scatterplot spins in the direction you dragged the mouse.

  Note: Click and drag on an empty area on the 3D scatterplot, not on an axis or data point. Dragging the axis rescales the axis. Dragging a data point selects only the point.

- Slide the mouse wheel. The 3D scatterplot spins up and down only.
- Hold down an arrow key. (Before using an arrow on the number keypad, verify that Num Lock is turned off.)
- Hold down the Esc key. The 3D scatterplot spins left and right only.

In each case, the 3D scatterplot spins as long as you hold down the mouse button, arrow key, or Esc key. The spinning also continues as you slide the mouse wheel.

You can also spin the 3D scatterplot continuously in any of these ways:

- Click and drag: Hold down the Shift key, click and drag an empty area on the plot, and release Shift. The faster you drag the mouse, the faster the 3D scatterplot spins.
- Mouse wheel: Hold down the Shift key, slide the wheel, and release the wheel. The 3D scatterplot spins up and down only.
- Arrow keys: Hold down the Shift key and press the arrow key, and then release Shift.
- Esc key: Press Shift+Esc. The 3D scatterplot spins left and right only.

In addition to automatically spinning the plot, you can oscillate the plot. Press Shift+Ctrl and then click and drag the plot. The plot shakes up and down or left to right, depending on the direction in which you dragged the plot.

To stop the spinning or oscillating, click the plot or press the Esc key.
Change Variables on the Axes

The variables on each axis are determined by the order in which you select the variables in the launch window. For example, the first variable that you select is displayed on the \( x \) axis. The second variable is displayed on the \( y \) axis, and the third variable is displayed on the \( z \) axis.

After you create a 3D scatterplot, you can change the variable assigned to an axis, plot a different set of variables, or sequence through all combinations of the variables.

1. To change the variable on a specific axis, select the axis control drop-down menu and select a different variable.
2. To add a different variable, click an axis control drop-down menu, select Other, select the variable, and then click OK.
3. To sequence through combinations of all variables, click the Next Axis Set button until the variables that you want to plot are displayed.

Adjust the Axes

You can manually move or rescale the axis coordinates by clicking and dragging the axis. This option shows a different set of coordinates on the 3D scatterplot. It also lets you change the space displayed between the coordinates (or the coordinate scaling).

You can also specify axis properties by double-clicking the axis and modifying settings in the specifications window.

To Move the Coordinates on the Axis

1. Hover over the middle of the axis.
2. Click and drag the axis.

To Modify Coordinate Scaling

1. Hover over the end of the axis.
2. Click and drag the axis.

To Rescale an Axis Precisely

1. Hover over the middle of the axis (the axis, not the label).
2. Double-click the axis.
3. Change the minimum and maximum coordinate values.

For more information about updating axes, see Using JMP.
Assign Colors and Markers to Data Points

Each point in the 3D scatterplot corresponds to a row in the associated data table. To highlight points on the 3D scatterplot, you assign colors and markers to the points. The colors and markers are then displayed on the 3D scatterplot and in the data table.

When you click a point, the following items are selected:

- the point in the 3D scatterplot
- the corresponding row in the associated data table
- the point in any other opened graphs, if applicable

To select one point, click the point.

To select several points, double-click the 3D scatterplot and drag the cursor over the points. A box is displayed to indicate which points are selected.

To deselect points, double-click the 3D scatterplot.

Assign a color or marker to selected data points:

1. To assign a color to the selected point, select Rows > Colors and then select the color.
2. To assign a marker to the selected point, select Rows > Markers and then select the marker.

Assign Colors and Markers in the Data Table

You can assign colors and markers to rows in the data table. The colors and markers appear next to the row number in the data table and on the 3D scatterplot. This option distinguishes points for each variable, and you can save the settings in the data table. Assigning colors and markers to specific data points (as described in “Assign Colors and Markers to Data Points” on page 211) only highlights them for the current open graphs.

See Using JMP for more information about assigning colors and markers in the data table. For more information about changing the size, quality, or transparency of markers, see “Scatterplot 3D Settings” on page 217.

Scatterplot 3D Platform Options

The red triangle menu next to Scatterplot 3D contains options to customize the display and to compute, rotate, and save principal or rotated components.

Show Points  Shows or hides the data points on the graph.

Show Controls  Shows or hides the source and axis controls displayed beneath the 3D scatterplot (Figure 9.4).
Drop Lines  Draws lines from each point to the plane created by the $x$ and $z$ variables that you selected on the launch window.

Connect Points  Connects the points with a line. Points can be connected on the data as a whole or in groups. You can also group data by a specific variable.

Jitter  Displays small spaces between the data points so that you can see each point more clearly.

Normal Contour Ellipsoids  Draws one or more normal contour ellipsoids, that is, three-dimensional ellipses that encompass a specified portion of points. You specify whether you want an ellipsoid for all of the data or for each group. You can also control the size and transparency of the ellipsoids. See “Normal Contour Ellipsoids” on page 214.

Ellipsoid Coverage  Changes the size of normal contour ellipsoids. Type a value between 0 and 1, where the greater the value creates a bigger the ellipsoid. The actual values “0” and “1” produce no ellipsoid, so a warning appears if you try to use those values.

This option only appears after you add a normal contour ellipsoid to the 3D scatterplot.

Ellipsoid Transparency  Changes the surface of normal contour ellipsoids. The greater the value, the more opaque the ellipsoid. This option only appears after you add a normal contour ellipsoid to the 3D scatterplot.

Nonpar Density Contour  Draws nonparametric density contours, which approximately encompass a specified proportion of the points. You specify whether you want a density contour for all of the data or for each group. See “Nonparametric Density Contours” on page 214.

Drop Line Thickness  Changes the width of drop lines. This option only appears after you add drop lines to the 3D scatterplot.

Principal Components  Calculates principal components on all variables. This changes the axes of the plot to have principal component scores.

Biplot rays are displayed by default. You can remove them by selecting Biplot Rays from the red triangle menu. For more information about principal components, see Multivariate Methods.

Std Prin Components  Calculates principal components (as with the Principal Components option) but scales the principal component scores to have unit variance. If this option is not selected, the scores have variance equal to the corresponding eigenvalue.

With standardized principal components, the correlation between the variables and the principal component scores is equal to the values in the eigenvector. This helps you quickly assess the relative importance of the variables. See Multivariate Methods.

Select this option if you want GH' rather than JK' biplots. GH' biplots try to preserve relationships between variables; JK' biplots try to preserve relationships between
observations. The interpoint distance shown by GH’ biplots is less meaningful, but the angles of the GH’ biplot rays measure correlations better.

**Rotated Components**  Specifies the number of factors that you want to rotate and the rotation method. You rotate components to better align the directions of the factors with the original variables so that the factors might be more interpretable. See *Multivariate Methods*.

**Biplot Rays**  Shows or hides biplot rays that correspond to the principal components. You must have already selected Principal Components, Std Prin Components, or Rotated Components for this option to appear.

**Show Ray Labels**  Shows or hides labels for the biplot rays. You must have already selected Biplot Rays for this option to appear.

**Remove Prin Comp**  Removes principal components, standardized principal components, and rotated components from the scatterplot 3D report. The 3D scatterplot reverts to its original display before principal components were selected. This option, however, does not remove any saved principal components from the data table.

This option only appears after you add principal, standard, or rotated components to the 3D scatterplot.

**Save Prin Components**  Saves the specified number of current principal component scores as new columns in the current data table. These columns also include the formulas used for the principal components. For *n* variables in the components list, *n* principal component columns are created and named Prin1, Prin2, ... Prinn.

This option only appears after you add principal, standard, or rotated components to the 3D scatterplot.

**Save Rotated Components**  Saves all rotated component scores as columns in the current data table. These columns also include the formulas that were used. If you requested *n* rotated components, then *n* rotated component columns are created and named Rot1, Rot2, ... Rotn.

This option only appears after you add rotated components to the 3D scatterplot.

See *Using JMP* for more information about the following options:

**Local Data Filter**  Shows or hides the local data filter that enables you to filter the data used in a specific report.

**Redo**  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

**Save Script**  Contains options that enable you to save a script that reproduces the report to several destinations.
Save By-Group Script  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.

Normal Contour Ellipsoids

A normal contour ellipsoid is a 3-dimensional ellipse that encompasses a specified portion of points. The ellipsoid is computed from a contour of the multivariate normal distribution fit to the points. The ellipsoid is a function of the means, standard deviations, and correlations of variables on the plot. See Multivariate Methods for more information about multivariate normal distributions.

When you add an ellipsoid, two formatting options are available:

- **Coverage** changes the portion of data points covered by the ellipsoid. The larger the value, the bigger the ellipsoid.
- **Transparency** changes the surface of the ellipsoid from transparent to opaque. The larger the value, the more opaque the ellipsoid.

The coverage and transparency options also appear in the red triangle menu after you add the ellipsoid.

When you add normal contour ellipsoids to a 3D scatterplot, you specify whether you want an ellipsoid for all of the data or for a specific group of data. The ellipsoid for each set of grouped data is color-coded to differentiate one group from another.

You display and remove normal contour ellipsoids by selecting and deselecting Normal Contour Ellipsoids from the red triangle menu.

Related Information

- “Example of an Ungrouped Normal Contour Ellipsoid” on page 219
- “Example of Grouped Normal Contour Ellipsoids” on page 220

Nonparametric Density Contours

The nonparametric density contour shows contours that approximately encompass a specified proportion of the points. You add nonparametric density contours to see patterns in point density when the scatterplot is darkened by thousands of points.

This feature is particularly valuable when you have many points on a 3D scatterplot; the contours can be so dark that you cannot see the structure. In this situation, you remove the points so that only the contours are displayed. See “Optimizing a Dense Nonparametric Density Contour” on page 216.
When you add nonparametric density contours to a 3D scatterplot, you specify whether you want a contour for all of the data or for a specific group of data. The contour for each set of grouped data is color-coded to differentiate one group from another.

You display and remove nonparametric density contours by selecting and deselecting Nonpar Density Contours from the red triangle menu.

**Related Information**

- “Example of a Grouped Nonparametric Density Contour” on page 221

**Density Contour Controls**

The Density Contour Controls options are displayed below the 3D scatterplot. These options let you select additional contours and change each contour’s formatting.

**Figure 9.5 The Density Contour Controls Window**

![Density Contour Controls Window]

**Contour Quantile** Controls which contours are shown and lets you customize the contour formatting.

- *Density level* represents the volume and density of the points. As the contours go from smaller to larger values, the contours cover less volume but more dense areas. A 0.9 contour represents the 10% densest part of the total, where the points are closest together. Click and drag the slider below “Contour Quantile,” or enter a value next to the slider.

- *Transparency* changes the surface of density contours. The greater the value, the more opaque the contour. Enter a value in the box.

- *Color* changes the color of the contour. Click the colored box and select a different color. (This option only appears for ungrouped density contours.)

Changes to these settings take effect immediately.
Resolution  Changes the resolution of the contours. A higher resolution results in a less granular drawing of the contours but takes more time to display.

Column Bandwidth  Changes the smoothness of the fitted density. A higher bandwidth results in a smoother fitted density.

Type a new bandwidth for each variable, or click and drag the sliders. Click Apply to display your changes.

Optimizing a Dense Nonparametric Density Contour

When you have many points on a 3D scatterplot, the contours can be so dark that you cannot see the structure. In this situation, you remove the points so that only the contours are displayed.

To remove points from a 3D scatterplot, select Show Points from the red triangle menu. You can further optimize the contours by changing their size, color, and transparency. See “Scatterplot 3D Platform Options” on page 211.

**Figure 9.6** Example of Optimizing a Dense Nonparametric Density Contour

![3D scatterplot with density contour and points](image1)

![3D scatterplot with density contour and no points](image2)

Pop-Up Menu

Right-click the 3D scatterplot to find the following options.

Show Legend  Shows and hides the color legend for the 3D scatterplot.

**Note:** This option requires the Coloring role.

Reset  Returns the orientation of the scatterplot to its original state.
Settings  Provides options to change the appearance of the 3D scatterplot. See “Scatterplot 3D Settings” on page 217.

Hide Lights Border  Shows and hides a border that displays the lights. The lights highlight different portions of the 3D scatterplot.

Right-click a light to turn it on or off and to change the color.

Wall Color  Changes the color of the 3D scatterplot.

Background Color  Changes the color surrounding the 3D scatterplot.

Rows  You can color, mark, exclude, hide, and label points that correspond to rows in the associated data table. You must select the points before selecting this option. See Using JMP.

Use Hardware Acceleration  Turns hardware acceleration on or off for machines that support acceleration. This option might display the scatterplot faster. If not, try updating your graphics drivers.

Show ArcBall  Shows and hides a globe around the 3D scatterplot. This option helps you visualize the rotation of the scatterplot. Select whether you want the ArcBall to appear always, only when you drag the scatterplot, or never.

Scatterplot 3D Settings

To customize properties such as the marker size, text size, and grid lines, right-click the 3D scatterplot and select Settings. The Settings window appears. As you modify the settings, a preview appears on the 3D scatterplot.

Figure 9.7  The Scatterplot 3D Settings Window
Note the following:

- Move the sliders left to decrease the selected property or to the right to increase the selected property.
- To move the Settings window around the scatterplot, click and drag the top portion of the window.

The following options are available:

**Reset**  
Resets the default settings.

**Done**  
Closes the window.

**Walls**  
Adds or removes the 3D scatterplot walls. Without walls, the background color of the 3D scatterplot is displayed.

**Grids**  
Shows or hides the coordinate lines.

**Axes**  
Shows or hides the variable names that appear above each axis.

**Box**  
Shows or hides the box. Without the box, the 3D scatterplot is displayed as an open plot.

**Zoom**  
Enlarges or shrinks the 3D scatterplot.

**Orthographic**  
Changes the view of the scatterplot from 3-dimensional to an orthographic projection. In the orthographic view, the walls of the scatterplot do not converge to a vanishing point. This means that you can compare near and far distances and see the structure between data points.

**Note:** If you turn off orthographic view and completely decrease the perspective, the walls of the scatterplot do not converge. This is the same effect that you get when you turn on orthographic view.

**Perspective**  
Increases or decreases the perspective. Large values create a view that is unnaturally large and visually disorienting. In this case, you need to resize the scatterplot window to show the entire plot.

**Marker Size**  
Increases or decreases the size of the data point markers.

**Marker Quality**  
Increases and decreases the data marker quality. For example, when you increase the marker quality, some markers have an opaque center. Other symbol markers are formatted in bold. Increase the zoom to see these changes in quality.

**Marker Transparency**  
Increases or decreases the transparency of the data markers.

**Text Size**  
Increases or decreases the text size.

**Line Width**  
Changes the width of the coordinate and axes lines.
Additional Examples of the Scatterplot 3D Platform

- “Example of an Ungrouped Normal Contour Ellipsoid”
- “Example of Grouped Normal Contour Ellipsoids”
- “Example of a Grouped Nonparametric Density Contour”

Example of an Ungrouped Normal Contour Ellipsoid

This example shows how to add a normal contour ellipsoid to more than 75% of the data points. The ellipsoid is 25% transparent.

1. Select Help > Sample Data Library and open Iris.jmp.
2. Select Graph > Scatterplot 3D.
4. Click OK.
5. Click the Scatterplot 3D red triangle and select Normal Contour Ellipsoids. Notice that Ungrouped is already selected.
6. Type 0.75 next to Coverage.
7. Type 0.25 next to Transparency.
8. Click OK.
Figure 9.8  Example of an Ungrouped Normal Contour Ellipsoid

Example of Grouped Normal Contour Ellipsoids

This example shows how to group measurements by species and to format each group with a normal contour ellipsoid. The ellipsoids cover 75% of the data points and are 50% transparent. The contours are color-coded (using JMP default colors) based on species.

1. Select Help > Sample Data Library and open Iris.jmp.
2. Select Graph > Scatterplot 3D.
4. Click OK.
5. Click the Scatterplot 3D red triangle and select Normal Contour Ellipsoids.
7. Select Species.
8. Type 0.75 next to Coverage.
9. Type 0.5 next to Transparency.
10. Click OK.
Example of a Grouped Nonparametric Density Contour

This example shows how to group data points and format each nonparametric density contour.

1. Select Help > Sample Data Library and open Iris.jmp.
2. Select Graph > Scatterplot 3D.
4. Click OK.
5. Click the Scatterplot 3D red triangle and select Nonpar Density Contour.
7. Select Species and click OK. A different colored contour is displayed for each of the three species.
8. Type 0.25 in the first Contour Quantile box. 25% of the data points appear outside the contour surfaces, which results in smaller contours.
9. Type 0.15 in the first Transparency box. The contours are 15% opaque.
Figure 9.10 Changing the Nonparametric Density Contour Transparency and Density

10. Select the second check box. The contour quantiles are the same (.25), so the new contours overlap the first ones.

11. Type 0.5 in the second Contour Quantile box. 50% of the data points appear outside the contour surfaces. A second set of contours appears within the first, to further illustrate the density of the data points.

Figure 9.11 Adding a Second Nonparametric Density Contour

You can now format the second levels of contours and turn on the third level of contours.
The options for formatting the grouped and ungrouped nonparametric density contours are similar. The only difference is that you cannot change the color of each *grouped* nonparametric density contour. See “Scatterplot 3D Platform Options” on page 211 for options.
Chapter 10

Contour Plots

View Multidimensional Relationships in Two Dimensions

The Contour Plot command in the Graph menu constructs contours of a response in a rectangular coordinate system. A contour plot shows a three-dimensional surface in two dimensions. Contours delineate changes in the third dimension.

Here are some of the options available with the Contour platform:

- specify the number of contour levels
- choose to plot contour lines or filled contours
- show or hide data points
- label contours with response values
- define and use a custom coloring scheme

Figure 10.1 Examples of Contour Plots

Example of a Contour Plot

To create a contour plot, you can use either the Contour platform or Graph Builder. This section provides examples for both.

- To see the example using the Contour platform, see “Example Using the Contour Platform” on page 227.
- To see the example using Graph Builder, see “Example of a Contour Plot in Graph Builder” on page 228.

Example Using the Contour Platform

To create a contour plot, you need two variables for the \(x\)- and \(y\)-axes and at least one more variable for contours. You can also use several \(y\)-variables. This example uses the Little Pond.jmp sample data table. \(X\) and \(Y\) are coordinates of a pond. \(Z\) is the depth.

1. Select Help > Sample Data Library and open Little Pond.jmp.
2. Select Graph > Contour Plot.
3. Select the \(X\) and \(Y\) coordinates and click \(X\).
4. Select the depth, \(Z\), and click \(Y\).

**Note:** In a contour plot, the \(X1\) and \(X2\) roles are used for the \(X\) and \(Y\) axes.

5. Click **OK**.
Figure 10.2 Example of a Contour Plot with Legend

The \(x\)- and \(y\)-axes are coordinates and the contour lines are defined by the depth variable. This contour plot is essentially a map of a pond showing depth. To see the contours more clearly, click the red triangle next to Contour Plot for \(Z\) and select **Fill Areas**.

**Example of a Contour Plot in Graph Builder**

You can create the same contour plot shown in Figure 10.2 using Graph Builder.

1. Select **Help > Sample Data Library** and open Little Pond.jmp.
2. Select **Graph > Graph Builder**.
3. Click and drag the \(X\) coordinate to the \(X\) zone.
4. Click and drag the \(Y\) coordinate to the \(Y\) zone.
5. Click and drag depth, \(Z\), to the **Color** zone.
6. Click the Contour icon.
Launch the Contour Plot Platform

Launch the Contour Plot platform by selecting Graph > Contour Plot.

By default, the contour levels used in the plot are values computed from the data. You can specify your own number of levels and level increments in the Launch window before you create the plot. You can also do so in the red triangle menu for Contour Plot after you create the plot. You can use a column formula to compute the contour variable values.
Figure 10.4  The Contour Plot Launch Window

**Y**  Columns assigned to the Y role are used as variables to determine the contours of the plot. You must specify at least one, and you can specify more than one.

You can also assign a column with a formula to this role. If you do so, the formula should be a function of exactly two variables. Those variables should be the x variables entered in the Launch window.

**X**  Columns assigned to the X role are used as the variables for the x- and y-axes. You must specify exactly two columns for X.

**By**  This option produces a separate graph for each level of the By variable. If two By variables are assigned, a separate graph for each possible combination of the levels of both By variables is produced.

**Options**

**Contour Values**  Specify your own number of levels and level increments. See “Contour Specification” on page 233.

**Fill Areas**  Fill the areas between contour lines using the contour line colors.

**Use Table Data and Specify Grid**  Most often, you construct a contour plot for a table of recorded response values. In that case, Use Table Data is selected and the Specify Grid button is unavailable.

However, if a column has a formula and you specify that column as the response (Y), the **Specify Grid** button becomes available. When you click **Specify Grid**, you can define the contour grid in any way, regardless of the rows in the existing data table. This feature is also available with table templates that have one or more columns defined by formulas but no rows. See “Use Formulas for Specifying Contours” on page 238.

After you click **OK**, the Contour plot appears. See “The Contour Plot” on page 231.
The Contour Plot

Follow the instructions in “Example of a Contour Plot” on page 227 to produce the plot shown in Figure 10.5.

The legend for the plot shows individual markers and colors for the Y variable. Replace variables in the plot by dragging and dropping a variable, in one of two ways: swap existing variables by dragging and dropping a variable from one axis to the other axis; or, click a variable in the Columns panel of the associated data table and drag it onto an axis.

For information about additional options for the report, see “Contour Plot Platform Options” on page 231.

Figure 10.5 The Contour Plot Report

Contour Plot Platform Options

Using the options in the red triangle menu next to Contour Plot, you can tailor the appearance of your contour plot and save information about its construction.

Show Data Points  Shows or hides ($x$, $y$) points. The points are hidden by default.
**Contour Plot Platform Options**

**Show Missing Data Points**  Shows or hides points with missing y values. Available only if **Show Data Points** is selected.

**Show Contours**  Shows or hides the contour lines or fills. The contour lines are shown by default.

**Show Boundary**  Shows or hides the boundary of the total contour area. The boundary is shown by default.

**Show Control Panel**  Shows or hides the **Alpha** slider that allows you to change the **Alpha** shapes filter.

**Transform**  If the contour plot includes a **Color** role, the **Transform** option is enabled. See “Additional Example of Contour Plots” on page 239.

- **None**  The triangulation is computed without any scaling to coordinates using Delaunay triangulation. Delaunay triangles are computed to maximize the minimum angle of the triangles in the triangulation. This value is selected by default.

- **Range Normalized**  The X1/X2 values are both scaled to [0,1] prior to computing the triangulation. If the X1/X2 limits are different, then this is a non-uniform scale. This option may be more desirable in cases where the X1/X2 units are very different.

**Fill Areas**  Fills the areas between the contours with a solid color. It is the same option that is available in the Launch window. If you leave it deselected in the Launch window, you can see the line contours before filling the areas. See “Fill Areas” on page 233.

**Label Contours**  Shows or hides the label (z-value) of the contour lines.

**Fit to Window**  Specifies the stretching behavior of the report.

**Change Contours**  Set your own number of levels and level increments. See “Contour Specification” on page 233.

**Save**  This menu has options to save information about contours, triangulation, and grid coordinates to data tables. See “Contour Plot Save Options” on page 237.

See *Using JMP* for more information about the following options:

**Local Data Filter**  Shows or hides the local data filter that enables you to filter the data used in a specific report.

**Redo**  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

**Save Script**  Contains options that enable you to save a script that reproduces the report to several destinations.
Save By-Group Script  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.

Fill Areas

If you select Fill Areas, the areas between contour lines are filled with the contour line colors. This option is available in the Launch window and in the red triangle menu for Contour Plot. Figure 10.6 shows a plot with contour lines on the left and a plot with the contour areas filled on the right.

Figure 10.6 Comparison of Contour Lines and Area Fills

Areas are filled from low to high values on a color gradient. An additional color is added in the filled contour plot for the level above the last, and highest, contour line.

Contour Specification

If you do not select options in the Launch window, the default plot spaces the contour levels equally within the range of the Y variable. You can specify a color theme by selecting a Continuous Color Theme in File > Preferences > Graphs. You can customize colors for individual contours by right-clicking on the contour color in the Contour Plot legend. You can customize the entire contour color gradient by right-clicking on the Contour Plot legend and selecting Gradient to open the Gradient Settings.
Figure 10.7 Gradient Settings Window

To format the labels in the legend, use the format menu, Width and Dec boxes, and the Use thousands separator (,) check box in the top left of the window.

**Color Theme**  Changes the color theme or defines a custom color theme. For more information about color options, see *Using JMP*.

**Lightness Range**  Sets the range of intensities for the gradient coloring.

**Number of Labels**  (Not available if the Scale Type is Custom.) Specifies the number of labels for your legend. The value of zero provides the default number of labels.

**Show Missing Color**  Specifies whether to show missing color in the legend. Auto shows the color only when there are missing values, Off never shows the color, On always shows the color.

**Scale Type**  Sets the scale for the gradient coloring. A description of the scale type is found below the Maximum value setting.

- **Linear**  The scale is piecewise linear between the Minimum and Center values and between the Center and Maximum values. This is the default scaling.
- **Quantile**  The scale is piecewise linear for quantiles of the gradient variable.
**Standard Deviation**  The gradient variable range is divided into standard deviation offsets from the mean. The scale is piecewise linear between these offset settings. The number of offsets is determined by the Number of Labels.

**Log**  The scale is linear for the logarithm of the gradient variable.

**Log Offset**  The scale is linear for the offset of the base 10 logarithm of the gradient variable.

**Custom**  The scale labels are specified by the user in the Levels setting.

**Range Type**  Sets the range of the legend values.

**Default**  Unless you specify values for the Minimum and Maximum, the minimum and maximum values include the range of the data and are chosen to be appropriately rounded values.

**Exact Data Range**  The minimum and maximum values are the exact minimum and maximum values for the data, or they are the values that you specify as Minimum and Maximum.

**Middle 90%**  The minimum and maximum values are the 5\textsuperscript{th} and 95\textsuperscript{th} quantiles, or they are the values that you specify as Minimum and Maximum. This option is resistant to outliers.

**Fill**  Determines how the endpoints of the range are specified in the contours.

**Between**  The contours stop at the endpoint and any data beyond the endpoint is not shown.

**Above**  Values above the range are included in the top contour level.

**Below**  Values below the range are included in the bottom contour level.

**Above Below**  Values at either end are included in their respective contour levels.

**Levels**  (Available only when the Custom Scale Type is specified.) Enables you to specify the number of labels and the label values for the legend.

**Horizontal**  Sets the orientation of the legend to horizontal.

**Reverse Colors**  Reverses the colors in the color scheme.

**Reverse Scale**  Reverses the scale for the color theme.

**Show Labels**  Shows or hides labels for the legend.
Specify

You can specify contour levels either in the Launch window (the **Specify** button) or in the report window from the red triangle menu for Contour Plot (the **Specify Contours** option). Selecting this option displays the Contour Specification window.

**Figure 10.8** Example of Contour Specification: Launch Window (on the left) and Menu (on the right)

You can use the Contour Specification window to do the following:

- change the number of contours
- specify minimum and maximum values to define the range of the response to be used in the plot
- change the increment between contour values

You supply any three of the four values, and the remaining value is computed for you. Click the check box to deselect one of the numbers and automatically select the remaining check box.

**Figure 10.9** The Contour Specification Window
Colors are automatically assigned and are determined by the number of levels in the plot. After the plot appears, you can right-click (press Control and click on macOS) on any contour in the plot legend and choose from the JMP color palette to change that contour color.

**Retrieve**

This option is both in the Launch window (the **Retrieve** button) and on the red triangle menu for Contour Plot (the **Retrieve Contours** option).

**Note:** Neither the button nor the menu option are active unless there is an open data table in addition to the table that has the contour plotting values. When you click **Retrieve** or select **Retrieve Contours**, a window with a list of open data tables appears.

Using this option, you can retrieve the following from an open JMP data table:

- the number of contours
- an exact value for each level
- a color for each level

From the list of open data tables, select the data table that contains the contour levels.

For level value specification, the Contour Plot platform looks for a numeric column with the same name as the response column that you specified in the Launch window. The number of rows in the data table defines the number of levels.

If there is a row state column with color information, those colors are used for the contour levels. Otherwise, the default platform colors are used.

**Revert Contours**

This option appears only on the red triangle menu for Contour Plot.

If you have specified your own contours, selecting this option reverts your Contour Plot back to the default contours.

**Contour Plot Save Options**

This menu has options to save information about contours, triangulation, and grid coordinates to data tables.

**Save Contours** Creates a new JMP data table with columns for the following:

- the \(x\) - and \(y\)-coordinate values generated by the Contour platform for each contour
- the response computed for each coordinate set
- the curve number for each coordinate set
The number of observations in this table depends on the number of contours you specified. You can use the coordinates and response values to look at the data with other JMP platforms. For example, you can use the Scatterplot 3D platform to get a three-dimensional view of the pond.

**Generate Grid** Displays a window that prompts you for the grid size that you want. When you click **OK**, the Contour platform creates a new JMP data table with the following:
- the number of grid coordinates you requested
- the contour values for the grid points computed from a linear interpolation

**Save Triangulation** Creates a new JMP data table that lists coordinates of each triangle used to construct the contours. By default, JMP uses Delaunay triangulation to connect the nearest data points to form triangles. The resulting set of triangles are calculated so that no other data points are inside a triangle’s circumscribed circle, that is, the circle that passes through the three vertices of the triangle. To change the triangulation to a normalized scale, select **Transform > Range Normalized**.

### Use Formulas for Specifying Contours

Most often you construct a contour plot for a table of recorded response values such as the Little Pond data table. In that case, in the launch window, **Use Table Data** is checked and the **Specify Grid** button is unavailable. However, if a column has a formula and you specify that column as the response (\(Y\)), the **Specify Grid** button becomes active.

When you click **Specify Grid**, the window shown in Figure 10.10 appears.

**Figure 10.10** Example of the Contour Specification for Formula Column

You can complete the Specify Grid window and define the contour grid in any way, regardless of the rows in the existing data table. This feature is also available with table templates that have one or more columns defined by formulas but no rows.
Additional Example of Contour Plots

This example illustrates how to create a triangulation data table, to transform the triangulation to use Delaunay triangles, and to filter Alpha shapes of the triangles.

1. Select Help > Sample Data Library and open Cities.jmp.
2. Select Graph > Contour Plot.
3. Select OZONE and click Y.
4. Select X and Y and click X.
5. Select to Fill Areas.
6. Click OK.
7. Click the red triangle next to Contour Plot for OZONE and select the following options:
   a. Transform > Range Normalized
      Instead of Delaunay triangulation, this changes the method for calculating the triangulations to a normalized scale ([0,1]) in both X and Y.
   b. Show Control Panel
      The Alpha slider appears.

Figure 10.11 Contour Plot for OZONE
8. Click and move the **Alpha** slider to the right.

**Figure 10.12** Alpha Shapes Filter

Using the Alpha slider filters out the larger Delaunay triangulation areas.
The Ternary Plot command in the Graph menu produces a three-axis plot. Ternary plots are a way of displaying the distribution and variability of three-part compositional data. (For example, the proportion of sand, silt, and clay in soil or the proportion of three chemical agents in a trial drug.) You can use data expressed in proportions or use absolute measures.

The ternary display is a triangle with sides scaled from 0 to 1. Each side represents one of the three components. A point is plotted so that a line drawn perpendicular from the point to each leg of the triangle intersect at the component values of the point.

Example of a Ternary Plot

This example uses the Pogo Jumps.jmp sample data table. The data, adapted from Aitchison (1986), show measurements for pogo jumps of seven finalists in the 1985 Hong Kong Pogo-Jump Championship. A single pogo jump is the total jump distance in three consecutive bounces, referred to as yat, yee, and sam.

1. Select Help > Sample Data Library and open Pogo Jumps.jmp.
2. From the Graph menu, select Ternary Plot.
3. Select Yat, Yee, and Sam and click X, Plotting.
4. Click OK.

Figure 11.2 Example of a Ternary Plot

Use the crosshairs tool to determine exact coordinates of points within the plot.
To get a better idea of how the three bounces contribute to total distance, assign each contestant’s points a different color and marker.

1. Right-click the plot and select **Row Legend**.
2. Select **Finalist** in the column list box.
   - **Colors** should be automatically set to **JMP Default**.
3. Select **Standard** from the **Markers** menu.
4. Click **OK**.
Figure 11.4 Pogo Data Colored by Finalist

Note that most of the finalists are consistent in the composition of total distance. However, two finalists, Jao and Ko, both have one jump that is not consistent with their other jumps. For example, for three of Jao’s jumps, the Yat composed about 50% of the total distance, but for the other jump, the Yat composed only 30% of the total distance. That jump is not consistent with the others. A similar observation can be made about Ko’s jumps.

Launch the Ternary Plot Platform

Launch Ternary Plot by selecting **Graph > Ternary Plot**.

Figure 11.5 The Ternary Plot Launch Window

Plot how components of a mixture add up

Select Columns

- Finalist
- Yat
- Yee
- Sam
- Total

Cast Selected Columns into Roles

- X, Plotting
  - required numeric
  - required numeric
  - required numeric
  - optional numeric

- Contour Formula
  - optional numeric

- By
  - optional numeric

Column values must not be negative
**X, Plotting**  Assign three columns to generate a ternary plot.

If you assign more than 3 variables to the **X, Plotting** role, a matrix of ternary plots is created. A separate variable is assigned to the first two axes of a plot, with the third axis being the sum of the other variables. If necessary, the variables are scaled so they sum to 1.

**Contour Formula**  To plot contours of a response surface, assign a column containing a formula to the **Contour Formula** role. If you have variables in a Contour formula that are not listed as **X, Plotting** variables, JMP appends sliders below the plot so that the values can be interactively adjusted. See “Example Using a Contour Function” on page 249.

**By**  This option produces a separate graph for each level of the By variable.

After you click **OK**, the Ternary Plot window appears. See “The Ternary Plot” on page 246.

---

**The Ternary Plot**

Follow the instructions in “Example of a Ternary Plot” on page 243 to produce the plot shown in Figure 11.6.

Each of the three sides of a ternary plot represents a proportion of 0%, with the point of the triangle opposite that base representing a proportion of 100%. As a proportion increases in any one sample, the point representing that sample moves from the base to the opposite point of the triangle.
Mixtures and Constraints

Ternary Plot uses the Mixture column property to shade the portion of the graph that is out of bounds. The Ternary plot recognizes the mixture sum, mixture bounds, and general linear constraints. For information about setting the Mixture column property in the Column Info window, see Using JMP.

Related Information
- “Example Using Mixture Constraints” on page 248

Ternary Plot Platform Options

The Ternary Plot red triangle menu contains options to modify the plot.

**Note:** To view more detailed options, right-click the plot.

**Show Constraints**  Shows or hides the constraints on the plot. The default plot shows the constraints.
**Contour Fill**  Allows filling of contours if a contour formula is specified in the plot. You can select Lines Only, Fill Above, or Fill Below. The default platform shows lines only.

**Color Theme**  Allows you to select a color theme. The default plot shows the Blue to Gray to Red color theme.

**Show Points**  Shows or hides the plotted points. The default plot shows the points.

**Fit to Window**  Specifies whether the graph is resized as you resize the JMP window. The default setting is Auto, which is usually set to On except when the window is shared with other content or if there is a Page variable. To always fit the graph inside the window, keep the setting at On. You can also maintain the aspect ratio. To prevent the graph from resizing, change the setting to Off.

See *Using JMP* for more information about the following options:

**Local Data Filter**  Shows or hides the local data filter that enables you to filter the data used in a specific report.

**Redo**  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

**Save Script**  Contains options that enable you to save a script that reproduces the report to several destinations.

**Save By-Group Script**  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.

---

**Additional Examples of the Ternary Plot Platform**

- “Example Using Mixture Constraints”
- “Example Using a Contour Function”

**Example Using Mixture Constraints**

1. Select **Help > Sample Data Library** and open Plasticizer.jmp.
   The p1, p2, and p3 columns all have Mixture Column Properties defined.
2. From the **Graph** menu, select **Ternary Plot**.
   Notice that p1, p2, and p3 appear next to **X, Plotting**.
3. Click **OK**.
Figure 11.7  Mixture Constraints in a Ternary Plot

For more information about mixtures, see *Profiler*.

**Example Using a Contour Function**

The data in Fish Patty.jmp is adapted from Cornell (1990) and comes from an experiment to optimize the texture of fish patties. The columns Mullet, Sheepshead, and Croaker represent what proportion of the patty came from those fish types. The column Temperature represents the oven temperature used to bake the patties. The column Rating is the response and is a measure of texture acceptability, where higher is better. A response surface model was fit to the data and the prediction formula was stored in the column Predicted Rating. See *Profiler*.

1. Select **Help > Sample Data Library** and open Fish Patty.jmp.
2. From the **Graph** menu, select **Ternary Plot**.
3. Select Mullet, Sheepshead, and Croaker and click **X, Plotting**.
4. Select Predicted Rating and click **Contour Formula**.
5. Click **OK**.
6. Click the Ternary Plot red triangle and select **Contour Fill > Fill Above**.
The manufacturer wants the rating to be at least 5. You can drag the slider for Temperature and see the contours for the Predicted Rating change. Each point represents a mixture of the three fish. Any given mixture of fish types receives different ratings according to the temperature at which the patties are baked.

In this example, the red shaded area shows the mixture of fish that results in a rating of 5 to 5.5. Any purple areas show the mixture of fish that results in a rating of 4 and below. At 400 degrees, a mixture of mostly sheepshead and mullet with very little croaker results in a rating of 5 and above.
JMP transforms numbers and geographic data into compelling images, and turns simple tables of numbers into captivating pictures that bring the story in your data to life. JMP can help you display your data on geographical maps. Choose from built-in high-quality images. Select Street Map Service or Web Map Service to get custom map images from the Internet. JMP includes shape files for borders or many geographic regions and lets you add your own custom shapes, such as for a manufacturing plant or campus.

Overview of Mapping

There are two types of map support in JMP: one where a map shows the data (Graph Builder) and one where a map provides context for the data (Background Maps). You can also create your own maps.

Graph Builder

You can interact with Graph Builder to create compelling visualizations of your data. JMP includes graphical support to display analyses using background maps and shape files. You can add color and geographical boundaries to maps through the following zones:

- The **Map Shape** zone assigns geographical boundaries to a map based on variables in the data table. The map shape value determines the x and y axes.
  
  Boundaries such as U.S. state names, Canadian provinces, and Japanese prefectures are installed with JMP. You can also create your own boundaries (geographical or otherwise) and specify them as a **Map Role** column property in the data table.

- The **Color** zone applies color based on a variable to geographical shapes.

- The **Size** element scales map shapes according to the size variable, minimizing distortion.

Background Maps

You can add background maps to any JMP graph through the Set Background Map window. You can use built-in background maps or connect to a Web Map Service (WMS) to display specialty maps like satellite images, radar images, or roadways. Right-click in a graph and select **Graph > Background Map** to choose from the following images and boundaries:

- **Simple Earth** and **Detailed Earth** maps are installed with JMP.

- **NASA server** provides maps using a WMS to show their most up-to-date maps.

- **Street Map Service** provides street maps. The OpenStreetMap and Open Database License links provide further information on the Street Map Service.

- **Web Map Service** lets you enter the URL for a website that provides maps using the WMS protocol. You can also specify the map layer.

- Boundaries for various regions.
Example of Creating a Map in Graph Builder

This example uses the Crime.jmp sample data table, which contains data on crime rates for each US state.

1. Select Help > Sample Data Library and open Crime.jmp.
2. Select Graph > Graph Builder.
3. Drag and drop State into the Map Shape zone.
4. Drag and drop Burglary into the Color zone.

Figure 12.2 Example of Burglary by State

Note the following:

- The latitude and longitude appear on the Y and X axes.
- The legend shows the colors that correspond to the burglary rates. Since Burglary is a continuous variable, the colors are based on a continuous color theme. Figure 12.2 uses the JMP default continuous theme. You can change the theme under File > Preferences > Graphs.
- The map is projected so that relative areas are not distorted (the 49th parallel across the top of the US is not a straight line).
Graph Builder

Open a data table that contains geographic data. Launch Graph Builder by selecting **Graph > Graph Builder**. The primary element in the Graph Builder window is the graph area. The graph area contains drop zones (Map Shape, Color and Size), and you can drag and drop variables into the zones. From here you can map shapes for data tables that include place names.

**Figure 12.3** The Graph Builder Window

Map Shape

When a column contains the names of geographical regions (such as countries, regions, states, provinces, counties), you can assign the column to the **Map Shape** zone. When a variable is dropped in **Map Shape**, Graph Builder looks for map shapes that correspond to the values of the variable and draws the corresponding map. The variable can have a column property that tells JMP where to find the map data. If not, JMP looks through all known map files. If you have a variable in the Map Shape zone, the X and Y zones disappear. The Map Shape zone is positional and influences the types of graph elements that are available.
For each map there are two .jmp files; one for the name data (one row per entity) and one for coordinate data (many rows per entity). They are paired via a naming convention; xxx-Name.jmp and xxx-XY.jmp, where "xxx" is some common prefix.

Some examples of sample files that are shipped with JMP are:

- World-Name.jmp
- World-XY.jmp
- US-State-Name.jmp
- US-State-XY.jmp

**Map Name Files**

Each xxx-Name.jmp can contain any number of shape name columns, which are identified with a column property. Multiple name columns support localizations and alternate names styles (such as abbreviations), but a given graph usage uses only one column of names. The first column of the Name file contains unique Shape ID numbers in ascending order. JMP creates this columns for you. The column values match those in the -XY.jmp map data table Shape ID column.

**Note:** The Shape ID column can also be named Shape.
Map XY Files

Each xxx-XY.jmp file has four columns. Each row is a coordinate in some shape. Each shape is made of one or more parts. Each part is a closed polygon. The first column is the same Shape ID as in the xxx-Name file. The second column is the Part ID. The next two columns are X and Y.

Color

The Graph Builder platform lets you add color to create choropleth maps. A choropleth map shows statistical differences in a geographic area while maintaining the proportion of the statistical variable.

Drag a column containing geographic place-names, like countries, regions, states, or provinces, into the Map Shape zone and create a map. Then drag a column to the Color zone to color the map by that column. The categorical or continuous color theme selected in your Preferences is applied to each shape.
Figure 12.7 Example of SAT.jmp After Dragging 2004 Verbal to Color

Use the Size element to scale map shapes according to the size variable, minimizing distortion.
Customizing Graphs

To change colors and transparency for a map, right-click the color bar in the legend. The right-click options vary, depending on whether the color variable is continuous or categorical (nominal or ordinal). However, for both types of variables, you can change the transparency.

To change the transparency of a graph:

1. Right-click the color of the variable level on the color bar that you want to change and select Transparency.
2. Specify the transparency between 0 (clear) and 1 (opaque).
3. Click OK.

You can also change the transparency of images (for example, Simple Earth and Detailed Earth). To set the transparency, right-click over the graph and select Customize.... This brings up the Customize Graph window, where you can select the Background Map and assign a value for transparency. A valid value for transparency goes from 0.0 (completely transparent) to 1.0 (completely opaque).

Categorical (nominal or ordinal) variables use a singular coloring system, where each level of the variable is colored differently.
To change the color of one of the variable levels:

1. Right-click the color of the variable level that you want to change and select **Fill Color**.
2. Select the new color.

Continuous variables use a color gradient.

**To change the color theme:**

1. Right-click the color bar and select **Gradient**.
2. In the Gradient Settings window, select a different **Color Theme**.

Graphs consist of markers, lines, text, and other graphical elements that you can customize. If you right-click an image, there are several options for working with the graph. The options differ based on what you clicked. See “Gradient Settings” on page 116 in the “Graph Builder” chapter and *Using JMP*. Below are a few options.

**Figure 12.9** Right-click Menu for Graphics

- **Map Shapes:**
  - Change To - Provides options for changing the map into another graph type.
  - Summary Statistics - Provides options for changing the statistic being plotted.
  - Show Missing Shapes - Shows or hides missing data from a map (turned off by default). Missing Shape means that there are some shape names that exist in the map file but not in the data table for analysis.
  - Remove - Removes the current map shape.

- **Customize** - You can change the properties of the graph such as contents, grid lines, or reference lines. The graphical elements that you can customize differ for each graph. Select **Background Map** to change the transparency of a background map or **Map Shape** to change the line color, line style and width, fill color, missing shape fill or missing value fill. Click **Help** in the Customize Graph window for a more detailed explanation of the customize options.
To change the shape file:

1. Right-click the Map Shapes zone and select Set Shape File.
2. Navigate to the shape file that contains the name data.
3. Click Open.
4. (Optional) To revert the changes, right-click the Map Shapes zone and select Reset Shape File.

Custom Map Files

You can create your own map files by following the same pattern as the built-in files. To add your own map files, you need two things: a series of XY coordinates for the vertices of the polygons that describe the shape, and a set of names for each polygon. Data and shape attributes are required to map custom shapes so that you can add your own shapes to JMP. There are two common sources for data like this: Esri shapefiles and SAS/GRAPH map data sets.

In order for JMP to automatically find your files, place them in the following directory:

- On Windows: C:/Users/<user name>/AppData/Roaming/SAS/JMP/Maps
- On macOS: /Users/<user name>/Library/Application Support/JMP/Maps

Note: On Windows, in JMP Pro, the “JMP” folder is named “JMPPro”. Or, you can link the map files to your data files explicitly with the Map Role column property.

Note the following when creating map files:

- Each set of map files that you create must contain a -Name file and a -XY file.
- The first column in both files must be the ascending, numeric Shape ID variable. The -Name file can contain any other columns. The shapes are built by rows. The XY coordinates have to go around the shape rather than just define the convex hull of the shape.
- For the Map Role column property, columns that are marked with the Shape Name Definition are searched for shape identification and must contain unique values.
- If you import an Esri SHP file, it is opened in the correct format. -Name files commonly have a .dbf extension. See “Esri Shapefiles” on page 265.
- SAS/GRAPH software includes a number of map data sets that can be used with JMP. See “SAS/GRAPH Map Data Sets” on page 266.
You might want to create choropleth maps of other non-geographic regions (for example, a floor of an office building). Simply, add the two shape files for your non-geographic space. If you do not have XY coordinates, but you do have a graphic image of the space, you can use the Custom Map Creator add-in for JMP. With this add-in, you can trace the outlines of the space and JMP creates the -XY and -Name files for you. You can download this add-in from the JMP File Exchange page.

**Map Role**

You can specify the attributes and properties of a column in a data table within the Column Info window in Column Properties. The **Map Role** property is set for a column like other column properties in the Column Info window.

If you have created your own data table that contains boundary data (such as countries, regions, states, provinces, or counties) and you want to see a corresponding map in Graph Builder, use the **Map Role** property within Column Properties. Each pair of map files that you create must contain a -Name file and a -XY file.

Note the following:

- If the custom boundary files reside in the default custom maps directory, then you need to specify only the **Map Role** property in the -Name file.
- If the custom boundary files reside in an alternate location, specify the **Map Role** property in the -Name file and in the data table that you are analyzing.
- The columns that contain the **Map Role** property must contain the same boundary names, but the column names can be different.

**To add the Map Role property into the -Name data table:**

1. Right-click the column containing the boundaries and select **Column Properties > Map Role**.
2. Select **Shape Name Definition** below **Map Role**.
3. Click **OK**.
4. Save the data table.
To add the Map Role property into the data table that you are analyzing:

**Note:** Perform these steps only if your custom boundary files do not reside in the default custom maps directory.

1. Right-click the column containing the boundaries and select *Column Properties > Map Role*.
2. Select *Shape Name Use* below *Map Role*.
3. Next to *Map name data table*, click ![browse icon] to browse to a -Name map data table. You can enter the relative or absolute path.
   If the map data table is in the same folder, enter only the filename. Quotation marks are not required when the path contains spaces.
4. From the *Shape definition column* list, select the column in the map data table whose values match those in the selected column.
   Figure 12.11 shows an example of the room/office column in the S4 Temps.jmp sample data table.
Figure 12.11  Shape Definition Column Example

5. Click OK.
6. Save the data table.

When you generate a graph in Graph Builder and assign the modified column to the **Map Shape** zone, your boundaries appear on the graph.

For numeric columns, the Format Menu appears in the Column Info window. Specify the format to tell JMP how to display numbers in the column. Latitude and Longitude for geographic maps are located under **Format > Geographic** when customizing axes and axes labels.

**Geographic**  Shows latitude and longitude number formatting for geographic maps.

Latitude and longitude options include the following:

- DDD (degrees)
- DMM (degrees and minutes)
- DMS (degrees, minutes, and seconds)

In each format, the last field can have a fraction part. You can specify the direction with either a signed degree field or a direction suffix. To show a signed degree field, such as -59°00′00″, deselect **Direction Indicator**. To show the direction suffix, such as 59°00′00″ S, select **Direction Indicator**.

To use spaces as field separators, deselect **Field Punctuation**. To use degrees, minutes, and seconds symbols, select **Field Punctuation**.
**Esri Shapefiles**

The Esri shapefile is a vector data format that contains data about geographic features such as terrain and oceans. It is developed and regulated by Esri as a specification for geographic mapping software.

Each shapefile is a set of files with the same name and different extensions.

**main file (.shp)**

The .shp file contains sequences of points that make up polygons. When opened with JMP, a .shp file is imported as a JMP table.

- The Shape column is added during import to uniquely identify each geographic region. Each coordinate point is in a separate row.
- The Part column to indicate discontiguous regions, and the XY coordinates (in latitude and longitude degrees).

JMP supports two-dimensional .shp files (no elevation information).

**dBase Table (.dbf)**

You add a Shape ID column to the .dbf table, which maps to the Shape column in the .shp file. Add any number of columns that provide common names or values to refer to specific regions.

To convert an Esri shapefile to a JMP map file:

1. Open the .shp file in JMP.
2. Make sure that the Shape column is the first column in the .shp file. Add formatting and axis settings for the X and Y columns (optional). Graph Builder uses those settings for the X and Y axes.
3. Save the .shp file as a JMP data table to the Maps folder with a name that ends in -XY.jmp.
4. Open the .dbf file.
5. Add a Shape ID column as the first column in the table. This column should be the row numbers from 1 to n, the number of rows in the data table.

   **Note:** You can use Cols > New Columns > Initialize Data > Sequence Data) to fill the column with sequential numbers.

6. Assign the Map Role column property to any column that you use for place names in the Shape role of Graph Builder. To do this, right-click at the top of the column and select Column Properties > Map Role.
7. Select Shape Name Definition from the drop-down box in the property definition.
8. Save the table as a JMP data table with a name that matches the earlier table and that ends in -Name.jmp.

JMP looks for these files in two locations. One location is shared by all users on a machine. This location is:

- Windows: C:/Program Files/SAS/JMP/16/Maps/
- macOS: /Library/Application Support/JMP/16/Maps

The other location is specific for an individual user:

- On Windows: C:/Users/<user name>/AppData/Roaming/SAS/JMP/Maps
- On macOS: /Users/<user name>/Library/Application Support/JMP/Maps

Note: On Windows, in JMP Pro, the JMP folder is named JMPPro.

SAS/GRAPH Map Data Sets

SAS/GRAPH® software includes a number of map data sets that can be converted for use with JMP. The data sets are in the Maps library. The traditional map data sets contain the XY coordinate data and the feature table contains the common place names. You need to convert both of these files to JMP data tables for use with JMP.

Most of the traditional map data sets have unprojected latitude and longitude variables in radians. The data sets can be used with JMP once they have been converted to degrees and the longitude variable has been adjusted for projection. The following is a DATA step that shows the conversion process for the Belize data set.

```plaintext
data WORK.BELIZE;
keep id segment x y;
rename segment=Part;
set maps.belize;
if x NE .;
if y NE .;
y=lat*(180/constant('pi'));
x=-long*(180/constant('pi'));
run;
```

You can now import the converted file and save it as Belize-XY.jmp.
The next step is to import the matching feature data set (in this case: MAPS.BELIZE2). After importing the feature data set, move the ID column to the first position in the data table. Then assign the Map Role column property to the columns that you use for place names in the Shape role of Graph Builder. To do this, right-click the top of the column and select **Column Properties > Map Role**. Then select **Shape Name Definition** from the drop-down box in the property definition. For MAPS.BELIZE2, use the IDNAME column. Save the feature data table as Belize-Name.jmp.

To convert SAS maps, download the SAS to JMP Map Converter add-in from the JMP File Exchange page. For each map, the add-in reads the data from the two SAS map tables, rearranges and formats the data and then places it into the two JMP map tables.

**Background Maps**

Adding map images and boundaries to graphs provides visual context to geospatial data. Affixing a background map generates an appealing map, providing your data a geographic context and giving you a whole new way to view your data. For example, you can add a map to a graph that displays an image of the U.S. Another option is displaying the boundaries for each state (when data includes the latitudes and longitudes for the U.S.). There are different types of background maps. Some maps are built into JMP and are delivered as part of the JMP install. Other maps are retrieved from an Internet source, and still other maps are user-defined.

The data should have latitudinal and longitudinal coordinates. Otherwise, the map has no meaning in the context of the data. The X and Y axes also have range requirements based on the type of map. These requirements are described in the following sections. Simply plot longitude and latitude on the X and Y axes, and then right-click within the graph and select **Graph > Background Map**.

The Background Map window shows two columns of choices: Images and Boundaries. On the left of the window that you can select from two built-in map images, or you can connect to a Web Map Service to retrieve a background image. On the right side of the window, you can select political boundaries for a number of regions.
The following Background Map options are available:

**Images**

**None**  Removes the background map that you selected in the Images column.

**Simple Earth**  Shows a map of basic terrain. For examples, run the associated scripts in these sample data tables: SAS Offices.jmp and Aircraft Incidents.jmp.

**Detailed Earth**  Shows a high-resolution map with detailed terrain.

**NASA Server**  Shows a map from the NASA server. Requires an Internet connection.

**Street Map Service**  Shows a map with an appropriate amount of detail based on the display’s zoom level. This enables you to zoom down to the street level. For example, run the associated script in the sample data table SAS Offices.jmp.

**Web Map Service**  Shows a map from the Uniform Resource Locator (URL) and the layer that you specify. Requires an Internet connection.

**Boundaries**

**None**  Removes the boundaries that you selected in the Boundaries column.

**Boundaries for various regions**  Shows borders for the map regions, such as Canadian provinces, U.S. counties, U.S. States, and world countries. The list varies based on your location. The maps that you created from Esri shapefiles are also listed here.

Two tools are especially helpful when you are viewing a map:

- The grabber tool ( ) lets you scroll horizontally and vertically through a map.
- The magnifier tool ( ) lets you zoom in and out.
Images in Maps

Every flat map misrepresents the surface of the Earth in some way. Maps cannot match a globe in truly representing the surface of the entire Earth. A map projection is used to portray all or part of the round Earth on a flat surface. This cannot be done without some distortion. Every projection has its own set of advantages and disadvantages. A map can show one or more, but not all, of the following: true direction, distance, area, or shape. JMP uses a couple of projections (Albers Equal Area Conic and Kavrayskiy VII) for its maps. Within Images, you can select from two built-in map images, or you can connect to a Web Map Service to retrieve a background image.

Earth Images Installed with JMP

JMP provides two levels of earth imagery; simple and detailed. Both maps show features such as bodies of water and terrain. However, detailed maps show more precise terrain. And with detailed maps, you can zoom in farther, and the map features remain clear. Image maps are raster images. The maps wrap horizontally, so you continue to see map details as you scroll from left to right. The maps do not wrap vertically. Beyond the -90 and 90 y-axis range, a plain background appears instead of the map.

Figure 12.13 Examples of Simple and Detailed Maps

As its name suggests, Simple Earth is a relatively unadorned image of the earth’s geography. It does not show clouds or arctic ice, and it uses a green and brown color scheme for the land and a constant deep blue for water. Detailed Earth has a softer color scheme than Simple Earth, lighter greens and browns for the land, as well as variation in the blue for the water. Detailed Earth also has a slightly higher resolution than Simple Earth. The higher resolution lets you zoom into a graph further with Detailed Earth than with Simple Earth before the quality of the background image begins to blur.

Another feature of Simple Earth and Detailed Earth is the ability to wrap. The Earth is round, and when you cross 180° longitude, the Earth does not end. The longitudinal value continues from -180° and increases. The map wraps continuously in the horizontal direction, much as the Earth does. The background map does not wrap in the vertical direction.
Simple Earth and Detailed Earth both support a geodesic scaling. In Figure 12.13 on page 269, the Earth appears as a rectangle, where the width is twice as wide as the height. If we were to take this rectangle and roll it up, we would have a cylinder. In reality, we know that the Earth does not form a cylinder, but rather a sphere. You can use a geodesic scaling, which transforms the map to a more realistic representation of the Earth. To use the geodesic scaling, change the type of scale on the axes.

To change the axes scale:

1. Right-click the X or Y axis and then select **Axis Settings**.
2. Change the Scale Type to **Geodesic** or **Geodesic US**.

**Figure 12.14 Y Axis Setting Window**

Both choices transform the map to a geodesic scaling. Use Geodesic US if you are viewing a map of the continental US and you want Alaska and Hawaii to be included in the map. It is important to note that you must set the scale to geodesic for both axes to get the transformation. You will not see a change in the map after setting only one of the axes. In the following figure, Simple Earth is used as the background map with the axes set to use a geodesic scale. The axes lines are turned on as well. Notice the longitudinal lines are now curved, instead of straight.
Since Detailed and Simple Earth are built into JMP, these options work anytime, without a
network connection. However, these images might not be all that you want, or they might not
be detailed at the resolution that you need. If this is the case, and if you have an Internet
connection, you can connect to a Web Map Service to retrieve a map image that meets your
needs.

Maps from the Internet

The National Aeronautics and Space Administration (NASA) and other organizations provide
map image data using a protocol called Web Map Service (WMS). These maps have the
advantage of showing the most up-to-date geographical information. However, the display of
the maps can be slow depending on the response time of the server, and the sites can change
or disappear at any time. An Internet connection is required to access the information.

The NASA server provides maps for the entire Earth. The following figure displays the Earth
using the NASA server as its source for the background map. The boundary map shows the
outlines of the countries.
Not only does this server cover the entire Earth, but you can also zoom in on a much smaller area of the Earth and still get a reasonable map. The following figure displays the Colorado River running through the Grand Canyon in Arizona. The Grand Canyon Village is visible in the bottom of the map.

If you look at the axes values, you can see that the area is less than 1/10° by 1/10°. The Simple Earth and Detailed Earth background maps do not display that type of resolution. The NASA server provides a fairly detailed view of any land mass on Earth. Water, however, is simply filled in as black. The NASA server is free to access, but it is also limited in availability. If the server is temporarily unavailable or becomes overloaded with requests, it delivers an error message instead of the requested map.
Another Internet-based option for background maps is a Web Map Service (WMS). The WMS option enables you to specify any server that supports the WMS interface. The NASA server is an example of a WMS server, but we have provided the URL and a layer name for you. With the WMS option, you must know the URL to the WMS server and a layer name supported by the server. Most WMS servers support multiple layers. For example, one layer can show terrain, another layer can show roads, and still another layer can include water, such as rivers and lakes. By specifying the URL for the server and the layer, JMP can make a request to the server and then display the map that is returned.

Unlike with simple and detailed maps, WMS maps do not wrap. You can scroll horizontally and vertically. However, beyond the -180 to 180 (x axis) and -90 to 90 (y axis) ranges, a plain background appears instead of the map. The limits of the axes are used to define the limits of the map that is displayed.

In order to use the WMS option for a background map, you need to decide which WMS server to use. There are many WMS servers freely available from the Internet. Most of them provide maps only for a particular area of the world, and each of them supports their own layers. So you have to search for the appropriate WMS server for your particular situation.

You can search for WMS servers on the Internet using your favorite search engine. Once you find one, you need to discover the layers that it supports. For this, you can use the WMS Explorer add-in. The WMS Explorer add-in generates a list of all the layers available on a server. You can select a layer from the list to see what it looks like. You can download the WMS Explorer add-in from the JMP File Exchange page.

**Note:** To use the WMS Explorer add-in and the WMS background map capabilities of JMP, your computer must be connected to the Internet.

To locate a server, launch the add-in through the menu items **Add-Ins > Map Images > WMS Explorer**. The add-in presents a text box for entering the url of a known WMS server. Alternatively, you can make a selection from a drop-down list of pre-discovered WMS servers (the list can be out of date). After specifying a WMS server, select **Get Layers**. Using Get Layers is not necessary if selecting from the drop-down list or if clicking **Enter** after entering a URL. This sends a request to the WMS server for a list of layers that the server supports. The returned list appears in the list box on the left, labeled **Layers**. A map of the world appears as an outline in the graph to the right. Selecting a layer makes a request to the WMS server to return a map, using the specified layer, that represents the entire earth. Selecting a different layer generates a different map.

The default maps do not cover the entire earth (for example, some WMS servers might provide mapping data for a particular county, within a state). In that case, it is likely that selecting a layer does not generate any visible map. You might have to zoom in on the appropriate area before any image map is visible. The standard JMP toolbar is available in the add-in window and the zoom tool works just like it does in any JMP window.
The graph is a typical graph in JMP, which means that all the regular JMP controls are available to you. You can adjust the axes or use the zoom tool (found on the menu bar) just as you would in JMP. You can also right-mouse-click to select **Size/Scale > Size to Isometric** to return the graph to a proper aspect ratio. You can also select Background Map, where you can adjust the boundary map.

Once a desirable map is determined, note the URL in the text box at the top and the selected layer in the Layers list. This is the information that you need to enter in the background map window when WMS is selected as the type of image background map.

Because requests are being made to a server across the Internet, there are a number of conditions that can generate an error. WMS servers often have limited availability and sometimes are not available at all. Occasionally a WMS server might return a name of a layer that it no longer supports. In these types of cases (and others), a server usually returns an error message in lieu of a map. If that happens, the error message is displayed below the Layers list in an area labeled **Errors**.

### Boundaries

JMP can display boundaries (such as U.S. states or French region boundaries). These boundaries draw an outline around a defined area and can be displayed alone on a graph or combined with image data. Several boundaries are installed with JMP. Alternatively, you can create your own boundaries from Esri shapefiles or from scratch. Because of this, the list of Boundaries that you see in the Set Background Map window can be different.

When you add shape files to the built-in locations in JMP, they are available for the Graph Builder platform and for the Boundaries option in the Background Map window. In this way, you can add more political boundaries for use with background maps. Boundary-style maps are vector-based shapes.

**Figure 12.19** Example of U.S. State Boundaries
Add a Background Map and Boundaries

To add a background map and boundaries:

1. Right-click a blank area on the graph and select Background Map (or select Graph > Background Map in Graph Builder).
   The Set Background Map window appears (Figure 12.12).
2. To display a background, do one of the following:
   – Select Simple Earth, Detailed Earth, NASA server, or Street Map Service in the Images column.
   – Select Web Map Service and paste a WMS URL next to URL. Enter the layer identifier next to Layer.
3. To display geographic borders on the map, select an option in the Boundaries column (If you installed your own boundary shapefiles, they are also listed in this column).
4. Click OK.
   If the NASA map, Street Map, or WMS map does not appear after you add it, the map server might not be available. View the error log to verify the problem.

Examples of Creating Maps

- “Louisiana Parishes Example”
- “Hurricane Tracking Examples”
- “Office Temperature Study”
- “Boundary Map with Clipped Elements”

Louisiana Parishes Example

In this example you work with custom map files and then create custom maps in two different ways:

- Set up custom map files initially and save them in the predetermined location. JMP finds and uses them in the future with any appropriate data.
- Point to specific predefined map files directly from your data. This step might be required each time you want to specify custom maps.
Set Up Automatic Custom Maps

Suppose that you have downloaded Esri shapefiles from the Internet and you want to use them as your map files in JMP. The shapefiles are named Parishes.shp and Parishes.dbf. These files contain coordinates and information about the parishes (or counties) of Louisiana.

**Note:** Pathnames in this section refer to the JMP folder. On Windows, in JMP Pro, the JMP folder is named JMPPro.

Save the .shp File

Save the .shp file with the appropriate name and in the correct directory.

1. In JMP, open the Parishes.shp file from the following default location:
   - On Windows: C:/Program Files/SAS/JMP/16/Samples/Import Data
   - On macOS: /Library/Application Support/JMP/16/Samples/Import Data

   **Note:** If you cannot see the file, you might need to change the file type to **All Files**.

   JMP opens the file as Parishes. The .shp file contains the x and y coordinates.

2. Save the Parishes file with the following name and extension: Parishes-XY.jmp. Save the file here:
   - On Windows: C:/Users/<user name>/AppData/Roaming/SAS/JMP/Maps
   - On macOS: /Users/<user name>/Library/Application Support/JMP/Maps

Save the .dbf File

Perform the initial setup and save the .dbf file.

1. Open the Parishes.dbf file from the following default location:
   - On Windows: C:/Program Files/SAS/JMP/16/Samples/Import Data
   - On macOS: /Library/Application Support/JMP/16/Samples/Import Data

   **Note:** If you cannot see the file, you might need to change the file type to **All Files**.

   JMP opens the file as Parishes. The .dbf file contains identifying information.

2. Right-click the PARISH column and select **Column Info**.

3. Select **Column Properties > Map Role**.

4. Select **Shape Name Definition**.

5. Click **OK**.
6. Save the Parishes file with the following name and extension: Parishes-Name.jmp. Save the file here:
   - On Windows: C:/Users/<username>/AppData/Roaming/SAS/JMP/Maps
   - On macOS: /Users/<username>/Library/Application Support/JMP/Maps
7. Close the Parishes-Name.jmp file.

**Create the Map in Graph Builder**

Once the map files have been set up, you can use them. The Katrina.jmp data table contains data on Hurricane Katrina’s impact by parish. You want to visually see how the population of the parishes changed after Hurricane Katrina.

1. Select Help > Sample Data Library and open Katrina.jmp.
2. Right-click the Parish column and select Column Properties > Map Role.
3. Select Shape Name Use.
4. Click the Map name data table button and browse to select Parishes-Name.jmp, which you previously created.
   
   This tells JMP where the data tables containing the map information reside.
5. Select PARISH from the Shape definition column list.
   
   In Parishes-Name.jmp, the PARISH column has the Shape Name Definition Map Role property assigned. The column consists of map shape data for each parish.
6. Click OK.
7. Select Graph > Graph Builder.
8. Drag and drop Parish into the Map Shape zone.
   
   The map appears automatically, since you defined the Parish column using the custom map files.
9. Drag and drop Population into the Color zone.
10. Drag and drop Date into the Group X zone.
Figure 12.20 Population of Parishes Before and After Katrina

11. Select the **Magnifier** tool to zoom in on the Orleans parish in both maps (Figure 12.21)

Figure 12.21 Orleans Parish

You can clearly see the drop in population as a result of Hurricane Katrina. The population of the Orleans parish went from 437,186 in July 2005 to 158,353 in January 2006.
Point to Existing Map Files Directly from Your Data

Suppose that you already have your custom map files and they are named appropriately. Your map files are US-MSA-Name.jmp and US-MSA-XY.jmp. They are saved in the sample data folder.

The PopulationByMSA.jmp data table contains population data from the years 2000 and 2010 for the metropolitan statistical areas (MSAs) of the United States. This example shows how the data table has been set up to create a map.

Add the Map Role Column Property

1. Select Help > Sample Data Library and open PopulationByMSA.jmp.
2. Right-click the Metropolitan Statistical Area column and select Column Info.
3. Select Column Properties > Map Role.
4. Select Shape Name Use.
5. Next to the Map name data table, type $SAMPLE_DATA/US-MSA-Name.jmp.
   This tells JMP where the data tables containing the map information reside.
6. Select MSA_Name from the Shape definition column list.

MSA_Name is the specific column within the US-MSA-Name.jmp data table that contains the unique names for each metropolitan statistical area. Notice that the MSA_Name column has the Shape Name Definition Map Role property assigned, as part of correctly defining the map files.

Note: Remember, the Shape ID column in the -Name data table maps to the Shape ID column in the -XY data table. This means that indicating where the -Name data table resides links it to the -XY data table, so that JMP has everything that it needs to create the map.
Figure 12.22 Map Role Column Property

7. Click OK.

Create the Map in Graph Builder

Once the Map Role column property has been set up, you can perform your analysis. You want to visually see how the population has changed in the metropolitan statistical areas of the United States between the years 2000 and 2010.

1. Select Graph > Graph Builder.
2. Drag and drop Metropolitan Statistical Area into the Map Shape zone.
   Since you have defined the Map Role column property on this column, the map appears.
3. Drag and drop Change in Population to the Color zone.
4. Select the **Magnifier** tool to zoom in on the state of Florida.
5. Select the **Arrow** tool and click the red area.
6. Select the **Magnifier** tool and hold down the Alt key while clicking on the map to zoom out.

7. Select the **Magnifier** tool and zoom in on the state of Utah.

8. Select the **Arrow** tool and click the area that is slightly red.
You can see that the areas of Palm Coast, Florida, and St. George, Utah had the most population change between 2000 and 2010. The Palm Coast area saw a population change of 92%, and the St. George area saw a population change of about 53%.

### Hurricane Tracking Examples

This example uses the Hurricanes.jmp sample data table, which contains data on hurricanes that have affected the east coast of the United States. Adding a background map helps you see the areas the hurricanes affected. A script has been developed for this example and is part of the data table.

1. Select **Help > Sample Data Library** and open Hurricanes.jmp.
2. In the Table panel, click the green triangle next to the **Bubble Plot** script.
3. Drag the Date slider to the right as shown in Figure 12.26.
4. Click the red dot to display the name of the hurricane. The date appears in the upper left corner of the window. The red dot shows the location of Hurricane Paloma on November 14, 2008.
Note that even though the location of the hurricane is plotted, it does not really tell us where it is. The axes information is there (27° North latitude and 86° West longitude), but we need a little more context. It is most likely over the middle of the Atlantic, but is it over a small island? This could make a big difference, especially for the inhabitants of the small island. Obviously, a map in the background of our graph would add a good deal of information.

5. Right-click the graph and select **Background Map**. The Set Background Map window appears (Figure 12.12).

6. Select **Detailed Earth** and click **OK**.
Now the coordinates make geographic sense. Click **Run** to view the animation of the hurricane data moving over the background map. Experiment with different options and view the displays. Adjust the axes or use the zoom tool to change what part of the world you are viewing. The map adjusts as the view does. You can also right-click the graph and select Size/Scale->Size to Isometric to get the aspect ratio of your graph to be proportional.

The next example uses the **Katrina Data.jmp** sample data table, which contains data on hurricane Katrina such as latitude, longitude, date, wind speed, pressure, and status. Adding a background map helps you see the path the hurricane took and impact on land based on size and strength. A script has been developed for this example and is part of the data table.

1. Select **Help > Sample Data Library** and open **Katrina Data.jmp**.
2. Select **Graph > Bubble Plot**.
3. Select LAT and click **Y**.
4. Select LON and click **X**.
5. Select Date and click **Time**.
6. Select WIND and click **Sizes**.
7. Select Stat and click **Coloring**.

---

**Figure 12.27** Bubble Plot of Hurricanes.jmp with Background Map

![Bubble Plot of Latitude by Longitude Sized by Wind (Knots) Across Date ID Name and ID](image-url)
8. Click **OK**.

The following image appears. The yellow dot shows the location of Tropical Depression Katrina on August 23, 2005.

Note that even though the location of the storm is plotted, it does not really tell us where it is. To add more context, add a map in the background.
9. Right-click the graph and select **Background Map**. The Set Background Map window appears.

10. Select **Detailed Earth** and click **OK**.

**Figure 12.30** Bubble Plot of Katrina Data.jmp with Background Map

Now the coordinates make geographic sense. You can edit the axes and the size/scale to change how the graph appears.

11. Right-click the X axis (LON) and select **Axis Settings**. The X Axis Specification window appears.

12. Select **Scale > Geodesic US**.

13. Select **Format > Geographic > Longitude DMM**.

14. Click **OK**.

15. Repeat the same for the Y axis (LAT) except select **Format > Geographic > Latitude DMM**.

16. Right-click the map and select **Size/Scale > Size to Isometric**.
**Office Temperature Study**

This example demonstrates the creation of a custom background map for an office temperature study and how JMP was used to visualize the results. Data was collected concerning office temperatures for a floor within a building. A map was created for the floor using the Custom Map Creator add-in from the JMP File Exchange ([https://community.jmp.com/docs/DOC-6218](https://community.jmp.com/docs/DOC-6218)). Using Graph Builder, the office temperature results were then analyzed visually.

The map shown below is the floor, grouped by *time of day*. The color reflects the Fahrenheit value. Exploring data visually in this way can give hints as to what factors are affecting office temperature. Looking at this map, it appears the offices on the east side of the building are warmer in the mornings than they are in the afternoons. On the western side of the building, the opposite appears to be true. From this visualization, we might expect that both of these variables are affecting office temperatures, or perhaps that the interaction between these terms is significant. Such visuals help guide decision-making during the analysis.
First, data was collected and input into a data table (S4 Temps.jmp). Note the Room/Office column. It contains the unique names for each office and was assigned the Map Role to correctly define the map files.

Figure 12.33 Partial View of the S4 Temps.jmp Data Table
Maps
Examples of Creating Maps

Then, a map of the floor was created using the Custom Map Creator add-in, which you can download from the JMP File Exchange at https://community.jmp.com/docs/DOC-6218. The add-in creates two tables to define the shapes; an XY table and a Name table. The instructions below describe how it was built.

Create a Map of the Floor

1. Launch the add-in through the menu items **Add-Ins > Map Shapes > Custom Map Creator**. Two tables open in the background followed by the Custom Map Creator Window.

2. Drag a background image into the graph frame. An image of the floor plan was available.

3. Perform any resizing on the background image and graph the frame.

4. Name the table (for example, S4).

5. Click **Next**.

6. Name the shape that you are about to define. For this example, each office was individually named for the map (for example, S4001).

7. Within the graph frame, use your mouse to click all of the boundaries of the shape that you want to define. A line appears that connects all of the boundary points.

8. As soon as you finish defining the boundaries of the shape, click **Next Shape**. Continue adding shapes until you have completed the floor plan. Note that you do not need to connect the final boundary point; the add-in automatically does that for you when you click **Next Shape**.

9. The line size and color can be changed. In addition, checking **Fill Shapes** fills each shape with a random color.

10. Click **Finish**.

The custom map files were created and named appropriately. The map files are S4-Name.jmp and S4-XY.jmp and have been saved in the JMP Samples/Data folder.

Add the Map Role Column Property

**Note:** Pathnames in this section refer to the JMP folder. On Windows, in JMP Pro, the JMP folder is named JMPPro.

The S4 Temps.jmp data table contains office data over a three-day period. Set up the **Map Role** column property in the data table:

1. Select **Help > Sample Data Library** and open S4 Temps.jmp.

2. Right-click the **Room/Office** column and select **Column Info**.

3. Select **Column Properties > Map Role**.

4. Select **Shape Name Use**.
5. Click the icon next to **Map name data table** and browse to the S4-Name.jmp file (located in the JMP Samples/Data folder).
This tells JMP where the data tables containing the map information reside.

6. Select **room** from the **Shape definition column** list.

   *Room* is the specific column within the S4-Name.jmp data table that contains the unique names for each office. Notice that the *room* column has the **Shape Name Definition Map Role** property assigned, as part of correctly defining the map files.

   **Note:** Remember, the Shape ID column in the -Name data table maps to the Shape ID column in the -XY data table. This means that indicating where the -Name data table resides links it to the -XY data table, so that JMP has everything that it needs to create the map.

---

**Figure 12.34  Map Role Column Property**

7. Click **OK**.

Once the **Map Role** column property has been set up, you can perform your analysis. You want to visually see the differences in office temperatures throughout the floor.

1. Select **Graph > Graph Builder**.
2. Drag and drop **room/office** into the **Map Shape** zone.
   Since you have defined the **Map Role** column property on this column, the map appears.
3. Drag and drop **Fahrenheit** to the **Color** zone.
Figure 12.35  Room/Office Colored by Fahrenheit

Figure 12.36  Room/Office Colored by Fahrenheit and Grouped by Time of Day
Note that only the offices that were part of the study and were created using the Custom Map Creator add-in are displayed. To add the entire floor plan image, the original floor plan graphic was dragged and dropped onto the Graph Builder window to create Figure 12.37.

To view Figure 12.37, select **Help > Sample Data Library** and open S4 Temps.jmp and run the **by Time of Day** script.

**Figure 12.37  Room/Office Map with Original Floor Plan**

There are several scripts provided with the data table that you can run to view the various analysis and modeling that can be performed and visually displayed.

**Boundary Map with Clipped Elements**

Graphical elements (display segments such as reference, grid lines, and contours) can be clipped to conform to the boundaries of a geographical map. The Customize Graph window provides Clip Shape options, where you can select a boundary around which to clip the shape.
Create the Background Map

1. Select Help > Sample Data Library and open Cities.jmp.
2. Select Graph > Graph Builder.
3. Drag the Latitude column to the Y axis.
4. Drag the Longitude column to the X axis.
5. Right-click the graph and select Graph > Background Map.
6. In the Boundaries column, select US States and click OK.
   
   A map of the United States appears on the graph.

Figure 12.38  Unclipped (Left) and Clipped (Right) Reference Lines and Contours
7. Click the Points icon 🗝️ to remove the points.
8. Click the Smoother icon 📊 to remove the smoother.
9. Click the Contour icon 🌋.
   A contour plot appears on the map.

**Figure 12.40** Unclipped Contours on Background Map
Add a Reference Line

1. On the Latitude axis, double-click 45°00' N to open the Y Axis Settings window.
2. In the Reference Lines pane, change the first number in the Value box to “40”.
   For example, in 44°40.11′ N, change “44” to “40”.
3. Click Add and then OK.

Figure 12.41 Unclipped Reference Line

Assign a Clip Shape

1. Right-click the graph and select Customize.
2. Select Reference Lines and select US States from the Clip Shape list.
3. Select Contour, select US States from the Clip Shape list, and click OK.

Figure 12.42 Clipped Reference Line and Contours

Tips:

- The boundaries that appear in the Background Map window are installed in the JMP Maps installation folder. See “Custom Map Files” on page 261 for more information about adding your own boundaries.
- Scripting provides additional options, such as specifying the clipping path in a matrix or string. See the Scripting Guide.
The following legacy platforms are deprecated. A deprecated platform is an older platform that contains features that can be accessed in a newer platform. The charts and plots in this appendix are all available in the Graph Builder platform. These legacy platforms might not be available in future releases of JMP.

### Table A.1 Legacy Platforms

<table>
<thead>
<tr>
<th>Platform</th>
<th>Graph Builder References</th>
</tr>
</thead>
<tbody>
<tr>
<td>Treemap</td>
<td>• “Treemap” on page 90 in the “Graph Builder” chapter</td>
</tr>
<tr>
<td>Chart</td>
<td>• Bar chart examples in Graph Builder Examples</td>
</tr>
<tr>
<td></td>
<td>• Bar, Line, or “Use a Heatmap to Apply Background Colors” on page 88 in the “Graph Builder” chapter</td>
</tr>
<tr>
<td>Overlay Plot</td>
<td>• “Example of an Overlaid Histogram and Ridgeline Chart” on page 143 in the “Graph Builder Examples” chapter</td>
</tr>
<tr>
<td></td>
<td>• “Graph Builder” chapter on page 27</td>
</tr>
</tbody>
</table>

**Treemaps**

Treemaps are useful for observing patterns among groups that have many levels. Use treemaps when your data contains many categories, to visualize many groups.

**Tip:** To create a treemap, consider using Graph Builder. See “Treemap” on page 90 in the “Graph Builder” chapter.

Launch the Treemap platform by selecting **Graph > Legacy > Treemap**.

When you click **OK** in the launch window, a treemap in Graph Builder is created by default. To produce a report in the legacy Treemap platform, you must first deselect the Use Graph Builder platform preference under Files > Preferences > Platforms > Treemap. Documentation for the legacy Treemap platform launch window, report, and options can be found here: https://www.jmp.com/support/help/en/15.2/#page/jmp/legacy-platforms.shtml.
Charts

The Chart platform on the Graph menu charts continuous variables versus categorical variables. The continuous variables are summarized for each categorical level.

If you want to make a plot of individual data points (rather than summaries of data points), we recommend using an overlay plot instead.

**Tip:** To create a chart, consider using Graph Builder. See “Example of an Overlaid Histogram and Ridgeline Chart” on page 143 in the “Graph Builder Examples” chapter.

Launch the Chart platform by selecting **Graph > Legacy > Chart**.

When you click **OK** in the launch window, a chart in Graph Builder is created by default. To produce a report in the legacy Chart platform, you must first deselect the Use Graph Builder platform preference under Files > Preferences > Platforms > Chart. Documentation for the legacy Chart platform launch window, report, and options can be found here:

Overlay Plots

The Overlay Plot option produces plots of a single X column and one or more numeric Ys and does not accept non-numeric values for the y-axis.

**Tip:** To create an overlay plot, consider using the Overlay zone in Graph Builder. See “Example of an Overlaid Histogram and Ridgeline Chart” on page 143 in the “Graph Builder Examples” chapter.

Launch Overlay Plot by selecting **Graph > Legacy > Overlay Plot**.

When you click **OK** in the launch window, an overlay plot in Graph Builder is created by default. To produce a report in the legacy Overlay Plot platform, you must first deselect the Use Graph Builder platform preference under Files > Preferences > Platforms > Overlay Plot. Documentation for the legacy Overlay Plot platform launch window, report, and options can be found here:

Profiling is an approach to visualizing response surfaces by seeing what would happen if you change just one or two factors at a time. Essentially, a profile is a cross-section view. The interactive profilers in JMP promote exploring opportunity spaces. In fitting equations to data, the fitting is only the first step. Interpreting the fit, understanding the fitted response surface, and finding factor values to optimize the responses is desirable.

Overview of the Profiler Platform

The Prediction Profiler displays profile traces (Figure 2.2) for each X variable. A profile trace is the predicted response as one variable is changed while the others are held constant at the current values. The Prediction Profiler recomputes the profiles and predicted responses (in real time) as you vary the value of an X variable.

- The vertical dotted line for each X variable shows its current value or current setting. If the variable is nominal, the X axis identifies categories.

  For each X variable, the value above the factor name is its current value. Change the current value by clicking in the graph or by dragging the dotted line where you want the new current value to be.

- The horizontal dotted line shows the current predicted value of each Y variable for the current values of the X variables.

- The black lines within the plots show how the predicted value changes when you change the current value of an individual X variable. In fitting platforms, the 95% confidence interval for the predicted values is shown by solid blue curves surrounding the prediction trace (for continuous variables) or the height of an error bar (for categorical variables). For continuous variables, the confidence interval region is shaded.

The Prediction Profiler is a way of changing one variable at a time and looking at the effect on the predicted response.

Figure 2.2 Illustration of Traces

The Prediction Profiler in some situations computes confidence intervals for each profiled column. If you have saved both a standard error formula and a prediction formula for the same column, the Prediction Profiler offers to use the standard errors to produce the confidence intervals rather than profiling them as a separate column.
Introduction to Profiling

It is easy to visualize a response surface with one input factor $X$ and one output factor $Y$. It becomes harder as more factors and responses are added. The profilers in JMP provide a number of highly interactive cross-sectional views of any response surface. In this guide we use the following terms interchangeably.

- factor, input variable, $X$ column, independent variable, setting, term
- response, output variable, $Y$ column, dependent variable, outcome

Desirability profiling and optimization features are available to help find good factor settings and produce desirable responses. Most profilers also incorporate multithreading for faster computation. Simulation and defect profiling features are available for when you need to make responses that are robust and high-quality when the factors have variation.

- “Fit Group”

Profiler Features in JMP

There are several profiler facilities in JMP, accessible from a number of fitting platforms and the main menu under Graph. They are used to profile data column formulas.

Table 2.1 Profiler Features Summary

**Profiler Launch Windows**

When a profiler is invoked as a platform from the Graph menu, rather than through a fitting platform, you provide columns with formulas as the Y, Prediction Formula columns. These formulas could have been saved from the fitting platforms.

**Figure 2.3** Profiler Launch Window

For more information about the options in the Select Columns red triangle menu, see *Using JMP*.

The columns referenced in the formulas become the X columns (unless the column is also a Y).

**Y, Prediction Formula**  The response columns containing formulas.

**Noise Factors**  Used only in special cases for modeling derivatives. For more information about noise factors, see “Noise Factors” on page 36.

**Expand Intermediate Formulas**  Tells JMP that if an ingredient column to a formula is itself a formula column that refers to other columns, to substitute the original columns into the inner formula. To prevent an ingredient column from expanding, add an Other column property, name it Expand Formula, and assign a value of 0. See Expand Intermediate Formulas.
The Surface Plot platform is discussed in the “Surface Plot” chapter on page 99. The Surface Profiler is very similar to the Surface Plot platform, except Surface Plot has more modes of operation. Neither the Surface Plot platform nor the Surface Profiler have some of the capabilities common to other profilers.

**Expand Intermediate Formulas**

The Profiler launch window has an Expand Intermediate Formulas check box. When this box is checked, the formula that is being profiled is handled differently. If the profiled formula contains another formula column that references other columns, then the original columns are substituted into the inner formula. Therefore, the formula being profiled is profiled with respect to the original columns instead of the intermediate column references. Expand Intermediate Formula also expands formula columns that have the Vector modeling type.

For example, when Fit Model fits a logistic regression for two levels (A and B), the end formulas (\(\text{Prob[A]}\) and \(\text{Prob[B]}\)) are functions of the \(\text{Lin[x]}\) column, which itself is a function of another column \(x\). If Expand Intermediate Formulas is selected, then when \(\text{Prob[A]}\) is profiled, it is with reference to \(x\), not \(\text{Lin[x]}\).

In addition, using the Expand Intermediate Formulas check box enables the Save Expanded Formulas command in the platform red triangle menu. This creates a new column with a formula, which is the formula being profiled as a function of the end columns, not the intermediate columns.

**Fit Group**

For the REML and Stepwise personalities of the Fit Model platform, if models are fit to multiple \(Y\)'s, the results are combined into a Fit Group report. This enables the different \(Y\)'s to be profiled in the same Profiler. The Fit Group red triangle menu has options for launching the joint Profiler. Profilers for the individual \(Y\)'s can still be used in the respective Fit Model reports.

Fit Group reports are also created when a By variable is specified for a Stepwise analysis. This allows for the separate models to be profiled in the same Profiler.

The Fit Group scripting command can be used to fit models in different platforms, and profile the individual models in the Profiler. See the *Scripting Guide*. 
Interpret the Profiles

The illustration in Figure 2.4 describes how to use the components of the Prediction Profiler. There are several important points to note when interpreting a prediction profile:

- The importance of a factor can be assessed to some extent by the steepness of the prediction trace. If the model has curvature terms (such as squared terms), then the traces might be curved.
- If you change the value of a factor, the prediction trace for that factor is not affected, but the prediction traces of all the other factors can change. The $Y$ response line must cross the intersection points of the prediction traces with their current value lines.

**Note:** If there are interaction effects or cross-product effects in the model, the prediction traces can shift their slope and curvature as you change current values of other terms. That is what interaction is all about. If there are no interaction effects, the traces change only in height, not slope or shape.

Figure 2.4 Changing One Factor from 0 to 0.75

Prediction profiles are especially useful in multiple-response models to help judge which factor values can optimize a complex set of criteria.
Click a graph or drag the current value line right or left to change the factor’s current value. The response values change as shown by a horizontal reference line in the body of the graph. Double-click in an axis to bring up a window that changes its settings.

The Profiler as a Cross-Section

In the following example using Tiretread.jmp, look at the response surface of the expression for MODULUS as a function of SULFUR and SILANE (holding SILICA constant). Now look at how a grid that cuts across SILANE at the SULFUR value of 2.25. Note how the slice intersects the surface. If you transfer that down below, it becomes the profile for SILANE. Similarly, note the grid across SULFUR at the SILANE value of 50. The intersection when transferred down to the SULFUR graph becomes the profile for SULFUR.

Figure 2.5 Profiler as a Cross-Section

Now consider changing the current value of SULFUR from 2.25 to 1.5.
In the Prediction Profiler, note the new value just moves along the same curve for SULFUR, the SULFUR curve itself does not change. But the profile for SILANE is now taken at a different cut for SULFUR. The profile for SILANE is also a little higher and reaches its peak in the different place, closer to the current SILANE value of 50.

**Set or Lock Factor Values**

If you press Alt (Option on macOS) and click in a graph, a window prompts you to enter specific settings for the factor.
For continuous variables, you can specify the following:

**Current Value**  The value used to calculate displayed values in the profiler, equivalent to the red vertical line in the graph.

**Minimum Setting**  The minimum value of the factor’s axis.

**Maximum Value**  The maximum value of the factor’s axis.

**Number of Plotted Points**  Specifies the number of points used in plotting the factor’s prediction traces.

**Show**  Show or hide the factor in the profiler.

**Lock Factor Setting**  Locks the value of the factor at its current setting.

---

### Profiler Platform Options

The Profiler red triangle menu contains the following options:

**Profiler**  Shows or hides the Prediction Profiler.

**Contour Profiler**  Shows or hides the Contour Profiler.

**Custom Profiler**  Shows or hides the Custom Profiler.

**Surface Profiler**  Shows or hides the Surface Profiler.

**Mixture Profiler**  Shows or hides the Mixture Profiler.

**Show Formulas**  Opens a JSL window showing all formulas being profiled.

**Formulas for OPTMODEL**  Creates code for the OPTMODEL SAS procedure. Press Ctrl+Shift and then select **Formulas for OPTMODEL** from the red triangle menu.

The following options are available in many platforms. See *Using JMP*.

**Redo**  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

**Save Script**  Contains options that enable you to save a script that reproduces the report to several destinations.
Common Profiler Topics

- “Linear Constraints”
- “Noise Factors”

Linear Constraints

The Prediction Profiler, Custom Profiler, and Mixture Profiler can incorporate linear constraints into their operations. Linear constraints can be entered in two ways, described in the following sections.

Red Triangle Menu Item

To enter linear constraints via the red triangle menu, select **Alter Linear Constraints** from either the Prediction Profiler or Custom Profiler red triangle menu.

Choose **Add Constraint** from the resulting window, and enter the coefficients into the appropriate boxes. For example, to enter the constraint $p1 + 2p2 \geq 0.9$, enter the coefficients as shown in Figure 2.8. As shown, if you are profiling factors from a mixture design, the mixture constraint is present by default and cannot be modified.

**Figure 2.8 Enter Coefficients**

After you click **OK**, the Profiler updates the profile traces, and the constraint is incorporated into subsequent analyses and optimizations.

If you attempt to add a constraint for which there is no feasible solution, a message is written to the log and the constraint is not added. To delete a constraint, enter zeros for all the coefficients.

Constraints added in one profiler are not accessible by other profilers until saved. For example, if constraints are added under the Prediction Profiler, they are not accessible to the Custom Profiler. To use the constraint, you can either add it under the Custom Profiler red triangle menu, or use the **Save Linear Constraints** command described in the next section.
**Constraint Table Property/Script**

If you add constraints in one profiler and want to make them accessible by other profilers, use the **Save Linear Constraints** command, accessible through the platform red triangle menu. For example, if you created constraints in the Prediction Profiler, choose **Save Linear Constraints** under the Prediction Profiler red triangle menu. The Save Linear Constraints command creates or alters a Table Script called Constraint. An example of the Table Property is shown in Figure 2.9.

*Figure 2.9 Constraint Table Script*

The Constraint Table Property is a list of the constraints, and is editable. It is accessible to other profilers, and negates the need to enter the constraints in other profilers. To view or edit Constraint, right-click the red triangle menu and select **Edit**. The content of the constraint from Figure 2.8 is shown below in Figure 2.10.

*Figure 2.10 Example Constraint*

The Constraint Table Script can be created manually by choosing **New Script** from the red triangle menu beside a table name.

**Note:** When creating the Constraint Table Script manually, the spelling must be exactly “Constraint”. Also, the constraint variables are case sensitive and must match the column name. For example, in Figure 2.10, the constraint variables are \( p_1 \) and \( p_2 \), not \( P_1 \) and \( P_2 \).

The Constraint Table Script is also created when specifying linear constraints when designing an experiment.

The Alter Linear Constraints and Save Linear Constraints commands are not available in the Mixture Profiler. To incorporate linear constraints into the operations of the Mixture Profiler, the Constraint Table Script must be created by one of the methods discussed in this section.
Noise Factors

Note: Noise factor optimization is also available in the Prediction Profiler, Contour Profiler, Custom Profiler, and Mixture Profiler.

Noise factors (robust process engineering) enables you to produce acceptable products reliably, despite variation in the process variables. Even when your experiment has controllable factors, there is a certain amount of uncontrollable variation in the factors that affects the response. This is called transmitted variation. Factors with this variation are called noise factors. Some factors you cannot control at all, like environmental noise factors. The mean for some factors can be controlled, but not their standard deviation. This is often the case for intermediate factors that are output from a different process or manufacturing step.

A good approach to making the process robust is to match the target at the flattest place of the noise response surface. Then, the noise has little influence on the process. Mathematically, this is the value where the first derivatives of each response with respect to each noise factor are zero. JMP computes the derivatives for you.

Figure 2.11 Noise Factor Example

To analyze a model with noise factors:

1. Fit the appropriate model (for example, using the Fit Model platform).
2. Save the model to the data table with the Save > Prediction Formula command.
3. Launch the Profiler (from the Graph menu).
4. Assign the prediction formula to the **Y, Prediction Formula** role and the noise factors to the **Noise Factor** role.

5. Click **OK**.

   The resulting profiler shows response functions and their appropriate derivatives with respect to the noise factors. The derivatives are set to have maximum desirability at zero.

6. Select **Optimization and Desirability > Maximize Desirability** from the **Profiler** menu.

   This finds the best settings of the factors, balanced with respect to minimizing transmitted variation from the noise factors.
The Prediction Profiler gives you a wealth of information about your model. Use the Prediction Profiler to do the following:

- See how your prediction model changes as you change settings of individual factors.
- Set desirability goals for your response or responses, and find optimal settings for your factors.
- Gauge your model’s sensitivity to changes in the factors, where sensitivity is based on your predictive model.
- Assess the importance of your factors relative to model predictions, in a way that is independent of the model.
- Simulate your response distribution based on specified distributions for both factors and responses, and control various aspects of the appearance of the profiler.

Example of the Prediction Profiler

This example uses the Tiretread.jmp sample data table. There are three factors (SILICA, SILANE, and SULFUR) and four responses (ABRASION, MODULUS, ELONG, and HARDNESS). The goal is to find the optimal combination of the three factors in the development of a tire tread compound. See Derringer and Suich (1980).

1. Select Help > Sample Data Library and open Tiretread.jmp.
2. Select Graph > Profiler.
3. Select Pred Formula Abrasion and click Y, Prediction Formula.
4. Click OK.

Figure 3.2 Prediction Profiler Report Window

The profiler is interactive. The vertical red lines correspond to the current value of the factors. The current value of each factor is also shown in red below the horizontal axis. The red value on the vertical axis is the predicted response based on the current values of the factors. Click and drag the vertical red lines to change the current values of the factors. Click a factor’s red value to set the factor to a specific value. Alternatively, you can animate the profiler to cycle through a variety of factor values.

5. Click the Prediction Profiler red triangle and select Factor Settings > Animation.
6. Click the play button to sequentially cycle through the factor values, one factor at a time.
7. Click the Prediction Profiler red triangle and select Optimize and Desirability > Desirability Functions.
8. Click the Prediction Profiler red triangle and select Optimize and Desirability > Maximize Desirability.

Tip: You might need to adjust the vertical axis of the prediction profiler to view the maximum value of ABRASION in the plot.
Launch the Prediction Profiler Platform

The Prediction Profiler can be accessed in the following ways:

- The Prediction Profiler can be accessed directly from the Graph menu. When you access the Prediction Profiler in this way, the Prediction Profiler launch window appears. See “Profiler Launch Windows” on page 28 in the “Introduction to Profilers” chapter.

- The Prediction Profiler can be accessed as a red triangle menu option in many modeling platforms. See “Where to Find JMP Profilers” on page 27 in the “Introduction to Profilers” chapter for more information about the availability of the Prediction Profiler in different platforms.

- The Prediction Profiler can be accessed from the Model Comparisons platform. Select Profiler from the Model Comparisons red triangle menu.

- The Prediction Profiler can be accessed from the Formula Depot platform. Select Profiler from the Formula Depot red triangle menu.

Prediction Profiler Options

The red triangle menu on the Prediction Profiler title bar has the following options:

- **Optimization and Desirability** Submenu that consists of the following options:

  By maximizing the desirability, you see that to maximize ABRASION, all factors are set to their highest levels.
Desirability Functions  Shows or hides the desirability functions. Desirability is discussed in “Desirability Profiling and Optimization” on page 51.

Maximize Desirability  Sets the current factor values to maximize the desirability functions. Takes into account the response importance weights.

Note: In many situations, the settings that optimize the desirability function are not unique. The Maximize Desirability option gives one such setting. The Contour Profiler is a good tool for finding alternative factor combinations that optimize desirability. For an example, see “Explore Optimal Settings” on page 95 in the “Contour Profiler” chapter.

Note: If a factor has a Design Role column property value of Discrete Numeric, it is treated as continuous in the optimization of the desirability function. To account for the fact that the factor can assume only discrete levels, it is displayed in the profiler as a categorical term and an optimal allowable level is selected.

Maximize and Remember  Maximizes the desirability functions and remembers the associated settings.

Maximization Options  Opens the Maximization Options window where you can refine the optimization settings. See “Maximization Options Window” on page 50.

Maximize for Each Grid Point  Used only if one or more factors are locked. The ranges of the locked factors are divided into a grid, and the desirability is maximized at each grid point. This is useful if the model that you are profiling has categorical factors. Then the optimal condition can be found for each combination of the categorical factors.

Save Desirabilities  Saves the three desirability function settings for each response, and the associated desirability values, as a Response Limits column property in the data table. These correspond to the coordinates of the handles in the desirability plots.

Set Desirabilities  Opens the Response Goal window where you can set specific desirability values.

Figure 3.4  Response Goal Window
**Save Desirability Formula**   Creates a column in the data table with a formula for Desirability. The formula uses the fitting formula when it can, or the response variables when it cannot access the fitting formula.

**Assess Variable Importance**   Provides different approaches to calculating indices that measure the importance of factors to the model. These indices are independent of the model type and fitting method. See “Assess Variable Importance” on page 57.

**Bagging**   (Available only when the Prediction Profiler is embedded in select modeling platforms.) Launches the Bagging window. Bootstrap aggregating (bagging) enables you to create multiple training data sets by sampling with replacement from the original data. For each training set, a model is fit using the analysis platform, and predictions are made. The final prediction is a combination of the results from all of the models. This improves prediction performance by reducing the error from variance. See “Bagging” on page 61.

**Simulator**   Launches the Simulator. The Simulator enables you to create Monte Carlo simulations using random noise added to factors and predictions for the model. A typical use is to set fixed factors at their optimal settings, and uncontrolled factors and model noise to random values. You then find out the rate of responses outside the specification limits. See the “Simulator” chapter on page 145.

**Interaction Profiler**   Shows or hides interaction plots that update as you update the factor values in the Prediction Profiler. Use this option to help visualize third degree interactions by seeing how the plot changes as current values for the factors change. The cells that change for a given factor are the cells that do not involve that factor directly.

**Confidence Intervals**   Shows or hides confidence intervals in the Prediction Profiler plot. The intervals are drawn by bars for categorical factors, and curves for continuous factors. The interval values are also displayed on the vertical axis in blue. These are available when the profiler is used inside certain fitting platforms or when a standard error column has been specified in the Prediction Profiler launch dialog.

**Prop of Error Bars**   (Appears when a Sigma column property exists in any of the factor and response variables.) Shows or hides the $3\sigma$ interval that is implied on the response due to the variation in the factor. The interval values are also displayed on the vertical axis in green. Propagation of error (POE) is important when attributing the variation of the response in terms of variation in the factor values when the factor values are not very controllable. See “Propagation of Error Bars” on page 82.

**Sensitivity Indicator**   Shows or hides a purple triangle whose height and direction correspond to the value of the partial derivative of the profile function at its current value. This is useful in large profiles to be able to quickly spot the sensitive cells.
When analyzing a mixture design, JMP constrains the ranges of the factors so that settings outside the mixture constraints are not possible. This is why, in some mixture designs, the profile traces turn abruptly.

When there are mixture components that have constraints, other than the usual zero-to-one constraint, a new submenu, called Profile at Boundary, appears on the Prediction Profiler red triangle menu. It has the following two options:

- **Turn At Boundaries**: Lets the settings continue along the boundary of the restraint condition.
- **Stop At Boundaries**: Truncates the prediction traces to the region where strict proportionality is maintained.

**Extrapolation Control**  Shows a submenu of options for extrapolation control. This feature helps identify possible extrapolated predictions. A prediction is considered an extrapolation when it is made using a combination of factor points that are not within the factor space of the original data. In the extrapolation control feature, the metric used to determine if a point is an extrapolation depends on the type of model fit. For models that are fit in the Standard Least Squares personality of the Fit Model platform, the leverage at the factor settings is used as the extrapolation metric. For all other models, the regularized Hotelling’s $T^2$ value is used as the extrapolation metric. See “Extrapolation Control Metrics” on page 84.

Extrapolation Control is available in profilers embedded in platforms and profilers launched from the Graph menu. The data used for the extrapolation control metrics depends on the type of profiler.
- When a model is built with validation, the embedded profiler and extrapolation control metrics are based on the training data.

- If you launch a profiler from the Graph menu the extrapolation control metrics are based on all data, unless you specifically exclude certain rows.

- When a model is built in a platform that ignores missing values during model fitting, those rows are excluded from the embedded profiler and extrapolation control metrics.

- When a model is built with Informative Missing, the embedded profiler and extrapolation control metrics reflect the informative missing.

- To include informative missing in the extrapolation control metrics when launching the profiler from the Graph menu use the Informative Missing column property.

- If you call Extrapolation Control from a profiler launched from the Graph menu, the regularized Hotelling’s $T^2$ value is always used as the extrapolation metric, regardless of the type of model fit. Therefore, the extrapolation control results from a profiler embedded in the Standard Least Squares platform will not match those from the Graph menu profiler.

The extrapolation control red triangle menu includes options to either warn of possible extrapolation or to restrict the factor settings so that extrapolated predictions are not shown.

**Off** Turns off all extrapolation controls and warnings.

**On** Turns on extrapolation control. When this option is selected, it is indicated at the top of the profiler and the profile traces are restricted to factor combinations that do not lead to extrapolations.

**Warning On** Turns on extrapolation warnings. When this option is selected, it is indicated at the top of the profiler. If a factor combination is selected that produces an extrapolation, an alert appears that reads --Possible Extrapolation--.

**Extrapolation Details** Shows or hides the extrapolation control details above the prediction profiler. The extrapolation control details include the value of the extrapolation metric at the current point, the value of the extrapolation threshold, the type of extrapolation metric, and the definition of the extrapolation threshold.

**Set Threshold Criterion** Opens a window that enables you to adjust the extrapolation threshold. When the extrapolation metric is the leverage at the factor settings, you can specify how the leverage is computed and the value of the corresponding multiplier. When the extrapolation metric is the regularized Hotelling’s $T^2$ value, you can specify the multiplier. See “Extrapolation Control Metrics” on page 84.

**Reset Factor Grid** Displays a window for each factor enabling you to enter a specific value for the factor’s current setting, to lock that setting, and to control aspects of the grid. See the section “Set or Lock Factor Values” on page 32.
Figure 3.6  Factor Settings Window

Factor Settings  Submenu that consists of the following options:

Remember Settings  Adds an outline node to the report that accumulates the values of the current settings each time the Remember Settings command is invoked. Each remembered setting is preceded by a radio button that is used to reset to those settings. There are options to remove selected settings or all settings in the Remember Settings red triangle menu.

Set To Data in Row  Assigns the values of a data table row to the $X$ variables in the Prediction Profiler.

Copy Settings Script  Copies the current Prediction Profiler’s settings to the clipboard.

Paste Settings Script  Pastes the Prediction Profiler settings from the clipboard to a Prediction Profiler in another report.

Append Settings to Table  Appends the current profiler’s settings to the end of the data table. This is useful if you have a combination of settings in the Prediction Profiler that you want to add to an experiment in order to do another run.

Broadcast Factor Settings  Sends the current profiler’s factor settings to all other profilers, but does not link the profilers. A change in a factor in one profiler does not cause changes in any other profilers unless Broadcast Factor Settings is selected again.

Link Profilers  Links all the profilers together. A change in a factor in one profiler causes that factor to change to that value in all other profilers, including Surface Plot. This is a global option, set, or unset for all profilers.

Set Script  Sets a script that is called each time a factor changes. The set script receives a list of arguments of the form:

{factor1 = n1, factor2 = n2, ...}

For example, to write this list to the log, first define a function:
ProfileCallbackLog = Function({arg}, show(arg));

Then enter ProfileCallbackLog in the Set Script dialog.

Similar functions convert the factor values to global values:
ProfileCallbackAssign = Function({arg}, evalList(arg));

Or access the values one at a time:
ProfileCallbackAccess = Function({arg}, f1= arg["factor1"]; f2= arg["factor2"]);

**Unthreaded**  Enables you to change to an unthreaded analysis if multithreading does not work.

**Animation**  Shows or hides animation controls that enable you to easily cycle through a variety of factor settings. See “Animation Controls” on page 49.

**Default N Levels**  Enables you to set the default number of levels for each continuous factor. This option is useful when the Prediction Profiler is especially large. When calculating the traces for the first time, JMP measures how long it takes. If this time is greater than three seconds, you are alerted that decreasing the Default N Levels speeds up the calculations.

**Output Grid Table**  Produces a new data table with columns for the factors that contain grid values, columns for each of the responses with computed values at each grid point, and the desirability computation at each grid point.

If you have a lot of factors, it is impractical to use the Output Grid Table command, because it produces a large table. A memory allocation message might be displayed for large grid tables. In such cases, you should lock some of the factors, which are held at locked, constant values. To get the window to specify locked columns, ALT- or Option-click inside the profiler graph to get a window that has a Lock Factor Setting check box.

**Output Random Table**  Prompts for a number of runs and creates an output table with that many rows, with random factor settings and predicted values over those settings. This is equivalent to (but much simpler than) opening the Simulator, resetting all the factors to a random uniform distribution, then simulating output. This command is similar to Output Grid Table, except it results in a random table rather than a sequenced one.

The prime reason to make uniform random factor tables is to explore the factor space in a multivariate way using graphical queries. This technique is called **Filtered Monte Carlo**.

Suppose you want to see the locus of all factor settings that produce a given range to desirable response settings. By selecting and hiding the points that do not qualify (using
graphical brushing or the Data Filter), you see the possibilities of what is left: the opportunity space yielding the result that you want.

Some rows might appear selected and marked with a red dot. These represent the points on the multivariate desirability Pareto Frontier - the points that are not dominated by other points with respect to the desirability of all the factors.

**Alter Linear Constraints** Enables you to add, change, or delete linear constraints. The constraints are incorporated into the operation of Prediction Profiler. See “Linear Constraints” on page 34.

**Save Linear Constraints** Enables you to save existing linear constraints to a table script called Constraint. See “Linear Constraints” on page 34.

**Conditional Predictions** Appears when random effects are included in the model. The random effects predictions are used in formulating the predicted value and profiles.

**Appearance** Submenu that consists of the following options:

- **Arrange in Rows** Enter the number of plots that appear in a row. This option helps you view plots vertically rather than in one wide row.

  **Note:** To set a default number of plots to appear in a row, go to File > Preferences > Platforms > Profiler and edit the Arrange in Rows preference.

- **Graph Spacing** Opens a window that enables you to set the amount of horizontal space between graph panels.

- **Reorder X Variables** Opens a window where you can reorder the model main effects by dragging them to the desired order.

- **Reorder Y Variables** Opens a window where you can reorder the responses by dragging them to the desired order.

- **Adapt Y Axis** Re-scales the vertical axis if the response is outside the axis range, so that the range of the response is included.

- **Show Creator** Shows or hides the name of the platform that created the formula in the response column. The platform name appears on the vertical axis. (Available only if the response column contains a “Creator” named argument in the “Predicting” column property.)

**Animation Controls**

**Figure 3.7** Animation Controls
**Play/Pause**  Press play to animate the profiler. Moves through a cycle of factor settings and loops back to the beginning when the cycle is complete. Press pause to stop the animation.

**Cycle Type**  Lists the types of cycles for factor settings.

- **Sequential**  Cycles through values for each factor, one factor after another. The name of the factor the animation is currently cycling through is displayed next to the speed slider bar.

- **Single Factor**  Cycles through values for the selected factor while all other factors are held constant. The name of the selected factor is displayed next to the speed slider bar.

- **Random**  Randomly cycles through different combinations of factor settings/values.

- **Data Sequential**  Sets the factor values to a row in the data table, one row at a time, starting with row 1. The row number of the current factor setting is displayed next to the speed slider bar.

- **Data Random**  Sets the factor values to a random row in the data table, one row at a time. The row number of the current factoring setting is displayed next to the speed slider bar.

**Speed Slider Bar**  Use the slider bar to adjust the speed of the animation.

### Maximization Options Window

**Figure 3.8** Maximization Options Window

- **Number of Trips**  The number of random starts in the optimization algorithm. Each trip starts with a randomly chosen value for each of the factors in the model.

- **Maximum Iterations**  The maximum number of steps taken within each trip. If the algorithm does not converge before the maximum iterations is reached, a new trip is started.
**Convergence Tolerance**  The upper limit for the convergence criterion for the optimization algorithm. If the convergence criterion is less than this value for two consecutive iterations, the algorithm stops.

**Maximum Cycles**  (Not applicable if there are linear constraints.) The maximum number of cycles in the algorithm.

**Genetic Algorithm Options**  (Available only if there is a disallowed combination constraint or if one of the extrapolation control features is turned on.) Provides additional options for the genetic algorithm. The genetic algorithm is used only if the solution from the regular optimization algorithm is not feasible.

**Maximum number of iterations**  The maximum number of iterations for the genetic algorithm.

**Convergence Tolerance**  The upper limit for the convergence criterion for the genetic algorithm.

---

**Desirability Profiling and Optimization**

You can define a desirability function for a single response variable or for several response variables. When you are optimizing relative to several responses, there can often be competing criteria. For example, you might want to maximize one response, minimize another, and keep a third response close to some target value.

In desirability profiling, you specify a desirability function for each response. The overall desirability for all responses is defined as the geometric mean of the desirability functions for the individual responses. See Derringer and Suich (1980) for information about combining responses.

To use desirability profiling, select **Optimization and Desirability > Desirability Functions** from the Prediction Profiler red triangle menu.

**Note:** If the response column has a Response Limits property, desirability functions are turned on by default.

This command appends a new row to the bottom of the plot matrix, dedicated to graphing desirability. The row has a plot for each factor showing its desirability trace, as illustrated in Figure 3.9. It also adds a column that has an adjustable desirability function for each $Y$ variable. The overall desirability measure shows on a scale of zero to one at the left of the row of desirability traces.
Construction of Desirability Functions

The individual desirability functions are smooth piecewise functions that pass through three defining points. These points are called control points (Low, Middle, High) and can be used to interactively control the shape of the desirability function.

- The Minimize and Maximize functions are three-part piecewise smooth functions that consist of interpolating cubics between the control points and exponentials in the tails.
- The Target function is a piecewise function that is a scale multiple of a normal density on either side of the Middle value (with different curves on each side), which is also piecewise smooth and fit to the control points. Exponential functions are fit to the tails.
- The None function enables you to specify an arbitrary desirability function. In particular, you can specify desirability to be lower at the Middle value than at the Low and High values. You can also construct custom desirability functions using formulas. See “Customized Desirability Functions” on page 55.

The Low and High control points are not allowed to reach all the way to zero or one. This approach to constructing the desirability functions results in good behavior as the desirability values switch between the maximize, target, and minimize values.

Note: JMP does not use the Derringer and Suich (1980) functional forms. Because they are not smooth, they do not always work well with JMP’s optimization algorithm.

Desirability Function for Multiple Optimization

When multiple responses are to be optimized, an overall desirability function is constructed and optimized. The overall desirability for all responses is defined as the geometric mean of the desirability functions for the individual responses.
Denote the individual desirability functions for \( k \) responses by \( d_1, d_2, \ldots, d_k \). Then the overall desirability function is the geometric mean of the individual desirability functions:

\[
D = \left( \frac{1}{k} \right)^{1/k} \frac{d_1^{1/k}}{d_2^{1/k}} \cdots \frac{d_k^{1/k}}{d_k^{1/k}}
\]

If Importance values are defined as part of the Response Limits column property or are defined in the Response Goal window, they are integrated into the overall desirability function. The Importance values are scaled so that they sum to 1. Denote the scaled importance values by \( w_1, w_2, \ldots, w_k \). Then the overall desirability is defined as a weighted geometric mean of the individual desirability functions:

\[
D = \frac{w_1}{d_1^{1/k}} \frac{w_2}{d_2^{1/k}} \cdots \frac{w_k}{d_k^{1/k}}
\]

**Optimization Algorithm**

The method used for optimization of the overall desirability function, or of the single desirability function if there is only one response, depends on the factor types.

- For categorical factors, a coordinate exchange algorithm is used.
- For continuous factors, a gradient descent algorithm is used.
- In the presence of constraints or mixture factors, a Wolfe reduced-gradient approach is used.
- To reduce the risk of finding local optima, JMP uses multiple random starts.

**How to Use the Desirability Function**

To use a variable’s desirability function, drag the function handles to represent a response value.

As you drag these handles, the changing response value shows in the area labeled Desirability to the left of the plots. The dotted line is the response for the current factor settings. The overall desirability shows to the left of the row of desirability traces. Alternatively, you can select **Optimization and Desirability > Set Desirabilities** to enter specific values for the points.

Figure 3.10 shows steps to create desirability settings.

**Maximize** The default desirability function setting is maximize (“higher is better”). The High control point is positioned at the maximum \( Y \) value and aligned at the high desirability, close to 1. The Low control point is positioned at the minimum \( Y \) value and aligned at a low desirability, close to 0.
Figure 3.10  Maximizing Desirability

<table>
<thead>
<tr>
<th>65.5</th>
</tr>
</thead>
<tbody>
<tr>
<td>61.83655, 69.16345</td>
</tr>
</tbody>
</table>

**Target**    You can designate a target value as “best.” In this example, the middle control point is positioned at \( Y = 70 \) and aligned with the maximum desirability of 1. \( Y \) becomes less desirable as its value approaches either 40 or 100. The High and Low control points at \( Y = 40 \) and \( Y = 100 \) are positioned at the minimum desirability close to 0.

Figure 3.11  Defining a Target Desirability

<table>
<thead>
<tr>
<th>65.5</th>
</tr>
</thead>
<tbody>
<tr>
<td>61.83655, 69.16345</td>
</tr>
</tbody>
</table>

**Minimize** The minimize (“smaller is better”) desirability function associates high response values with low desirability and low response values with high desirability. The curve is the maximization curve flipped around a horizontal line at the center of plot.

Figure 3.12  Minimizing Desirability

<table>
<thead>
<tr>
<th>65.5</th>
</tr>
</thead>
<tbody>
<tr>
<td>61.83655, 69.16345</td>
</tr>
</tbody>
</table>

**Note:** Dragging the High or Low control point of a maximize or minimize desirability function across the \( y \)-value of the middle point results in the opposite point reflecting. A Minimize becomes a Maximize, and vice versa.

**The Desirability Profile**

The last row of plots shows the desirability trace for each factor. The numerical value beside the word Desirability on the vertical axis is the geometric mean of the desirability measures. This row of plots shows both the current desirability and the trace of desirabilities that result from changing one factor at a time.
For example, Figure 3.13 shows desirability functions for two responses. You want to maximize ABRASION and MODULUS. The desirability plots indicate that you could increase the desirability by increasing any of the factors.

**Figure 3.13** Prediction Profile Plot with Adjusted Desirability and Factor Values

![Prediction Profiler](image)

### Customized Desirability Functions

It is possible to use a customized desirability function. For example, suppose you want to maximize using the following function.

**Figure 3.14** Maximizing Desirability Based on a Function

\[
\begin{align*}
\text{Pred Formula ABRASION} &\quad 96 \\
\text{Pred Formula MODULUS} &\quad + 700 \\
\text{Pred Formula ELONG-450} &\quad + 33 \\
\left(\text{Pred Formula HARDNESS-67}\right) &\quad + 1
\end{align*}
\]
First, create a column called Custom Desirability that contains the above formula. Then, select **Graph > Profiler** to launch the platform. Select all the Pred Formula columns and the Custom Desirability column and select **Y, Prediction Formula**. Check the **Expand Intermediate Formula** option. Turn on the desirability functions by selecting **Optimization and Desirability > Desirability Functions** from the red triangle menu. All the desirability functions for the individual effects must be turned off. To do this, first double-click in a desirability plot window, and then select **None** in the window that appears. Set the desirability for Custom Desirability to be maximized.

**Figure 3.15** Selecting No Desirability Goal

At this point, selecting **Optimization and Desirability > Maximize Desirability** uses only the custom Custom Desirability function.
Assess Variable Importance

The Variable Importance report calculates indices that measure the importance of factors in a model in a way that is independent of the model type and fitting method. The fitted model is used only in calculating predicted values. The method estimates the variability in the predicted response based on a range of variation for each factor. If variation in the factor causes high variability in the response, then that effect is important relative to the model.

Note: In some platforms, Assess Variable Importance is not available for categorical responses with more than two levels.

Assess Variable Importance can also be accessed in the Prediction Profiler that is obtained through the Graph menu.

For statistical details, see “Assess Variable Importance” on page 80. See also Saltelli (2002).
Note: Assess Variable Importance requires that all columns reside in the same data table.

The Assess Variable Importance Report

The Assess Variable Importance menu has the following options that address the methodology used in constructing importance indices:

**Independent Uniform Inputs**  For each factor, Monte Carlo samples are drawn from a uniform distribution defined by the minimum and maximum observed values. Use this option when you believe that your factors are uncorrelated and that their likely values are uniformly spread over the range represented in the study. This is the appropriate option for designed experiments that do not involve constraints or mixture factors.

**Independent Resampled Inputs**  For each factor, Monte Carlo samples are obtained by resampling its set of observed values. Use this option when you believe that your factors are uncorrelated and that their likely values are not represented by a uniform distribution.

**Dependent Resampled Inputs**  Factor values are constructed from observed combinations using a $k$-nearest neighbors approach, in order to account for correlation. This option treats observed variance and covariance as representative of the covariance structure for your factors. Use this option when you believe that your factors are correlated. Note that this option is sensitive to the number of rows in the data table. If used with a small number of rows, the results can be unreliable.

Note: The Independent Resampled Inputs and Dependent Resampled Inputs options are intended for observational studies. The Independent option is faster than the Dependent option, but the Dependent option handles multicollinearity better and does not extrapolate into regions far away from the data.

**Linearly Constrained Inputs**  For each factor, Monte Carlo samples are drawn from a uniform distribution over a region defined by linear constraints. The linear constraints can be defined in the Prediction Profiler or constructed in connection with a designed experiment. In addition, the samples are restricted to fall within the minimum and maximum observed values. Use this option in the presence of linear constraints, when you believe that these constraints impact the distribution of the inputs.

The speed of these algorithms depends on the model evaluation speed. In general, the fastest option is Independent Uniform Inputs and the slowest is Dependent Resampled Inputs. You have the option to Accept Current Indices when the estimation process is unable to complete instantaneously.

Note: Variable importance indices are constructed using Monte Carlo sampling. For this reason, you can expect some variation in importance index values from one run to another.
Variable Importance Report

Each Assess Variable Importance option presents a Summary Report and Marginal Model Plots. When the Assess Variable Importance report opens, the factors in the Prediction Profiler are reordered according to their Total Effect importance indices. When there are multiple responses, the factors are reordered according to the Total Effect importance indices in the Overall report. When you run several Variable Importance reports, the factors in the Prediction Profiler are ordered according to their Total Effect indices in the most recent report.

Summary Report

For each response, a table displays the following elements:

- **Column**  The factor of interest.
- **Main Effect**  An importance index that reflects the relative contribution of that factor alone, not in combination with other factors.
- **Total Effect**  An importance index that reflects the relative contribution of that factor both alone and in combination with other factors. The Total Effect column is displayed as a bar chart. See “Weights” on page 59.
- **Main Effect Std Error**  The Monte Carlo standard error of the Main Effect’s importance index. This is a hidden column that you can access by right-clicking in the report and selecting Columns > Main Effect Std Error. By default, sampling continues until this error is less than 0.01. Details of the calculation are given in “Variable Importance Standard Errors” on page 82. (Not available for Dependent Resampled Inputs option.)
- **Total Effect Std Error**  The Monte Carlo standard error of the Total Effect’s importance index. This is a hidden column that you can access by right-clicking in the report and selecting Columns > Total Effect Std Error. By default, sampling continues until this error is less than 0.01. Details of the calculation are given in “Variable Importance Standard Errors” on page 82. (Not available for Dependent Resampled Inputs option.)
- **Weights**  A plot that shows the Total Effect indices, located to the right of the final column. You can deselect or reselect this plot by right-clicking in the report and selecting Columns > Weights.
- **Proportion of function evaluations with missing values**  The proportion of Monte Carlo samples for which some combination of inputs results in an inestimable prediction. When the proportion is nonzero, this message appears as a note at the bottom of the table.

**Note:** When you have more than one response, the Summary Report presents an Overall table followed by tables for each response. The importance indices in the Overall report are the averages of the importance indices across all responses.
Marginal Model Plots

The Marginal Model Plots report (Figure 3.37) shows a matrix of plots, with a row for each response and columns for the factors. The factors are ordered according to the size of their overall Total Effect importance indices.

For a given response and factor, the plot shows the mean response for each factor value, where that mean is taken over all inputs to the calculation of importance indices. These plots differ from profiler plots, which show cross sections of the response. Marginal Model Plots are useful for assessing the main effects of factors.

Note that your choice of input methodology impacts the values plotted on marginal model plots. Also, because the plots are based on the generated input settings, the plotted mean responses might not follow a smooth curve.

The red triangle menu options enable you to show or hide the following aspects of the plots:

**Estimate**  A smoothed estimate of the mean of the simulated values calculated as a function of the factor values.

*Note:* The estimates of the mean are simulated, so the values change when you rerun the analysis.

**Confidence Interval**  A 95% confidence band for the simulated means. This band is often narrow and might not be visible unless you expand the scale. Not available for Dependent Resampled Inputs.

*Note:* The confidence bounds are simulated, so the bands change when you rerun the analysis.

**Data**  The actual (unsimulated) values of the response plotted against the factor values.

Variable Importance Options

The Variable Importance red triangle menu contains the following options:

**Reorder factors by main effect importance**  Reorders the cells in the Prediction Profiler in accordance with the importance indices for the main effects (Main Effect).

**Reorder factors by total importance**  Reorders the cells in the Prediction Profiler in accordance with the total importance indices for the factors (Total Effect).

**Colorize Profiler**  Colors cells in the profiler by Total Effect importance indices using a red to white intensity scale.

*Note:* You can click rows in the Summary Report to select columns in the data table. This can facilitate further analyses.
Bagging

Bootstrap aggregating (bagging) is a technique to improve predictive performance while also gaining insight into the reliability of predictions. Bagging is especially useful in unstable methods, including neural networks, classification trees, and regression trees.

Bagging creates $M$ training data sets by sampling with replacement from the original data. All training data sets are of the same size as the original. For each training data set, a model is fit using the analysis platform, and predictions are made. Therefore, there are a total of $M$ predictions for each observation in the original data set. The final prediction is the average of the $M$ predictions.

Bagging is available in many analysis platforms. To use bagging, select **Save Bagged Predictions** from the Prediction Profiler red triangle menu. A window appears with the following options for Bagging:

**Number of Bootstrap Samples**  Sets the number of times that you want to resample the data and build a model. A larger number results in more precise predictions. By default, the number of bootstrap samples is 100.

**Random Seed**  Sets a random seed that you can re-enter in subsequent runs of the bagging analysis to duplicate your current results. By default, no seed is set.

**Fractional Weights**  Performs a Bayesian bagging analysis. In each bootstrap iteration, each observation is assigned a nonzero weight. The model that makes the predictions uses the weighted observations. By default, the Fractional Weights option is not selected, and a simple bagging analysis is conducted.

**Tip:** Use the Fractional Weights option if the number of observations that are used in your analysis is small or if you are concerned about separation in a logistic regression setting.

Suppose that Fractional Weights is selected. For each bootstrap iteration, each observation that is used in the report is assigned a nonzero weight. These weights sum to $n$, the number of observations used in the model. For more information about how the weights are calculated and used, see “Calculation of Fractional Weights” on page 375 in the “Bootstrapping” chapter.

**Save Prediction Formulas**  For each bagged prediction, this option saves the formula used to make that prediction in the column properties. This option is available in only a subset of the analysis platforms that offer bagging.

**Note:** If Save Prediction Formulas is not available, a note appears, stating that only the predicted values will be saved.
Bagging automatically creates new columns in the original data table. All $M$ sets of bagged predictions are saved as hidden columns. The final prediction is saved in a column named “Pred Formula <colname> Bagged Mean”. The standard deviation of the final prediction is saved in a column named “<colname> Bagged Std Dev”. The standard error of the bagged mean is saved in a column named “StdError <colname> Bagged Mean.” The standard error is the standard deviation divided by $\sqrt{M-1}$. Here, <colname> identifies the column in the report that was bagged.

The standard error gives insight about the precision of the prediction. A very small standard error indicates a precise prediction for that observation. For more information about bagging, see Hastie et al. (2009).

Figure 3.17 Bagging Columns

Additional Examples of the Prediction Profiler

This section contains additional examples illustrating various aspects of the Prediction Profiler platform and the Prediction Profiler embedded in many analysis platforms.

- “Example of Desirability Profiling for Multiple Responses”
- “Example of a Noise Factor in the Prediction Profiler”
- “Example of Variable Importance for One Response”
- “Example of Variable Importance for Multiple Responses”
- “Example of Bagging to Improve Prediction”
- “Example of Bagging to Indicate the Accuracy of Predictions”

Example of Desirability Profiling for Multiple Responses

A desirability index becomes especially useful when there are multiple responses. The idea was pioneered by Derringer and Suich (1980), who give the following example. Suppose there are four responses, ABRASION, MODULUS, ELONG, and HARDNESS. Three factors, SILICA, SILANE, and SULFUR, were used in a central composite design.

1. Select Help > Sample Data Library and open Tiretread.jmp.
2. Click the green triangle next to RSM for 4 Responses to run the script. This script defines a model for the four responses with a full quadratic response surface. The summary tables and effect information appear for all the responses, followed by the prediction profiler shown in Figure 3.18.

**Figure 3.18** Prediction Profiler for Multiple Responses before Optimization

Note the following about the desirability functions:
- Maximum ABRASION and maximum MODULUS are most desirable.
- ELONG target of 500 is most desirable.
- HARDNESS target of 67.5 is most desirable.

3. Select **Optimization and Desirability > Maximize Desirability** from the Prediction Profiler red triangle menu to maximize desirability.
Figure 3.19 Prediction Profiler after Optimization

The desirability traces at the bottom decrease everywhere except the current values of the effects, which indicates that any further adjustment could decrease the overall desirability.

Example of a Noise Factor in the Prediction Profiler

This example uses the Tiredtread.jmp sample data set. This data set shows the results of a tire manufacturer’s experiment whose objective is to match a target value of HARDNESS= 70 based on three factors: SILICA, SILANE, and SULFUR content. Suppose the SILANE and SULFUR content are easily (and precisely) controllable, but SILICA is not easily controlled.

For comparison, first optimize the factors for hardness without considering variation from the noise factor, SILICA.

1. Select Graph > Profiler to launch the Prediction Profiler.
2. Assign Pred Formula HARDNESS to the Y, Prediction Formula role.
3. Click OK.
4. Click the Prediction Profiler red triangle and select Optimization and Desirability > Desirability Functions.
5. Click the Prediction Profiler red triangle and select Optimization and Desirability > Set Desirabilities to open the Response Goal window.
Tip: Alternatively, you can double-click in the Desirability plot to open the Response Goal window.

6. Select Match Target from the list and click OK.

7. Click the Prediction Profiler red triangle and select Optimization and Desirability > Maximize Desirability to find the optimum factor settings for the target value of HARDNESS.

We get the following Prediction Profiler display. Notice that the SILICA factor’s optimum value is on a sloped part of a profile curve. This means that variations in SILICA settings impact the response, HARDNESS.

Note: You might get different results from these because different combinations of factor values can all hit the target.

Figure 3.20 Maximizing Desirability for HARDNESS

Now, we would like to not just optimize for a specific target value of HARDNESS, but also find a setting that is insensitive to the variability in the setting of Silica. Repeat the optimization process with SILICA as a noise factor.

1. Select Graph > Profiler.
2. Select Pred Formula HARDNESS and click Y, Prediction Formula.
3. Select SILICA and click Noise Factors.
4. Click OK.
5. Select Optimization and Desirability > Desirability Functions in the Prediction Profiler menu.
6. Double-click in the Desirability plot for the response Pred Formula HARDNESS to open the Response Goal window.

7. Select **Match Target** from the list and click **OK**.

   The resulting profiler has the appropriate derivative of the fitted model with respect to the noise factor, set to be maximized at zero, its flattest point.

**Figure 3.21** Derivative of the Prediction Formula with Respect to Silica

8. Click the Prediction Profiler red triangle and select **Optimization and Desirability > Maximize Desirability** to find the optimum values for the process factor, balancing for the noise factor.

   This time, we have also hit the targeted value of HARDNESS, but our value of SILICA is on its flatter region. This means variation in SILICA does not transmit as much variation to HARDNESS as when it was set at a value on the steep part of the SILICA curve.
Figure 3.22 Maximize Desirability

You can see the effect of accounting for the SILICA variation on the variance of the predictions by following these steps for each profiler (one without the noise factor, and one with the noise factor):

1. In the Profiler without the noise factor, click the Prediction Profiler red triangle and select Simulator.

2. Assign SILICA to have a random Normal distribution with a standard deviation of 0.05. Use the default setting for the mean.
Figure 3.23 Setting a Random Normal Distribution

3. Click Simulate.
4. Click the Simulate to Table gray triangle and then click the Make Table button.
5. Rename the Pred Formula HARDNESS column to Without Noise Factor.
6. In the Profiler with the noise factor, click the Prediction Profiler red triangle and select Simulator.
7. Assign SILICA to have a random Normal distribution with a standard deviation of 0.05. Use the default setting for the mean.
8. Click Simulate.
9. Click the Simulate to Table gray triangle and then click the Make Table button.

Completing these steps for both the original and noise-factor-optimal simulations results in two similar data tables, one for each simulation. We want to compare the distributions of the predicted hardness from the two simulations. To facilitate the comparison we put the two prediction columns in a single data table.

1. Select the Pred Formula HARDNESS column in the current simulation table and select Edit > Copy With Full Precision.
2. In the other current simulation table, select Cols > New Columns.
3. Type With Noise Factor next to Column Name and click OK.
4. Select the With Noise Factor column and select Edit > Paste.
5. Select Analyze > Distribution.
7. Click OK.
8. Click the Distribution red triangle and select Uniform Scaling.

**Figure 3.24** Comparison of Distributions with and without Noise Factors

The histograms show that there is much more variation in predicted Hardness when the noise factor was not included in the analysis.

It is also interesting to note the shape of the histogram when the noise factor was included. In the comparison histograms above, note that the With Noise Factor distribution has data trailing off in only one direction. The skewness in the With Noise Factor is clear if you deselect Uniform Scaling from the Distributions red triangle menu. The predictions are skewed because Hardness is at a minimum with respect to SILICA, as shown in Figure 3.25. Therefore, variation in SILICA can make only HARDNESS increase. When the non-robust solution is used, the variation could be transmitted either way.

**Figure 3.25** Prediction Profiler Showing the Minima of HARDNESS by SILICA
Example of Variable Importance for One Response

The Boston Housing.jmp sample data table contains data on 13 factors that might relate to median home values. You fit a model using a neural network. Because neural networks do not accommodate formal hypothesis tests, these tests are not available to help assess which variables are important in predicting the response. However, for this purpose, you can use the Assess Variable Importance profiler option.

Note that your results might differ from, but should resemble, those shown here. There are two sources of random variability in this example. When you fit the neural network, $k$-fold cross validation is used. This partitions the data into training and validation sets at random. Also, Monte Carlo sampling is used to calculate the factor importance indices.

1. Select Help > Sample Data Library and open Boston Housing.jmp.
2. Select Analyze > Predictive Modeling > Neural.
3. Select mvalue from the Select Columns list and click Y, Response.
4. Select all other columns from the Select Columns list and click X, Factor.
5. Click OK.
6. In the Neural Model Launch panel, select KFold from the list under Validation Method. When you select KFold, the Number of Folds defaults to 5.
7. (Optional) Enter 123 next to Random Seed.

**Note:** Results vary due to the random nature of choosing a validation set in the Neural Network model. Entering the seed above enables you to reproduce the results shown in this example.

8. Click Go.
9. Click the red triangle next to Model NTanH(3) and select Profiler.
   The Prediction Profiler is displayed at the very bottom of the report. Note the order of the factors for later comparison.
   Because the factors are correlated, you take this into account by choosing Dependent Resampled Inputs as the sampling method for assessing variable importance.
10. Click the Prediction Profiler red triangle and select Assess Variable Importance > Dependent Resampled Inputs.
   The Variable Importance: Dependent Resampled Inputs report appears. Check that the Prediction Profiler cells have been reordered by the magnitude of the Total Effect indices in the report. In Figure 3.26, check that the Total Effect importance indices identify rooms and lstat as the factors that have most impact on the predicted response.
Figure 3.26  Dependent Resampled Inputs Report

You might be interested in comparing the importance indices obtained assuming that the factors are correlated, with those obtained when the factors are assumed independent.

11. Click the Prediction Profiler red triangle and select **Assess Variable Importance > Independent Resampled Inputs**.

The resampled inputs option makes sense in this example, because the distributions involved are not uniform. The Variable Importance: Independent Resampled Inputs report is shown in Figure 3.27. Check that the two factors identified as having the most impact on the predicted values are lstat and radial.

Figure 3.27  Independent Resampled Inputs Report
Example of Variable Importance for Multiple Responses

The data in the Tiretread.jmp sample data table are the result of a designed experiment where the factors are orthogonal. For this reason, you use importance estimates based on independent inputs. Suppose that you believe that, in practice, factor values vary throughout the design space, rather than assume only the settings defined in the experiment. Then you should choose Independent Uniform Inputs as the sampling scheme for your importance indices.

1. Select Help > Sample Data Library and open Tiretread.jmp.
2. Run the script RSM for 4 Responses.
   The Prediction Profiler is displayed at the very bottom of the report.
3. Click the Prediction Profiler red triangle and select Assess Variable Importance > Independent Uniform Inputs.
   The Summary Report is shown in Figure 3.28. Because the importance indices are based on random sampling, your estimates might differ slightly from those shown in the figure.
   The report shows tables for each of the four responses. The Overall table averages the factor importance indices across responses. The factors in the Prediction Profiler (Figure 3.29) have been reordered to match their ordering on the Overall table’s Total Effect importance.

Figure 3.28  Summary Report for Four Responses
4. Click the red triangle next to Variable Importance: Independent Uniform Inputs and select **Colorize Profiler**.

Colors from a red to white intensity scale are overlaid on profiler panels to reflect Total Effect importance. For example, you easily see that the most important effect is that of Silane on Hardness.

**Figure 3.29** Prediction Profiler for Four Responses

The Marginal Model Plots report shows mean responses for each factor across a uniform distribution of settings for the other two factors.

**Figure 3.30** Marginal Model Plots for Four Responses
Example of Bagging to Improve Prediction

Bagging is used in a number of situations. One situation is to improve predictive power. Bagging is especially helpful for unstable models. This example uses the Tiretread.jmp sample data table. There are three factors (SILICA, SILANE, and SULFUR) and four responses (ABRASION, MODULUS, ELONG, and HARDNESS). First, you fit a neural network model to simultaneously predict the four response variables as a function of the three factors. Then, you perform bagging on the neural network model. Last, you compare the predictions to show the improvements obtained through bagging.

Fit Neural Network Model

1. Select Help > Sample Data Library and open Tiretread.jmp.
2. Select Analyze > Predictive Modeling > Neural.
3. Select ABRASION, MODULUS, ELONG, and HARDNESS and click Y, Response.
4. Select SILICA, SILANE, and SULFUR and click X, Factor.
5. Click OK.
6. (Optional) Enter 2121 next to Random Seed.

**Note:** Results vary due to the random nature of choosing a validation set in the Neural Network model. Entering the seed above enables you to reproduce the results shown in this example.

7. Click Go.
8. Click the red triangle next to Model NTanH(3) and select Save Formulas.

**Note:** This option saves the predicted values for all response variables from the neural network model to the data table. Later, these values are compared to the predictions that are obtained from bagging.

Perform Bagging

Now that the initial model has been constructed, you can perform bagging using that model. Access the Bagging feature through the Prediction Profiler.

1. Click the red triangle next to Model NTanH(3) and select Profiler.
   The Prediction Profiler appears at the bottom of the report.
2. Click the Prediction Profiler red triangle and select Save Bagged Predictions.
3. Enter 100 next to Number of Bootstrap Samples.
4. (Optional) Enter 2121 next to Random Seed.
Note: Results vary due to the random nature of sampling with replacement. To reproduce the exact results in this example, set the Random Seed.

5. Click OK.

Return to the data table. For each response variable, there are three new columns denoted as Pred Formula <colname> Bagged Mean, StdError <colname> Bagged Mean, <colname> Bagged Std Dev. The Pred Formula <colname> Bagged Mean columns are the final predictions.

Figure 3.31 Columns Added to Data Table After Bagging

Compare the Predictions

To see how bagging improves predictive power, compare the predictions from the bagged model to the original model predictions. Use the Model Comparison platform to look at one response variable at a time.

1. Select Analyze > Predictive Modeling > Model Comparison.
2. Select Predicted ABRASION and click Y, Predictors.
3. Select Pred Formula ABRASION Bagged Mean and click Y, Predictors.
4. Click OK.

A window that contains a list of columns appears.

5. Select ABRASION and click OK.
6. Click the Model Comparison red triangle and select Plot Actual by Predicted.
Figure 3.32 Comparison of Predictions for ABRASION

The Measures of Fit report and the Actual by Predicted Plot are shown in Figure 3.32. The predictions that were obtained from bagging are shown in blue. The predictions that were obtained from the original neural network model are shown in red. In general, the bagging predictions are closer to the line than the original model predictions. Because the bagging predictions are closer to the line, the RSquare value of 0.8379 for the bagged predictions is higher than the RSquare value for the original model predictions. You conclude that bagging improves predictions for ABRASION.

This example compared the predictions for ABRASION. To compare predictions for another response variable, follow step 2 through step 6, replacing ABRASION with the desired response variable. As another example, Figure 3.33 shows the Measures of Fit report for HARDNESS. The report shows similar findings as the Measures of Fit report for ABRASION. The RSquare value for the bagged predictions is slightly higher than the RSquare value for the original model predictions, which indicates a better fit and improved predictions.
Example of Bagging to Indicate the Accuracy of Predictions

Bagging is also used to indicate the accuracy of the prediction through standard errors and other distributional measures. In platforms where the Save Predicted Formulas option is available in Bagging, you can make predictions on new observations and determine how accurate they are. The Save Predicted Formulas option is available in the Standard Least Squares, Generalized Regression, and Generalized Linear Models platforms.

In the Tiretread.jmp data table, suppose that you are interested in only predicting ABRASION as a function of the three factor variables. In this example, you fit a generalized regression model to predict ABRASION. Then, you perform bagging on that model. Last, you make a prediction for a new observation and investigate the accuracy of that prediction. This is done by obtaining a confidence interval for the prediction.

Fit a Generalized Regression Model

1. Select Help > Sample Data Library and open Tiretread.jmp.
2. Select Analyze > Fit Model.
3. Select ABRASION and click Y.
4. Select Generalized Regression from the Personality list.
5. Select SILICA, SILANE, and SULFUR and click Macros > Full Factorial.

This adds all terms, including interactions, to the model.
6. Click Run.
7. Click Go.

</tbody>
</table>

**Perform Bagging**

1. Click the red triangle next to Normal Lasso with AICc Validation and select **Profilers > Profiler**.
   - The Prediction Profiler appears at the bottom of the report.
2. Click the Prediction Profiler red triangle and select **Save Bagged Predictions**.
3. Enter 500 next to Number of Bootstrap Samples.
4. (Optional) Enter 4321 next to Random Seed.
   - **Note:** Results vary due to the random nature of sampling with replacement. To reproduce the exact results in this example, set the Random Seed.
5. Confirm that **Save Prediction Formulas** is selected.
6. Click **OK**.
   - **Note:** This might take longer to run than the “Example of Bagging to Improve Prediction” on page 74. The larger number of samples gives a better estimate of the prediction distributions.

Return to the data table. For each response variable, there are three new columns denoted as Pred Formula <colname> Bagged Mean, StdError <colname> Bagged Mean, <colname> Bagged Std Dev. The Pred Formula ABRASION Bagged Mean column is the final prediction.
Prediction for a New Observation

You now have predictions for ABRASION for each observation in the data table, as well as the standard errors for those predictions. Suppose that you have an observation with new values of 0.9, 43, and 2 for SILICA, SILANE, and SULFUR, respectively. You can predict the ABRASION response and obtain a confidence interval for that prediction because the Save Prediction Formulas option saves the regression equation for each bagged model. Therefore, \( M \) predictions are made with the new factor values to create a distribution of possible predictions. The mean is the final prediction, but analyzing the distribution tells you how accurate the prediction is.

1. In the data table, select **Rows > Add Rows**.
2. Enter 1 in the **How many rows to add** box and click **OK**.
3. Under the **SILICA** column, type 0.9 in the box for the new row.
4. Under the **SILANE** column, type 43 in the box for the new row.
5. Under the **SULFUR** column, type 2 in the box for the new row.

All of the prediction columns for the new row are automatically calculated.

**Figure 3.35  Values for New Row**

6. Select **Tables > Transpose**.
7. Select ABRASION Bags (500/0) and click **Transpose Columns**.
8. Click **OK**.
9. Select **Analyze > Distribution**.
10. Select Row 21 and click **Y, Columns**.
11. Click **OK**.

12. Click the red triangle next to Row 21 and select **Display Options > Horizontal Layout**.

**Figure 3.36** Distribution Report

The Distribution Report in Figure 3.36 contains information about the distribution of the predicted values of ABRASION from each bagged model. The final prediction of ABRASION for the new observation is 112.3, which is the mean of all the $M$ bagged predictions. This prediction has a standard error of 6.39. You can also create confidence intervals for the new prediction using the quantiles. For example, a 95% confidence interval for the new prediction is 100.85 to 127.93.

**Statistical Details for the Prediction Profiler**

- “Assess Variable Importance”
- “Propagation of Error Bars”
- “Extrapolation Control Metrics”

**Assess Variable Importance**

The details that follow relate to the how the variable importance indices are calculated.
Background

Denote the function that represents the predictive model by \( f \), and suppose that \( x_1, x_2, \ldots, x_n \) are the factors, or main effects, in the model. Let \( y = f(x_1, x_2, \ldots, x_n) \).

- The expected value of \( y \), \( E(y) \), is defined by integrating \( y \) with respect to the joint distribution of \( x_1, x_2, \ldots, x_n \).
- The variance of \( y \), \( \text{Var}(y) \), is defined by integrating \( (y - E(y))^2 \) with respect to the joint distribution of \( x_1, x_2, \ldots, x_n \).

Main Effect

The impact of the main effect \( x_j \) on \( y \) can be described by \( \text{Var}(E(y \mid x_j)) \). Here the expectation is taken with respect to the conditional distribution of \( x_1, x_2, \ldots, x_n \) given \( x_j \) and the variance is taken over the distribution of \( x_j \). In other words, \( \text{Var}(E(y \mid x_j)) \) measures the variation, over the distribution of \( x_j \), in the mean of \( y \) when \( x_j \) is fixed.

It follows that the ratio \( \frac{\text{Var}(E(y \mid x_j))}{\text{Var}(y)} \) gives a measure of the sensitivity of \( y \) to the factor \( x_j \). The importance index in the Main Effect column in the Summary Report is an estimate of this ratio (see “Adjustment for Sampling Variation” on page 82).

Total Effect

The Total Effect column represents the total contribution to the variance of \( y = f(x_1, x_2, \ldots, x_n) \) from all terms that involve \( x_j \). The calculation of Total Effect depends on the concept of functional decomposition. The function \( f \) is decomposed into the sum of a constant and functions that represent the effects of single variables, pairs of variables, and so on. These component functions are analogous to main effects, interaction effects, and higher-order effects. See Saltelli (2002); Sobol (1993).

Those component functions that include terms containing \( x_j \) are identified. For each of these, the variance of the conditional expected value is computed. These variances are summed. The sum represents the total contribution to \( \text{Var}(y) \) due to terms that contain \( x_j \). For each \( x_j \), this sum is estimated using the selected methodology for generating inputs. The importance indices reported in the Total Effect column are these estimates (see “Adjustment for Sampling Variation” on page 82).

Consider a simple example with two factors, \( x_1 \) and \( x_2 \). Then the Total Effect importance index for \( x_1 \) is an estimate of the following:

\[
\frac{\text{Var}(E(y \mid x_1)) + \text{Var}(E(y \mid x_1, x_2))}{\text{Var}(y)}
\]
Adjustment for Sampling Variation

Due to the fact that they are obtained using sampling methods, the Main Effect and Total Effect estimates shown in the Summary Table might have been adjusted. Specifically, if the Total Effect estimate is less than the Main Effect estimate, then the Total Effect importance index is set equal to the Main Effect estimate. If the sum of the Main Effect estimates exceeds one, then these estimates are normalized to sum to one.

Variable Importance Standard Errors

The standard errors that are provided for independent inputs measure the accuracy of the Monte Carlo replications. Importance indices are computed as follows:

- Latin hypercube sampling is used to generate a set of data values.
- For each set of data values, main and total effect importance estimates are calculated.
- This process is replicated until the estimated standard errors of the Main Effect and Total Effect importance indices for all factors fall below a threshold of 0.01.

The standard errors that are reported are the standard error values in effect when the replications terminate.

Propagation of Error Bars

Propagation of error (POE) is important when attributing the variation of the response in terms of variation in the factor values when the factor values are not very controllable.

In JMP’s implementation, the Prediction Profiler first looks at the factor and response variables to see whether there is a Sigma column property (a specification for the standard deviation of the column, accessed through the Cols > Column Info dialog box). If the property exists, then the Prop of Error Bars command becomes accessible in the Prediction Profiler drop-down menu. This displays the $3\sigma$ interval that is implied on the response due to the variation in the factor.
Figure 3.37  Green Propagation of Errors Bars in the Prediction Profiler

The POE is represented in the graph by a green bracket. The bracket indicates the prediction plus or minus three times the square root of the POE variance. The POE variance can be expressed as follows:

\[
\sum_{i=1}^{N} \left( \sigma_{x_i}^2 \times \left( \frac{\partial f}{\partial x_i} \right)^2 \right) + \sigma_y^2
\]

where \(\sigma_y\) is the user-specified sigma for the response column, and \(\sigma_x\) is the user-specified sigma for the factor column.

Currently, these partial derivatives are calculated by numerical derivatives:

centered, with \(\delta=\text{xrange}/10000\)

POE limits increase dramatically in response surface models when you are over a more sloped part of the response surface. One of the goals of robust processes is to operate in flat areas of the response surface so that variations in the factors do not amplify in their effect on the response.
Extrapolation Control Metrics

Leverage

In models that are fit in the Standard Least Squares personality of the Fit Model platform, the leverage at the factor settings is used as the extrapolation metric.

The leverage of the \(i\)th observation, \(h_{ii}\), is the \(i\)th diagonal entry of the matrix \(X(X'X)^{-1}X'\), sometimes called the hat matrix. The leverage for a new prediction point is calculated as
\[
h_{\text{pred}} = x'_{\text{pred}}(X'X)^{-1}x_{\text{pred}}.\]
The following two criteria can be used to determine if a prediction with leverage \(h_{\text{pred}}\) is an extrapolation:

- \(h_{\text{pred}} > K \times \max(h_{ii})\), where \(K\) is a customizable multiplier
- \(h_{\text{pred}} > L \times p/n\), where \(L\) is a customizable multiplier, \(p\) is the number of variables, \(n\) is the number of observations, and \(p/n\) is the average leverage

You can use the Set Threshold Criterion option to specify which criterion is used and the value of the multiplier. The default values of the multipliers are \(K = 1\) and \(L = 3\).

Note: Extrapolation control on profilers run from the graph menu using a saved least squares model do not implement the leverage methodology. Instead, the Regularized Hotelling’s \(T^2\) methodology is used.

Regularized Hotelling’s \(T^2\)

In models other than least squares models, the Regularized Hotelling’s \(T^2\) value is used as the extrapolation metric. The \(T^2\) value for the training data and \(T^2\) values for the prediction points are calculated as follows:
\[
T^2 = (x - \bar{x})^\top \Sigma^{-1} (x - \bar{x})
\]
\[
T^2_{\text{pred}} = (x_{\text{pred}} - \bar{x})^\top \Sigma^{-1} (x_{\text{pred}} - \bar{x})
\]

where \(\Sigma\) is the Schafer and Strimmer regularized covariance matrix estimator estimated on the training data. The target matrix used for the Schafer Strimmer estimator is a diagonal covariance matrix. See Schafer and Strimmer (2005). In platforms that train models using observations with missing values, the covariance matrix is estimated with pairwise deletion.

Note: Categorical variables are converted to indicator variables for these calculations.

The calculation of the threshold depends on the number of nonmissing \(T^2\) values computed on the training data.

- If there are ten or more nonmissing \(T^2\) values, the threshold is set as follows:
\[ \overline{T^2} + K \hat{\sigma}_{T^2} \]

where

- \( K \) is a customizable multiplier and is set to 3 by default
- \( \hat{\sigma}_{T^2} \) is the standard deviation of the \( T^2 \) values.

- If there are less than ten nonmissing \( T^2 \) values, the threshold is set using an \( F \) distribution quantile equivalent to a \( K \sigma \) limit.

\[ Q_{T^2}(q) \]

where

- \( q = \Phi(K) \)
- \( \Phi(\cdot) \) is the standard normal distribution
- \( K \) is a customizable multiplier and is set to 3 by default

\[ T^2 \sim \frac{(n + 1)(n - 1)p}{n(n - p)} F(p, n - p) \]

- \( p \) is the number of parameters
- \( n \) is the number of nonmissing \( T^2 \) values

Overview of the Contour Profiler

The Contour Profiler shows plots of response contours for two factors at a time. Multiple contour plots for different combinations of factors can be viewed at the same time. Factors can be set to specific values to show how this affects the contours. The interactive contour profiling facility is useful for optimizing response surfaces graphically. Separate surface plots for each response are also available. Figure 4.2 shows an example of the Contour Profiler for the Tiretread.jmp sample data.

Figure 4.2 Contour Profiler

Example of the Contour Profiler

This example uses the Tiretread.jmp sample data table. There are three factors (SILICA, SILANE, and SULFUR) and four responses (ABRASION, MODULUS, ELONG, and HARDNESS). This data table already contains saved prediction formula columns for the four response variables.

1. Select Help > Sample Data Library and open Tiretread.jmp.
2. Select **Graph > Contour Profiler**.
3. Select Pred Formula ABRASION, Pred Formula MODULUS, Pred Formula ELONG, and Pred Formula HARDNESS and click **Y, Prediction Formula**.
4. Click **OK**.
5. Click the Contour Profiler red triangle and select **Multiple Contour Frames**.
6. Under Horizontal Factor, select SILICA and under Vertical Factor, select SULFUR.
7. Click **OK**.

On both contour plots, the values for SILICA are on the horizontal axis. The values for SILANE and SULFUR are on the vertical axes. In the first contour plot, the value for SULFUR is fixed at 2.25. In the second contour plot, the value for SILANE is fixed at 50 (Figure 4.2).

8. Click the **Current X** box for SULFUR and type 2. Click anywhere outside the box to set the value.
9. In the **Lo Limit** box for Pred Formula ABRASION, type 100.
10. In the **Hi Limit** box for Pred Formula ABRASION, type 160.
11. Click anywhere outside the box to update the plot.

**Figure 4.3** Contour Profiler for Tiretread.jmp
The contour lines in the first contour plot differ from those in Figure 4.2 because SULFUR is set at a different value. This can be seen in the placement of the horizontal line at 2 in the second contour plot. Move the slider bar for SULFUR to see how different values further change the contour lines in the first contour plot. Move the slider bar for SILANE to see how different values change the contour lines in the second contour plot. The shaded area on the contour plots represent the regions of the graphs that are not feasible, based on the Lo Limit and Hi Limit values for ABRASION.

Launch the Contour Profiler Platform

The Contour Profiler can be accessed in the following ways:

- The Contour Profiler can be accessed directly from the Graph menu. When you access the Contour Profiler in this way, the Contour Profiler launch window appears. See “Profiler Launch Windows” on page 28 in the “Introduction to Profilers” chapter.

- The Contour Profiler can be accessed as a red triangle menu option in many modeling platforms. See “Where to Find JMP Profilers” on page 27 in the “Introduction to Profilers” chapter for more information about the availability of the Contour Profiler in different platforms.

- The Contour Profiler can be accessed from the Model Comparisons platform. Select Profiler from the Model Comparisons red triangle menu. Then, select Contour Profiler from the Profiler red triangle menu.

- The Contour Profiler can be accessed from the Formula Depot platform. Select Profiler from the Formula Depot red triangle menu and select the models to be profiled. Then, select Contour Profiler from the Profiler red triangle menu.

The Contour Profiler Report

The initial Contour Profiler report shows a contour profiler plot, factor settings and controls, and response settings and controls. The colored lines on the graph are the contours for the responses set by the Y slider controls or by entering values in the Contour column. There is a separately colored contour for each response. For each contour, there is a dotted line in the direction of higher response values, so that you get a sense of direction. To change the factor assignments to the horizontal and vertical axes of a contour plot, click the red triangle on the axis and select a factor. If you select the factor that is on the opposite axis, the factor assignments are interchanged.

- “Factor Settings and Controls”
- “Response Settings and Controls”
Factor Settings and Controls

**Factor**  The list of factors.

**Current X**  The current factor settings. Click in a box to change the value of a factor or use the slider controls. Right-click the slider control and select **Rescale Slider** to change the scale of the slider. When one value is changed, the values for the other factors remain the same, but the values in the response settings and controls report change accordingly. The **Current X** location is shown by the crosshair lines on the graph.

**Lock**  A column that appears for mixture designs with more than three predictors. This column enables you to lock settings for mixture values so that they are not changed when the mixture needs to be adjusted due to other mixture effects being changed. When locked columns exist, the shaded area for a mixture recognizes the newly restricted area.

**Figure 4.4** Lock Column

![Lock Column](image)

**Note:** If one or more of the factors have specification limits, a dotted rectangle is drawn on the contour plot to show the joint spec limit range.

Response Settings and Controls

**Response**  The list of one or more responses, with a color legend. To change the color of a response, right-click the color legend for that response.

**Contour**  The current value of the contour on the contour profiler. Click in the box to change the value. The slider control can also be used to change the value of the contour.

**Current Y**  The predicted response based on the current X settings. The value is at the red line on the slider control. This value updates as the factor settings are changed.

**Lo Limit**  Enables you to set a lower limit for your response. Click in a box to set the limit or click the left triangle of the slider control for that response. If a response column’s Spec Limits column property has a value for Lower Spec Limit, that value is used as the initial value for Lo Limit.
**High Limit**  Enables you to set an upper limit for your response. Click in a box to set the limit or click the right triangle of the slider control for that response. If a response column’s Spec Limits column property has a value for Upper Spec Limit, that value is used as the initial value for Hi Limit.

When response limits are used, the profiler shows regions that are not feasible as shaded in the contour profiler plot.

**Note:** If your response has a Response Probability column property, the High Limit is automatically set to 0.5. In this case, the shaded region is the region where that response level is predicted.

---

### Contour Profiler Platform Options

**Grid Density**  Sets the density of the mesh plots in the surface plots.

**Graph Updating**  Contains options to change the frequency of updates for the graph. (The difference might not be noticeable on a fast machine.) The following two options are available:

- **Per Mouse Move**  Updates the graph continuously as you drag the mouse. This is the default setting.
- **Per Mouse Up**  Updates the graph each time the mouse is released.

**Surface Plot**  Shows or hides the mesh plots.

**Contour Label**  Shows or hides a label for the contour lines. The label colors match the contour colors.

**Contour Grid**  Draws contours on the Contour Profiler plot at intervals that you specify.

**Remove Contour Grid**  Enables you to remove a contour grid once one is drawn.

**Factor Settings**  Provides a submenu of commands that enables you to save and transfer the Contour Profiler’s settings to other parts of JMP. See “Factor Settings” on page 47 in the “Profiler” chapter.

**Simulator**  Launches the Simulator. See the “Simulator” chapter on page 145.

**Up Dots**  Shows or hides dotted lines that correspond to each contour. The dotted lines show the direction of increasing response values.

**Set Contours to Current**  Resets the contour lines to be where the current Y values are located. This means that all contour lines cross where the crosshairs are on the contour plot and the controls agree in the Y sliders.
**Arrange X Controls Left**  Rearranges the X and Y controls horizontally with the X controls on the left or vertical with the X controls at the top.

**Hide X Controls**  Shows or hides the X controls (Factor Settings and Controls).

**Hide Y Controls**  Shows or hides the Y controls (Response Settings and Controls).

**Multiple Contour Frames**  Enables you to add one or more contour plots to the report that represent different combinations of factor settings. When you select this option, the Multiple Contour Frames dialog appears. Use the dialog to specify additional individual contour plots or a matrix of contour plots. You can specify a lower triangular, upper triangular, or full square matrix of contour frames. By default, the new contour plots will be added to the current contour plots in the report. Click the **Remove previous frames** check box to remove the current contour plots and replace them with your new selections.
Constraint Shading Settings

If you specify limits for the response columns, the areas of the plot that are outside of the feasible region are shaded. The unshaded white area represents the feasible region.

**Figure 4.5 Settings for Contour Shading**

Additional Example of the Contour Profiler

**Explore Optimal Settings**

Desirability functions are often used to determine the optimal settings for a response surface. The Maximize Desirability feature in the Prediction Profiler provides one combination of factor level settings that results in a predicted response that optimizes the desirability. However, there are often many factor level combinations that can optimize the desirability function. The Contour Profiler is a useful tool for finding alternative settings that optimize desirability.
This example uses the Bounce Data.jmp data table, which contains data for a tire tread experiment. The response, Stretch, is a function of three variables, Silica, Silane, and Sulfur. A model is built and the optimal settings are determined such that the value of Stretch maximizes the desirability function using the Maximize Desirability option in the Prediction Profiler. You use the Contour Profiler to explore other optimal settings for the specified value of Stretch.

1. Select Help > Sample Data Library and open Design Experiment/Bounce Data.jmp.
2. Click the green triangle next to the Model script, and then click Run in the launch window.
3. Click the Prediction Profiler red triangle and select Optimization and Desirability > Maximize Desirability.

The value of Stretch that maximizes the desirability function is 450. One combination of factor level settings that results in a predicted Stretch of 450 is Silica = 1.0101, Sulfur = 2.0437, and Silane = 43.5792.

4. Click the Response Stretch red triangle and select Factor Profiling > Contour Profiler.

To ensure that your new setting combinations maximize desirability, you want to make sure that the settings predict Stretch within 2 units of 450. In addition, you would like a high level of Silane, a fixed value of 60.
The initial plot shows the contour values of Silica and Sulfur for Stretch at 425 and Silane at 50.

5. In the response controls, set the Contour value for Stretch to 450. Set the Lo Limit and High Limit for Stretch to 448 and 452, respectively. Press Enter.

6. Set the Current X for Silane to 60.
The values on the solid red curve are the Silica and Sulfur values that predict Stretch to be 450. The values within the unshaded band predict values of Stretch between 448 and 452. You can drag the crosshairs that appear on the plot to the unshaded sections to find specific settings for Silica and Sulfur. One such setting is seen in Figure 4.8.
A surface plot is a three-dimensional plot with one or more dependent variables represented by a smooth surface. You can display up to four dependent variables on the same surface plot.

JMP produces surface plots in the following two situations:

- The Surface Plot platform creates a stand-alone report that contains a surface plot for formulas. The formulas can be formula columns in your data table or mathematical formulas that do not involve any data points.
- The Surface Profiler option in many model fitting platforms produces a surface plot for the fitted model in the existing platform report.

Overview of the Surface Plot and Surface Profiler

The Surface Plot and Surface Profiler platforms are used to plot points and surfaces in three dimensions.

Surface plots are available as a separate platform (Graph > Surface Plot) and as options in many reports (known as the Surface Profiler). The surface plot functionality is similar in both situations.

The plots can be of points or surfaces or both. When the points are visible in the surface plot, the points are linked to the data table. You can click the points or use the Brush tool to select rows in the data table. The colors and markers assigned in the data table are also reflected in the surface plot.

Surfaces can be defined by a mathematical equation, or through a set of points defining a polygonal surface. Each surface can be displayed as a smooth surface or as a mesh, with or without contour lines. The labels, axes, and lighting for the surface plot are fully customizable.

The Surface Plot is built using the 3D scene commands from the JMP Scripting Language (JSL). When you right-click in the surface plot, the pop-up menu contains Open GL Scene commands. For more information about the Open GL Scene commands, see the Scripting Guide.

Example of the Surface Plot Platform

This example uses the Tiretread.jmp sample data table. There are three factors (SILICA, SILANE, and SULFUR) and four responses (ABRASION, MODULUS, ELONG, and HARDNESS). This data table already contains saved prediction formula columns for the four response variables. Use these prediction formula columns to examine the surfaces of two of the response variables.

1. Select Help > Sample Data Library and open Tiretread.jmp.
2. Select Graph > Surface Plot.
3. Select Pred Formula ABRASION and Pred Formula MODULUS, click Columns, and then click OK.
Initially, only the prediction surface for ABRASION appears in the plot. Note that in the Independent Variables report, there is a large difference between the values for ABRASION and MODULUS. The two responses are on different scales.

4. In the Dependent Variables report, select **Both Sides** from the Surface list for Pred Formula MODULUS.

5. Click the Surface Plot red triangle and select **Scale response axes independently**.
Figure 5.3 Prediction Surface for ABRASION and MODULUS

Pred Formula ABRASION is on one Z axis and Pred Formula MODULUS is on the other Z axis. Each response has its own scale. In this plot, the two factors considered are SILICA and SILANE. You can rotate the surface plot by clicking and dragging inside the graph. This enables you to view the prediction surfaces from different perspectives. For example, in Figure 5.4, you can see that predictions for ABRASION and MODULUS based on the two listed predictors have a similar surface shape, just on a different scale. Use the Independent Variables controls to see how different combinations of predictors affect the surface plot.

Tip: To see the original view after rotating, right-click anywhere on the surface plot and select Reset.
Figure 5.4 Rotated Prediction Surfaces

Launch the Surface Plot Platform

The Surface Plot Profiler can be accessed in the following ways:

- To launch the Surface Plot Profiler platform directly, select Surface Plot from the Graph menu. If there is a data table open, this displays the window in Figure 5.5. If you do not want to use a data table for drawing surface plots, click OK without specifying any columns. If there is no data table open, you are presented with the default surface plot shown in Figure 5.13.

- The Surface Plot Profiler can be accessed as a red triangle menu option in many modeling platforms. In the red triangle menus, it is referred to as Surface Profiler. See “Where to Find JMP Profilers” on page 27 in the “Introduction to Profilers” chapter for more information about the availability of the Surface Profiler in different platforms.

- The Surface Plot Profiler can be accessed from the Model Comparisons platform. Select Profiler from the Model Comparisons red triangle menu. Then, select Surface Profiler from the Profiler red triangle menu.

- The Surface Plot Profiler can be accessed from the Formula Depot platform. Select Profiler from the Formula Depot red triangle menu and select the models to be profiled. Then, select Surface Profiler from the Profiler red triangle menu.
**Figure 5.5** Surface Plot Launch Window

**Columns**  Specifies the columns that you want to plot. Only numeric variables can be assigned to the Columns role.

**By**  Specifies a variable to create separate surface plots for each level of the variable.

**Scale response axes independently**  Assigns a separate scale to each response on the surface plot.

**Note:** When not selected, the axis scale for all responses is the same as the scale for the first item entered in the Columns role.
The Surface Plot Report

The initial Surface Plot report shows the surface plot, the appearance controls, the Independent Variables controls, and the Dependent Variables controls. If more than one prediction formula column is specified, only the first surface is displayed in the initial report. However, if more than one observed response column is specified, all points are displayed in the initial report.

Figure 5.6 Example of the Surface Plot Report

The Surface Plot

The surface plot has the following controls and settings:

**Rotate**  Click anywhere that the cursor appears with a circular arrow icon on the surface plot and drag to rotate the plot in any direction.

*Note:* The Up, Down, Left, and Right arrow keys can also be used to rotate the plot.

**Axis Settings**  Double-click an axis to reveal the axis settings window. The axis settings window enables you to change the scale, tick mark increment, and axis label settings. Like
other JMP graphs, the axes can be adjusted, stretched, and compressed using the grabber tool. Hover over an axis to use the grabber tool.

**Lights**  By default, the plot has lights shining on it. There are eight control knobs on the plot for changing the position and color of the lights. This is useful for highlighting different parts of a plot and creating contrast. Four of the eight knobs are shown in Figure 5.7.

You can perform the following actions to adjust the lights shining on the surface:

- Right-click a knob to turn that light on or off. More lights turned on brighten a plot, and fewer lights darken it.
- Drag a knob to change the position of a light.
- Change the color of a light by right-clicking on the knob. The default color is white.

**Figure 5.7 Control Knobs for Lights**

![Activated light](image)

**Activated light**  Light is off. Right-click knob to turn it on.

Right-click the border to reset lights.

Light is off. Right-click knob to turn it on.

**Appearance Controls**

If you select the Surface Profiler option from the red triangle menu of a modeling platform, the Appearance Control options are different than the Appearance Controls in the stand-alone Surface Plot platform. See Figure 5.8 for an example of what the Appearance Controls look like in a modeling platform.

**Surface Plot Appearance Controls**

The set of controls in the top right of the report enables you to specify the overall appearance of the surface plot.

**Sheet, points**  The setting for displaying sheets, points, and lines.

**Isosurface**  Changes the display to show isosurfaces. See “Plotting Isosurfaces” on page 116.

**Show formula**  Shows the formula edit box, which enables you to edit the formula of the surface. The formula edit box appears only if you specified a column that contains a formula in the launch window.
Resolution A slider that affects how many points are evaluated for a formula. If the resolution is too coarse, a function with a sharp change might not be represented very well. However, if the resolution is set too high, evaluating and displaying the surface is slower than for lower resolutions.

Surface Profiler Appearance Controls

Figure 5.8 Appearance Controls

The Appearance Controls in modeling platforms contain the following controls:

- **data points are** Contains the following options that control the appearance of the data points:
  - **Off** Turns the data points off.
  - **Surface plus Residual** Shows the difference between the predicted value and actual value on the surface.
  - **Actual** Shows the actual data points.
  - **Residual** Shows the residual values (if they are not off the plot).

- **Resolution** A slider that affects how many points are evaluated for a formula. If the resolution is too coarse, a function with a sharp change might not be represented very well. However, if the resolution is set too high, evaluating and displaying the surface is slower than for lower resolutions.

- **Orthogonal Projection** Changes the view of the graph, such that the axes form right angles.

- **Contour** Determines the placement of the contour lines on the plot in relation to the surface. Options are off, below, above, and on surface.

Independent Variables

The Independent Variables report contains the following controls:

- **X, Y** Radio buttons that enable you to select which independent variables are displayed on the x- and y-axes. This feature is useful when you have more than two independent variables.
Value  The sliders and text boxes set the current values of each variable. These settings are most important for the variables that are not displayed on the axes. The plot shows the three-dimensional slice of the surface at the value shown in the text box. Move the slider to see different slices.

Lock Z Scale  Locks the Z axis to its current values. This is useful when moving the sliders that are not on an axis.

Grid  Selecting a check box activates a grid that is perpendicular to the selected variables axis. The sliders enable you to adjust the placement of each grid. The resolution of each grid can be controlled by adjusting axis settings. Figure 5.9 shows a surface with the X and Y grids activated.

Figure 5.9 Activated X and Y Grids

Dependent Variables

The Dependent Variables controls that are available depend on whether you have selected Sheet, points or Isosurface in the Appearance Controls.

Controls for Sheet and Points

The Dependent Variables controls that appear by default when Sheet, points is selected are shown in Figure 5.6.

Formula  Enables you to select one or more formulas that are displayed as surfaces in the plot.
**Point Response Column** Enables you to select the column that contains values that are plotted as points.

**Style** (Menus appear only after you have selected a Point Response Column.) The Style menu enables you to choose how the points are displayed. The menu has the following options:

- **Points** Shows individual points, which change according to the color and marker settings of the row in the data table.

- **Needles** Draws lines from the $x$-$y$ plane to the points, or, if a surface is also plotted, connects the surface to the points.

- **Mesh** Connects the points into a triangular mesh.

- **Surface** Overlays a smooth, reflective surface on the points.

- **Off** Points are not shown at all.

**Surface** Enables you to show or hide the top or bottom of a surface. If **Above only** or **Below only** is selected, the opposite side of the surface is darkened.

**Grid, Grid Value** Provides a slider and check box that activate a grid for the dependent variable. You can use the slider to adjust the value at which the grid is drawn. You can also enter the value into the Grid Value text box above the slider.

**Controls for Isosurface**

Most of the controls for Isosurface are identical to those of Sheet, points. Figure 5.10 shows the default controls, illustrating the slightly different presentation.

**Figure 5.10** Dependent Variable Controls for Isosurfaces

**Value** Slider and text box that activate an isosurface for the dependent variable. You can use the slider to adjust the value at which the isosurface is drawn. You can also enter the value into the text box next to the slider.
Surface Plot Platform Options

The Surface Plot red triangle menu contains the following options:

**Control Panel**  Shows or hides the Control Panel, which includes the controls for Appearance, Independent Variables, and Dependent Variables.

**Scale response axes independently**  Scales response axes independently. See “Launch the Surface Plot Platform” on page 104.

**Fit to Window**  Determines whether the plot is resized as you resize the report window.

- **Auto (default)**  Bases the scaling on the contents of the plot. For example, a plot with By variables or used as a Surface Profiler in a Fit Model platform does not stretch to fit the resized window; the plot extends beyond the viewing area.

- **On**  Always fits the plot inside the window.

- **Off**  Prevent the plot from resizing.

See *Using JMP* for more information about the following options:

**Local Data Filter**  Shows or hides the local data filter that enables you to filter the data used in a specific report.

**Redo**  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

**Save Script**  Contains options that enable you to save a script that reproduces the report to several destinations.

**Save By-Group Script**  Contains options that enable you to save a script that reproduces the platform report for all levels of a By variable to several destinations. Available only when a By variable is specified in the launch window.

Pop-Up Menu Options

You can right-click in the plot area to reveal the following pop-up menu options:

**Sheet Properties**  (Option appears only if you right-click the sheet.) Displays the Sheet Properties window. Available only if Sheet, points is selected in the Appearance Controls. See “Sheet or Surface Properties” on page 113.

**Surface Properties**  (Options appears only if you click the surface.) Displays the Surface Properties window. Available only if Isosurface is selected in the Appearance Controls. See “Sheet or Surface Properties” on page 113.
**Show Legend**  Shows or hides a legend.

**Reset**  Resets the plot to the original viewpoint. Changes in wall and background color are not affected.

**Settings**  Opens a window for changing many plot settings. For more information about the OpenGL Scene commands, see the *Scripting Guide*.

**Figure 5.11** OpenGL View Settings

![OpenGL View Settings](image)

**Hide Lights Border**  Shows or hides lighting controls.

**Wall Color**  Enables you to change the plot wall color.

**Background Color**  Enables you to change the plot background color.

**Rows**  Enables you to change row colors or markers, and also exclude, hide, and label points.

**Use Hardware Acceleration**  Provides for faster rendering of the display. For example, if the plot redraws slowly when rotating, this option can help it redraw faster.

**Show ArcBall**  Provides options for using the ArcBall. The ArcBall is a sphere drawn around the plot to help visualize the directions of rotation.

### Dependent Variables Options

The Dependent Variables red triangle menu provides the following options:

**Formula**  Shows or hides the Formula column in the Dependent Variables controls.

**Surface**  Shows or hides the Surface column in the Dependent Variables controls.

**Points**  Shows or hides the Point Response Column column in the Dependent Variables controls.

**Response Grid**  Shows or hides the Grid controls.
Sheet or Surface Properties

If you have selected the Sheet, points option in the Appearance Controls, you can right-click the sheet inside the plot and select Sheet Properties to reveal a window that enables you to change the sheet properties. If you are plotting an Isosurface, right-click the surface and select Surface Properties to reveal a similar window. The Sheet Properties and Surface Properties windows enable you to modify the appearance of the surface plot, including the surface color, opacity, and contours. You can also show or hide a mesh that appears on the surface plot.

Figure 5.12 Sheet Properties Window

- **Surface** Enables you to show or hide the top or bottom of a surface. If Above only or Below only is selected, the opposite side of the surface is darkened.
- **Fill Type** Enables you to color the surface using a solid color, or continuous or discrete gradients.
- **Solid Color** (Available only when Solid is selected for Fill Type.) Enables you to choose a color for the surface.
- **Surface Fill** (Available only when a gradient is selected for Fill Type.) Specifies the dependent variable’s surface to which the fill type is applied. When Continuous Gradients is selected for Fill Type, you can also choose the Custom option for Surface Fill.
- **Custom** (Available only when Continuous Gradients is selected for Fill Type and when Custom is selected for Surface Fill.) Enables you to specify an equation that defines a response value. This equation is specified using JSL and can refer to columns in the data table using column scoping.
- **Surface Color Theme** (Available only when a gradient is selected for Fill Type.) Enables you to change the color theme for the surface or define a custom color theme. For more information about color themes, see Using JMP.
- **Gradient Levels** (Available only when Discrete Gradients is selected for Fill Type.) Enables you to specify the number of different colors used on the surface plot.
**Surface Color Range** (Available only when a gradient is selected for Fill Type.) Enables you to choose the endpoints for the color gradient. If you choose Data, the endpoints of the color gradient are determined by the range of the data in the column selected for Surface. If you choose Axis, the endpoints of the color gradient are determined by the range of the axis for the dependent variable.

**Caution:** If you choose Axis for Surface Color Range and change the endpoints of the axis in the surface plot, the cutoff values for the color gradient change as well.

**Lighting** Enables you to change the lighting of the surface plot. Choose between None, Low Reflection, and Normal.

**Mesh** Enables you to turn on or off a surface mesh, for either the X or Y directions or both.

**Mesh Color** (Available only when a value other than Off is selected for Mesh.) Enables you to select the color for the surface mesh.

**Contour** Enables you to turn on or off a contour grid, either above, below, or on the surface. If turned on, the Contour Color option is revealed enabling you to change the color.

**Contour Color** (Available only when a value other than Off is selected for Contour.) Enables you to select the color for the contour grid.

**Limit X and Y to Point Response Column** Enables you to limit the range of the plot to the range of the data in the Point Response Column, if one is activated. If checked, this option essentially restricts the plot from extrapolating outside the range of the data in the Point Response Column.

**Note:** The equivalent JSL command for this option is `Clip Sheet( Boolean )`. You can send this message to a particular response column by appending the number of the response column. For example, `Clip Sheet2( 1 )` limits the range of the plot to the range of the data of the second response column. See the Scripting Index in the JMP Help menu for an example.
Keyboard Shortcuts

The following keyboard shortcuts can be used to manipulate the surface plot.

<table>
<thead>
<tr>
<th>Key</th>
<th>Function</th>
</tr>

Additional Examples of the Surface Plot Platform

- “Construct a Surface Plot for a Single Mathematical Function”
- “Plotting Isosurfaces”

Construct a Surface Plot for a Single Mathematical Function

You can use the Surface Plot platform to produce the graph of a mathematical function without any data points.

1. Select **Graph > Surface Plot**.
   
   **Note:** This can be done with or without a data table open.

2. Click **OK**.
   
   When you click OK in the Surface Plot launch window without selecting any columns, the default surface plot report appears. If no data tables are open, the launch window does not appear and this step can be skipped.

3. In the Appearance Controls, select the **Show Formula** check box to show the formula space.
Figure 5.13 Default Surface Plot with Formula

The default function shows in the box. To plot your own function, enter it in this box.

Plotting Isosurfaces

Isosurfaces are the 3-D equivalent to a 2-D contour plot. An isosurface requires a formula with three independent variables. The Resolution slider determines the $n \times n \times n$ cube of points over which the formula is evaluated. The Value slider in the Dependent Variable section selects the isosurface (that is, the contour level) value.
This example uses the Tiretread.jmp data table. The RSM for 4 Responses script produces a response surface model for dependent variables ABRASION, MODULUS, ELONG, and HARDNESS. The predicted formulas for these four responses are in the data table.

1. Select Help > Sample Data Library and open Tiretread.jmp.
2. Select Graph > Surface Plot.
3. Select Pred Formula ABRASION, Pred Formula MODULUS, and Pred Formula ELONG and click Columns.
4. Click OK.
5. Select the Isosurface radio button in the appearance controls.
6. In the Dependent Variables report, select Both Sides from the Surface menu for all three variables.

**Figure 5.14**  Isosurface of Three Variables

For the tire tread data, one might set the abrasion at a fixed minimum setting and the elongation at a fixed maximum setting. Use the MODULUS slider to see which values of MODULUS are inside the limits set by the other two surfaces.
Surface Plot
Additional Examples of the Surface Plot Platform
The Mixture Profiler displays response contours on a ternary plot for mixture models, where three or more factors in the model are components (ingredients) in a mixture. The Mixture Profiler is useful for visualizing and optimizing response surfaces resulting from mixture experiments.

Overview of the Mixture Profiler

The Mixture Profiler shows response contours on a ternary plot for mixture models, where three or more factors in the model are components (ingredients) in a mixture. The Mixture Profiler is useful for visualizing and optimizing response surfaces resulting from mixture experiments.

Many of the Mixture Profiler features are similar to those of the Contour Profiler as described in “Contour Profiler Platform Options” on page 93. Unique to the Mixture Profiler is the use of a ternary plot.

Ternary Plot Overview

A ternary plot is a two-dimensional representation of three mixture components that sum to a constant. The plot is an equilateral triangle with an edge for each component. When unconstrained, each vertex of the triangle corresponds to a pure blend where one component is 1 (100%) and all other components are 0. When components are constrained, the feasible mixtures are represented by a portion of the ternary plot. Shading is used to exclude infeasible portions of the plot.

Figure 6.2 displays three components P1, P2, and P3. The three components are unconstrained with the range of each proportion ranging from 0 to 1 (100%). Three points are labeled with their coordinates (P1, P2, P3). One point (0.2, 0.2, 0.6) includes blue lines along the axis grid lines for each mixture component to guide you in reading the axes.
Ternary Plots with More Than Three Components

The ternary plot can display only three components at a time. For a model with more than three components, the total of the three on-axis (displayed) components is 1 minus the total of the off-axis (non-displayed) components. The plot axes are scaled such that the maximum value a component can attain is 1 minus the total for the off-axis components.

Figure 6.3 shows the Mixture Profiler Ternary Plot for an experiment with 5 factors. The Five Factor Mixture.jmp data table is being used, with the Y1 Predicted column as the formula. The on-axis factors are x1, x2, and x3, and the factors x4 and x5 are off-axis. There are no constraints on any of the mixture components. Note that all Lo Limit values are set to 0 and all Hi Limit values set to 1. The value for x4 is 0.1 and the value for x5 is 0.2, for a total of 0.3. The sum of x1, x2, and x3 is equal 1 – 0.3 = 0.7. Note that the maximum value for a plot axis is now 0.7, not 1.

If you change the value for either x4 or x5, then the values for x1, x2, and x3 change, maintaining their relative proportions, to accommodate the constraint that factor values sum to 1.
Example of the Mixture Profiler

This example uses the Plasticizer.jmp sample data table. There are three mixture components (p1, p2, and p3) and one response (Y). There are constraints on the component levels. This data table already contains a saved prediction formula column for the response.

1. Select Help > Sample Data Library and open Plasticizer.jmp.
2. Select Graph > Mixture Profiler.
4. Select Y from the Y, Prediction Formula role and click Remove.

Note: The Y column role is set to Y in the Columns list. The role automatically assigns columns in launch windows. In this case, the Y column was assigned to the Y role when the mixture profiler was launched. However, the Y column does not contain a formula, and the Mixture Profiler Y column requires a formula column.
5. Click **OK**.

**Figure 6.4** Example of Mixture Profiler

Use the factor sliders to explore how changes impact the response. The unshaded region is the feasible region for this data set.

---

**Launch the Mixture Profiler Platform**

The Mixture Profiler can be accessed in the following ways:

- **The Mixture Profiler can be accessed directly from the Graph menu.** When you access the Mixture Profiler in this way, the Mixture Profiler launch window appears. See “Profiler Launch Windows” on page 28 in the “Introduction to Profilers” chapter.

- **The Mixture Profiler can be accessed as a red triangle menu option in many modeling platforms.** See “Where to Find JMP Profilers” on page 27 in the “Introduction to Profilers” chapter for more information about the availability of the Mixture Profiler in different platforms.
The Mixture Profiler can be accessed from the Model Comparisons platform. Select Profiler from the Model Comparisons red triangle menu. Then, select Mixture Profiler from the Profiler red triangle menu.

The Mixture Profiler can be accessed from the Formula Depot platform. Select Profiler from the Formula Depot red triangle menu and select the models to be profiled. Then, select Mixture Profiler from the Profiler red triangle menu.

The Mixture Profiler Report

The initial Mixture Profiler report shows a mixture profiler plot, factor settings and controls, and response settings and controls.

T, L, R  Radio buttons to control factor assignments to the axes in the mixture profiler plot. T = top, L = left, and R = right.

Factor  The list of factors.

Current X  The current factor settings. Click in a box to change the value of a factor. The values for the other factors adjust proportionally to maintain the mixture sum. The slider controls can also be used to change factor settings.

Lo Limit  The lower limit on each factor. Click in a box to change the value.

Hi Limit  The upper limit on each factor. Click in a box to change the value.

Note: When factor limits are used, the profiler shows regions that are feasible as unshaded.

Change  Opens the Factor Settings window. See “Mixture Profiler Platform Options” on page 126.
Response Settings and Controls

Figure 6.6  Response Settings and Controls

</tbody>
</table>

**Response**  The list of one or more responses.

**Contour**  The current value of the contour on the mixture profiler. Click in the box to change the value. The slider control can also be used to change the value of the contour.

**Current Y**  The predicted response based on the current X settings. The value is at the center of the cross hairs on the profiler plot. This value updates as the factor settings are changed.

**Lo Limit**  Enables you to set a lower limit for your response.

**Hi Limit**  Enables you to set an upper limit for your response.

**Note:** When response limits are used, the profiler shows regions that are feasible as unshaded.

Mixture Profiler Platform Options

**Specify Factor Values**  Opens a dialog for specifying factor values. The entered values should sum to 1. If needed, JMP adjusts the specified values to feasible settings. The option is also available from the Change button on the report window.

**Show Points**  Shows or hides the individual points on the plot.

**Show Current Value**  Shows or hides the three-way crosshairs on the plot. The intersection of the crosshairs represents the current factor values. The Current X values above the plot give the exact coordinates of the crosshairs.

**Show Constraints**  Shows or hides the shading resulting from any constraints on the factors. Those constraints can be entered in the Lo Limits and Hi Limits columns above the plot, or in the Mixture Column Property for the factors.

**Up Dots**  Shows or hides the dotted lines corresponding to each contour. The dotted lines show the direction of increasing response values, so that you get a sense of direction.

**Contour Grid**  Draws contours on the plot at intervals that you specify.

**Remove Contour Grid**  Removes the contour grid if one is on the plot.
**Factor Settings**  A submenu of commands that enables you to save and transfer the Mixture Profiler settings to other parts of JMP. For more information on this submenu, see the discussion of the profiler in “Factor Settings” on page 47.

**Customizations for the Mixture Profiler**

Customize the Mixture Profiler by right-clicking on the plot, and selecting **Customize**.

**Contour**  Alter line color, fill color, and level of line transparency. If there are multiple contour lines on the plot, each appears individually on the list of options.

**Component Constraints**  Alter component constraint display properties.

**Linear Constraints**  Alter linear constraint display properties.

**Grid Lines**  Use Axis Settings window to modify grid lines.

**Reference Lines**  Use Axis Settings window to modify reference lines.

Double-click an axis on the plot to view the Axis Settings window. Here you can specify axis properties in detail, such as tick marks, grid lines and reference lines.

**Crosshairs**  Alter the display properties of the crosshairs on the plot.

**Marker**  Alter the display properties of the plot marker.

---

**Linear Constraints**

The Mixture Profiler can display linear constraints. To do this, a Constraint Table Script must be part of the data table. For more information about creating the Table Script, see “Linear Constraints” on page 34 in the “Introduction to Profilers” chapter.

When using constraints, unfeasible regions are shaded in the profiler. Figure 6.7 shows an example of a mixture profiler with shaded regions due to four constraints. The unshaded portion is the resulting feasible region. The constraints are below:

- $4p_2 + p_3 \leq 0.8$
- $p_2 + 1.5p_3 \leq 0.4$
- $p_1 + 2p_2 \geq 0.8$
- $p_1 + 2p_2 \leq 0.95$
Additional Examples of the Mixture Profiler Platform

- “Mixture Variables with a Process Variable”
- “Multiple Responses with Five Mixture Variables”

Mixture Variables with a Process Variable

This example uses the Fish Patty.jmp sample data table. The data, adapted from Cornell (1990), comes from an experiment to optimize the texture of fish patties. The columns Mullet, Sheepshead, and Croaker are mixture components. Each column represents the proportion of a fish type in the fish patty. The Temperature column is a process variable. It is the oven temperature used to bake the patties. The column Rating is the response and is a measure of texture acceptability, where higher is better. A response surface model was fit to the data and the prediction formula was stored in the column Predicted Rating.

1. Select Help > Sample Data Library and open Fish Patty.jmp.
2. Select Graph > Mixture Profiler.
4. Click OK.
5. The manufacturer wants the rating to be at least 5. Use the slider control for Predicted Rating to move the contour close to 5. Alternatively, you can enter 5 in the Contour edit box to set the contour to 5.
Figure 6.9 Contour Showing a Predicted Rating of 5

The Up Dots shown along the contour indicate the direction of increasing Predicted Rating.

6. Enter 5 in the Lo Limit edit box for the Predicted Rating. The resulting shaded region represents factor combinations that yield a rating less than 5. To produce patties with at least a rating of 5, the manufacturer can set the factors values anywhere in the feasible (unshaded) region. The region has small proportions of Croaker (<10%), mid to low proportions of Mullet (<70%) and mid to high proportions of Sheepshead (>30%). This region is for a baking temperature of 400 degrees.
7. Move the slide control for Temperature to observe how the feasible region changes for different temperature settings.

Additional analyses might include:

- Optimize the response across all four factors simultaneously. See the “Custom Profiler” chapter on page 137 or “Desirability Profiling and Optimization” on page 51 in the “Profiler” chapter.

- Simulate the response as a function of the random variation in the factors and model noise. See the “Simulator” chapter on page 145.

**Multiple Responses with Five Mixture Variables**

This example uses the Five Factor Mixture.jmp sample data table. There are five components (x1 to x5), one categorical process factor (Type), and three responses, Y1, Y2, and Y3. A response surface model is fit to each response and the prediction equations are saved in Y1 Predicted, Y2 Predicted, and Y3 Predicted.

1. Select Help > Sample Data Library and open Five Factor Mixture.jmp.
2. Select **Graph > Mixture Profiler**.

3. Select Y1 Predicted, Y2 Predicted, and Y3 Predicted and click **Y, Predicted**.

4. Click **OK**.

5. Enter 3 in the Contour edit box for Y3 Predicted so that the contour is visible on the plot.

**Figure 6.11** Mixture Profiler with Y3 Predicted Contour Set to 3

A few items to note about the output.

- The on axis factors are X1, X2, and X3 as indicated by the axes labels and the radio buttons in the factor settings. All of the factors have low and high limits, which were entered previously as Column Properties. See *Using JMP* for more information about entering column properties. Alternatively, you can enter the low and high limits directly by entering them in the Lo Limit and Hi Limit boxes.

- The white unshaded region is the feasible region. This is determined by the factor limits.

- The on-axis factors, x1, x2, and x3, radio buttons are selected.
• The categorical factor, Type, has a radio button, but it cannot be assigned to the plot. The current value for Type is L1, which is listed immediately to the right of the Current X box. The Current X box for Type uses a 0 to represent L1.

• All three prediction equations have contours on the plot and are differentiated by color.

Suppose the manufacturer desires to hold Y1 less than 1, Y2 greater than 8 and Y3 between 4 and 5, with a target of 4.5. The Mixture Profiler can help you investigate the response surface and find optimal factor settings.

6. Enter 1 in the Y1 Predicted Hi Limit edit box. Enter 8 in the Y2 Predicted Lo Limit edit box. Enter 4 in the Y3 Predicted Lo Limit edit box and 5 in the Y3 Predicted Hi Limit edit box.

7. The feasible region remains white (unshaded). Use the Response slider controls to position the contours in the feasible region. Alternatively, move the cross hair into the feasible region.

Figure 6.12  Feasible Region After Setting Response Limits

8. Select the magnifier tool to zoom in on the feasible region.
The manufacturer wants to maximize Y1, minimize Y2, and have Y3 at 4.5.

9. Use the slider controls or Contour edit boxes for Y1 Predicted to maximize the red contour within the feasible region. The Up Dots show direction of increasing predicted response.

10. Use the slider controls or Contour edit boxes for Y2 Predicted to minimize the green contour within the unshaded region.

11. Enter 4.5 in the Contour edit box for Y3 Predicted to set the blue contour to the target value.

The resulting three contours do not all intersect at one spot. Y1 and Y2 cannot be optimized with Y3 on target, so you have to compromise. Position the three-way crosshairs in the middle of the contours to explore the factor levels that produce those response values. Note that these response contours are for the current settings of x4, x5, and Type.
Figure 6.14  Factor Settings for Optimal Results

12. Click the Mixture Profiler red triangle and select **Factor Settings > Remember Settings** to save the current settings. The settings are appended to the bottom of the report window.

Figure 6.15  Remembered Settings

With the current settings saved, you can now change the values of x4, x5 and Type to explore their impact on the feasible region. You can compare the factor settings and response values for each level of Type by referring to the Remembered Settings report.
The Custom Profiler enables you to optimize factor settings without graphical output. This is useful for large problems that would have too many graphs to visualize well.

Overview of the Custom Profiler

The Custom Profiler enables you to optimize factor settings without graphical output. The Custom Profiler can be used for problems of any size. It is especially useful for large problems where the standard graphical profiler has too many graphs to visualize well.

The Custom Profiler report has many fields in common with other profilers. The Benchmark field holds a value, or benchmark, of the predicted response. You can compare new results to the benchmark value and update the value based on the current factor settings.

The Optimization report enables you to specify the formula to be optimized and specifications for the optimization.

Figure 7.2 Custom Profiler

Example of the Custom Profiler

This example uses data that demonstrates the flow of water through a borehole that is drilled from the ground surface through two aquifers. You want to optimize the predicted value.

1. Select Help > Sample Data Library > Design Experiment and open Borehole Latin Hypercube.jmp
2. Select Graph > Custom Profiler.
3. Select prediction formula and click Y, Prediction Formula.
4. Click OK.
Note that the Benchmark value is 70.83. The Current Y value is also 70.83. This value is the predicted response with all factors set to their mean values.

You would like to find the X values of the factors that optimize the predicted value. However, of the factors in the model, only those related to the borehole can be manipulated in practice. The other factors are out of human control. You can lock the uncontrollable factors at their mean values and optimize the factors that can be controlled.

**Note:** To view the description of a factor, right-click the corresponding column in the data table and select **Column Info**.

5. In the Custom Profiler Report, select the Lock check box next to R, Tu, Hu, Hl, and log10 R.
6. In the Custom Profiler Report, click **Optimize**.
The optimization routine found an optimum predicted response at 221.66. In order to obtain the optimum of 221.66, $R_w$ and $K_w$ are set to their maximum values and $L$ is set to its minimum value. The optimum is greater than the initial Benchmark value of 70.83.

**Launch the Custom Profiler Platform**

The Custom Profiler can be accessed in the following ways:

- The Custom Profiler can be accessed directly from the Graph menu. When you access the Custom Profiler in this way, the Custom Profiler launch window appears. See “Profiler Launch Windows” on page 28 in the “Introduction to Profilers” chapter.

- The Custom Profiler can be accessed as a red triangle menu option in many modeling platforms. See “Where to Find JMP Profilers” on page 27 in the “Introduction to Profilers” chapter for more information about the availability of the Custom Profiler in different platforms.

- The Custom Profiler can be accessed from the Model Comparisons platform. Select Profiler from the Model Comparisons red triangle menu. Then, select Custom Profiler from the Profiler red triangle menu.

- The Custom Profiler can be accessed from the Formula Depot platform. Select Profiler from the Formula Depot red triangle menu and select the models to be profiled. Then, select Custom Profiler from the Profiler red triangle menu.
The Custom Profiler Report

</tr>
</tbody>
</table>

**Response**  The list of one or more responses.

**Current Y**  The predicted response based on the current X settings. This value updates as the factor settings are changed.

**Lo Limit**  Enables you to set a lower limit for your response.

**High Limit**  Enables you to set an upper limit for your response.

**Benchmark**  A saved predicted value of the response. Initially, this value is set to the predicted value when all factors are at their mean value.

**Reset Benchmark**  Updates the benchmark value to the current predicted value.

Optimization Settings and Controls

Figure 7.7 Optimization Settings and Controls

**Formula**  The formula to be optimized. When a single response is used, the expression is the response column name. When multiple responses are used, the expression is a sum of desirability functions. You can edit the objective expression.

**Objective**  The current value of the objective function. When a single response is used, the objective expression is the predicted response. When multiple responses are used, the objective expression is the desirability function. For more information about desirability functions, see “Desirability Profiling and Optimization” on page 51 in the “Profiler” chapter.

**Trips**  The number of random starts in the optimization algorithm. Each trip restarts the algorithm at a different starting point. This guards against finding local solutions.
**Max Cycles**  The maximum number of cycles used in the optimization algorithm. Each cycle is a single pass through the input parameters and optimizes each one individually.

**Max Iter**  The maximum number of optimization iterations per cycle for each input parameter.

**Convergence Limit**  The upper limit for the convergence criterion for the optimization algorithm. If the convergence criterion becomes less than this value, the algorithm stops.

**Convergence Criterion**  The value of the convergence criterion for the optimization algorithm.

**Maximize**  Enables you to choose to maximize or minimize the objective function.

**Optimize**  Starts the optimization algorithm.

---

**Custom Profiler Platform Options**

**Factor Settings**  Contains options identical to the Factor Settings submenu in the Prediction Profiler. See “Factor Settings” on page 47 in the “Profiler” chapter.

**Log Iterations**  Creates a data table that contains iterations of the optimization algorithm. The data table appears after the **Optimize** button is clicked.

**Alter Linear Constraints**  Enables you to add, change, or delete linear constraints. The constraints are used in the Custom Profiler. See “Linear Constraints” on page 34 in the “Introduction to Profilers” chapter.

**Save Linear Constraints**  Saves existing linear constraints as a data table script that is named Constraint. See “Linear Constraints” on page 34 in the “Introduction to Profilers” chapter.

**Simulator**  Launches the Simulator. See “Simulator” on page 145 in the “Simulator” chapter.
Simulation enables you to discover the distribution of model outputs as a function of the random variation in the model inputs and noise. The Simulator in the profilers enables you to define random inputs, run simulations, and produce output tables of simulated values.

In the Prediction Profiler, the Simulator is integrated into the graphical layout. Factor specifications are displayed below each factor’s profile. A simulation histogram is shown for each response.

Overview of the Simulator

Simulation enables you to discover the distribution of model outputs as a function of the random variation in the model inputs and noise. The Simulator in the profilers enables you to define random inputs, run simulations, and produce output tables of simulated values.

For example, you can use the simulator to model the defect rate of a process and to explore the robustness of the defect rate with respect to variation in the model factors. If specification limits have been set for the responses, they are displayed in the simulation output. The inclusion of specification limits enables you to perform a prospective capability analysis of the simulated model. For information about adding specification limits, see Using JMP.

You can access the Simulator through the Prediction, Contour, and Custom Profilers. The appearance of the Simulator depends on the profiler platform in which it appears.

Prediction Profiler

In the Prediction Profiler, the Simulator is integrated into the graphical layout. Factor specifications are displayed below each factor’s profile. A simulation histogram is shown on the right for each response.

Contour Profiler and Custom Profiler

In the Contour and Custom profilers, the Simulator is not integrated into the graphical layout. There are no integrated histograms, and the interface is textual. However, the process is the same and the resulting output tables are the same as in other profilers.

Note: The Simulator supports mixture terms. The simulation assigns the random value to each mixture factor and then proportionally adjusts the values to maintain the factor constraints.

Example of the Simulator

Use sequencing to examine how the distribution of the response changes when the mean (sequencing location) and variability (sequencing spread) of the inputs change.

1. Select Help > Sample Data Library and open Tiretread.jmp.
2. Select Graph > Profiler.
3. Select Pred Formula ABRASION and Pred Formula MODULUS and click Y, Prediction Formula.
4. Click OK.
5. Click the Prediction Profiler red triangle and select Simulator.

**Note:** The default random distribution is a normal distribution.

7. Change the N Runs value to 1000.

8. Open Simulate to Table outline and then open the Sequencing outline.

**Figure 8.2** Simulator Settings

You want to examine how the responses change as the input factors change locations. To explore changes in factor mean, use sequence location. To instead explore changes in the variability of the factor, use sequence spread.

9. For SILICA, select Sequence Location. Leave the number of steps set to 5. Set the Lower limit to 1 and the Upper limit to 2.

10. For SILANE, select Sequence Location. Leave the number of steps set to 5. Set the Lower limit to 40 and the Upper limit to 60.

11. For SULFUR, select Sequence Location. Leave the number of steps set to 5. Set the values Lower limit to 2 and the Upper limit to 3.
12. Click **Make Table**.

The SILICA Mean, SILANE Mean, and SULFUR Mean columns contain five steps across their respective range of values. For example, the Silica Mean values are 1, 1.25, 1.5, 1.75, and 2. The SILICA, SILANE, and SULFUR columns are the simulated values from a normal distribution with a mean defined by the corresponding mean columns and a fixed standard deviation. **Pred Formula ABRASION** and **Pred Formula MODULUS** values are calculated for set of simulated values, so that you can explore how the responses change as the factor values change.

13. Select **Analyze > Distribution**.

14. Select SILICA Mean and Pred Formula ABRASION and click **Y, Columns**.

15. Click **OK**.

**Figure 8.4** Distribution of SILICA Mean by Pred Formula ABRASION

Click a histogram bar that corresponds to a SILICA Mean to see how the predicted value for abrasion varies across the simulated silane and sulfur ranges given the selected value of silica.
Launch the Simulator

The Simulator can be accessed as a red triangle menu option in the Prediction Profiler, the Contour Profiler, and the Custom Profiler. When you launch the Simulator from the Prediction Profiler, factor specifications are displayed below each factor’s profile. When you launch the Simulator from the Contour or Custom profilers, factor specifications appear in a Factors report, located below the respective profiler report. See “Factors Simulation Settings” on page 150.

Once the Simulator is accessed, you can define simulation parameters for the responses in the Responses report. See “Response Simulation Settings” on page 153. The Responses report also enables you to set the number of simulations.

A histogram is also added to the right of each response when the Simulator is accessed from the Prediction Profiler. Below the histograms is a Simulate button. Once you specify settings for the factors and responses, click Simulate to simulate response values. The histograms of the simulated responses are updated each time the simulate button is clicked. To simulate responses in the Contour and Custom profilers, open the Simulate to Table report and click Make Table. See “Defect Profiler” on page 154.

Factors Simulation Settings

By default, factors (inputs) and responses (outputs) are defined by the functions that you select when the Profiler is launched. Simulation options enable you to modify how your factors and responses are simulated. There are controls for location, error, and noise.

**Fixed**  
Fixes the factor at the current value in the profiler for all simulation runs.

**Random**  
Draws a random value of the factor for each simulation run from the specified distribution and distributional parameters. When you select Random, distribution options appear. For more information about the options, see “Continuous Factors” on page 151 and “Categorical Factors” on page 152.

**Note:** The default random distribution is a normal distribution with a mean at the current factor setting and a standard deviation estimated by the range of the factor divided by 5. The mean of the normal distribution is automatically updated if you change the factor setting in the profiler. There are other random distributions that also update parameters automatically when the factor settings are changed. The Triangular distribution updates all three parameters, the Cauchy distribution updates the mode, and the Johnson Su distribution updates \( \theta \).
Figure 8.5 Example of Three Random Distributions

**Expression**  Generates values for the factor based on a JSL expression. This gives you flexibility to use a random distribution of your choice. For example, you could create a censored normal distribution that guaranteed nonnegative values with an expression such as the following:

\[
\text{Max}(0, \text{RandomNormal}(5, 2))
\]

After entering the expression, click the **Reset** button to submit the expression.

**Multivariate**  Generates values for the factor based on a multivariate normal distribution. Specify the mean and standard deviation for each factor. The correlation matrix is defined separately in the X Correlation Specification report. You can use this option to accommodate correlated factors.

Figure 8.6 Defining a Correlation Matrix for the Multivariate Option

**Continuous Factors**

Many of the distributions available use standard random functions that are described in *Using JMP*. Descriptions of the specialized distributions available follow:

**Normal weighted**  Generates values from a weighted normal distribution with the given mean and standard deviation. The weighting is a specific sampling scheme used to simulate rare events from the tails of the distribution. This is a good choice when you want to simulate very low defect rates. See “Statistical Details for the Simulator” on page 175.

**Normal truncated**  Generates values from a normal distribution limited by lower and upper limits. Any randomly generated value that exceeds a limit is discarded and another value is generated. This is a good choice when you want to simulate an inspection system where inputs that do not satisfy specification limits are discarded.
Normal censored  Generates values from a normal distribution limited by lower and upper limits. Any randomly generated value that exceeds a limit is set to that limit, putting a density mass at the limits. This is a good choice when you want to simulate systems where inputs that do not satisfy specification limits are reworked until they are at the specification limit.

Sampled  Generates factor values by selecting a value at random from that factor’s column in the data table.

External  Generates factor values by selecting a value at random from a column in another table. You are prompted to choose the table and column.

Note: The Aligned check box appears when you select Sampled or External. It is used when two or more factors are set to Sampled or External. When checked, the random draws come from the same row of the table. This maintains the correlation structure between two columns. If the Aligned option is used to associate two columns in different tables, the columns must have the same number of rows.

Categorical Factors

If a factor is categorical, then the random distribution is characterized by probabilities specified for each category. By default, the probabilities are set to the observed probabilities in the data table. You can change the probabilities using the handles in the plot or by changing the numerical values in the Prob column. The probabilities must sum to 1.

Note: If the probabilities that you select do not sum to 1, they are automatically regularized to sum to 1 once you click the Simulate button.

When the simulation for a factor is set to Random, a graphical representation of the random distribution density is shown. The graph shows the form of the density for the continuous distributions, and provides control points that can be dragged to change the distribution. The drag points for the Normal are the mean and the mean plus or minus one standard deviation. The Normal truncated and censored add points for the lower and upper limits. The Uniform and Triangular have limit control points, and the Triangular adds the mode.
Response Simulation Settings

Simulation settings for the responses enable you to simulate random noise in the responses. Often your factors explain part of the variation in the response with the rest of the variation of the response attributed to random noise. This is how the random noise is specified in your simulation.

No Noise  Generates the response from the model based on the factor settings. No random noise added to the response.

Add Random Noise  Adds a normal random value with mean zero and specified standard deviation to the generated response.

Add Random Weighted Noise  Adds an error term to the generated response based on a weighted sampling scheme used to simulate rare events from the tails of the distribution.

Add Multivariate Noise  Adds an error term to the generated response based on a multivariate normal distribution. Specify the standard deviation for the response. Specify the correlation structure between responses in the Y Correlation Specification report.

Random by Model  (Available only within the Standard Least Squares and Generalized Regression personalities of the Fit Model platform.) Adds an error term to the generated response based on the model distribution specified in the Fit Model launch window.

The Simulator Report

The Simulator report contains the following items:

Simulate to Table  Contains a Make Table button that saves the results of the simulation to a data table. If a response has specification limits, the table includes a Y In Spec column that indicates whether the simulated response is within the specification limits. The table also includes an Objective column, labeled Obj. If you added Desirability functions to your profiler prior to simulation, this column is the evaluation of the desirability function. If the Desirability functions were not present prior to simulation, the column contains all missing values.

Sequencing  (Available only when the distribution is Normal, Uniform, or Triangular random.) Sequencing enables you to simulate across a range of locations or spreads for each factor. The simulations are saved to a data table. Select an option to sequence the location or spread of each factor. Specify the number of steps and the range for the sequencing. For each combination of the number of steps, the simulation runs N Runs. If you have two terms, each with 5 steps, and N Runs = 100, the resulting simulation table has 2,500 rows.
The Simulator Report Options

The Simulator red triangle menu contains the following options:

**Automatic Histogram Update**  Toggles the histogram update. When this option is selected, the histograms update with new simulated values when you drag factor setting handles. By default, this option is not selected.

**Defect Profiler**  (Available only when spec limits are specified.) Shows the defect rate as an isolated function of each factor. See “Defect Profiler” on page 154.

**Defect Parametric Profile**  (Available when the Defect Profiler is launched.) Shows the defect rate as an isolated function of the parameters of each factor’s distribution. See “Defect Parametric Profiler” on page 158.

**N Strata**  (Appears only when you press Shift before clicking the Simulator red triangle menu.) Enables you to specify the number of strata for the Normal Weighted distribution. See “Statistical Details for the Simulator” on page 175.

**Set Random Seed**  (Appears only when you press Shift before clicking the Simulator red triangle menu.) Enables you to specify a seed for the simulation starting point. This enables the simulation results to be reproducible, unless the seed is set to zero. The seed is set to zero by default. If the seed is nonzero, then the latest simulation results are output when the Make Table button is clicked.

**Simulation Experiment**  (Available for Normal, Uniform, and Triangular random distributions.) Runs a designed simulation experiment on the locations of the factor distributions. A window appears that enables you to specify the number of design points, the portion of the factor space to be used in the experiment, and which factors to vary in the experiment. Factors that are not selected for the experiment are set to their current Profiler value. See “Simulation Experiment” on page 158.

**Spec Limits**  Opens a table to set or edit specification limits for the responses. Click the Save button to save specification limits to the response column properties in the data table. See “Specification Limits” on page 159.

Defect Profiler

To use the Defect Profiler, spec limits must be defined for at least one response. The Defect Profiler shows the probability of an out-of-spec output defect as a function of each factor while the other factors vary randomly. This is used to help visualize the changes in a factor’s distribution that the process is most sensitive to, often as part of tolerance design.
Specification limits are used to define a defect, and the random distributions assigned to each factor are used to simulate responses.

Define at least one of the factors as Random in the simulation settings to obtain useful results. Otherwise, the simulation outputs are constant and the defect rate is zero if the outcome falls within spec or one if the outcome falls out of spec.

**Tip:** If you need to estimate very small defect rates, consider the Normal weighted random option. This random distribution estimates stable defect rates of just a few parts per million with only a few thousand simulation runs.

---

**Introduction to Tolerance Design**

*Tolerance design* is the investigation of how defect rates can be controlled by controlling variability in the input factors.

Input factors have variation. Specification limits are used to define acceptable ranges for each input. The variability in the input factors impacts the outputs. Specification limits are also used to define the acceptable range for output variables.

Sometimes, a tolerance design study shows that spec limits on an input are unnecessarily tight. Loosening such limits can result in reduced costs without sacrificing product quality. In these cases, tolerance design can save money.

In other cases, a tolerance design study might find that either tighter limits or different targets result in higher quality. In all cases, it is valuable to understand how the inputs and their variability impact that the defect rates.

The Defect Profiler shows the defect rate as a function of each factor fixed at the specified mean value while all other factors are varied according to their random specification. If there are multiple outputs with spec limits, each has a different colored defect rate curve. A black curve shows the overall defect rate.
Defect rates are shown on a cubic root scale, so that both large and small defect rates are shown in some detail.

Defect Rates

The mean and standard deviation (SD) of the simulated overall defect rate are reported below each defect profile plot. This mean is calculated by integrating the defect profile curve with the specified factor distribution. Because of numerical error in the estimations, the overall mean defect rate reported under each factor can differ slightly.

The defect rates that are reported in the Defect Profiler are estimates of the simulated overall defect rate. This rate is also reported in the Rate column of the defect table that is in the Prediction Profiler outline.

Note: The defect table is added to the Prediction Profiler outline after you run a simulation and one or more of your responses has defined spec limits.

Because the rate estimates are obtained differently, by integration and simulation, they might differ slightly. If they are very different, you might consider increasing the number of simulation runs. In addition, verify that the range of the factor scale is wide enough so that the integration covers the distribution well.
The standard deviation is a measure of the sensitivity of the defect rate to the factor. It is small when either the factor profile is flat or the factor distribution has a small variance. The larger the standard deviation, the larger the impact that changes in that factor have on the defect rate variability. Comparing SDs across factors enables you to select factors for improvement to reduce defect rates.

The mean and SD values are updated when you change the factor distribution settings. This is one way to explore how to reduce defects as a function of one particular factor at a time. You can click and drag a handle point on the factor distribution and watch the mean and SD change as you drag. However, changes are not updated across all factors until you click the Rerun button to generate updated simulation runs.

**Simulation Method and Details**

Suppose you want a defect profile for factor $X_1$, in the presence of random variation in $X_2$ and $X_3$. A series of $n = N$ Runs simulation runs is done at each of $k$ points in a grid of equally spaced values of $X_1$. (By default, $k$ is set at 17.) At each grid point, suppose that there are $m$ defects due to the specification limits. At that grid point, the defect rate is $m/n$. These defect rates are connected and plotted as a continuous function of $X_1$.

**Notes**

- The profile curve is not recalculated automatically when distributions change. Click **Rerun** to update the curve.
- Defect Profiling does not address the general optimization problem of optimizing quality against cost, given functions that represent all aspects of the problem. This more general problem would benefit from a surrogate model and space filling design.
- The defect profiles tend to be uneven when they are low. This is due, in part, to the use of the cubic scale where differences in low values are exaggerated. Jagged defect profiles could be due to limited simulation runs. If the overall defect curve (black line) is smooth, and the individual defect rates are fairly consistent, then your simulation probably has enough runs to provide a stable solution. If the overall defect rate curve is jagged, then consider increasing the number of runs. 20,000 runs is generally enough to stabilize the curves.
Defect Parametric Profiler

The Defect Parametric Profiler report shows the impact of process changes on the defect rate. The impacts are based on the simulation parameter settings for each factor. Four scenarios are considered.

**Mean Shift**  The impact of shifting the mean is shown by a red curve. The current mean is shown by a red dotted vertical line.

**Std Narrow**  The impact of a reduction in variability is shown by a blue curve. The dotted blue vertical lines are set at the mean plus and minus one standard deviation. The minimum value on the curve corresponds to the defect rate when there is no variability.

**LSL Chop**  The impact of inspection to remove all parts below the lower specification limit is shown by a green curve.

**USL Chop**  The impact of inspection to remove all parts above the upper specification limit is shown by an orange curve.

**Figure 8.8** Defect Parametric Profile

Simulation Experiment

Use the Simulation Experiment option to run a designed simulation experiment on the locations of the factor distributions. When you select Simulation Experiment, you to specify the number of design points, the portion of the factor space to be used in the experiment, and which factors to include in the experiment. For factors that are not included in the experiment, the current value set in the Profiler is used in the experiment.
The experimental design is a Latin Hypercube. At each design point, N Runs random draws are generated with the design point serving as the center of the random draws. The shape and variability come from the specified distributions. The output has one row for each design point. The responses include the defect rate for each response with spec limits and an overall defect rate. You can use a Gaussian Process model to model the overall defect rate from the simulation experiment. For more information about Gaussian Process models, see Predictive and Specialized Modeling.

### Specification Limits

To add specification limits to a variable, right-click the desired column and select **Column Properties > Spec Limits.** In the Column Properties window, there are boxes to enter values for the Lower Spec Limit, Target, and Upper Spec Limit. Alternatively, you can define Specification Limits using the **Spec Limits** option in the Simulator red triangle menu.

The profilers support specification limits on the responses and provide a number of features:

- In the Profiler, if the Response Limits are not set up in the input data table to provide desirability coordinates, JMP looks for a Spec Limits column property and constructs desirability functions appropriate to those spec limits. For more information about Response Limits see *Using JMP*.
- If you use the Simulator to output simulation tables, JMP includes the Spec Limits column properties in the output data tables. This makes accounting for defect rates and capability indices easy.
- Adding spec limits enables the Defect Profiler.

### Additional Examples of the Simulator

- “Example of the Defect Profiler”
- “Example of Stochastic Optimization”
- “Example of Simulating General Formulas”
Example of the Defect Profiler

To demonstrate a possible workflow with the Defect Profiler, we use Tiretread.jmp. The experimental data in the Tiretread.jmp sample data table comes from an experiment to study the effects of SILICA, SILANE, and SULFUR on four measures of tire tread performance.

Add Specification Limits in the Simulator

1. Select Help > Sample Data Library and open Tiretread.jmp.
2. Select Graph > Profiler.
3. Select Pred Formula ABRASION, Pred Formula MODULUS, Pred Formula ELONG, and Pred Formula HARDNESS and click Y, Prediction Formula.
4. Click OK.
5. Click the Prediction Profiler red triangle and select Simulator.
6. Click the Simulator red triangle and select Spec Limits.

   **Note:** If your columns have spec limits saved as a column property, those spec limits are shown in the Simulator Spec Limits table.

7. Set the spec limits:
   - For ABRASION set the LSL to 110.
   - For MODULUS set the USL to 2000.
   - For ELONG set the LSL to 350 and the USL to 550.
   - For HARDNESS set the LSL to 66 and the USL to 74.
8. Click Save to save the Spec Limits to the data table.
10. For each factor, enter the random specifications as shown in Figure 8.9.

**Figure 8.9** Profiler Random Specifications

Open the Defect Profiler and Defect Parametric Profile

1. Click the Simulator red triangle and select Defect Profiler.
Figure 8.10  Defect Profiler

Note: The defect profiler is based on simulation with random inputs. The values that you obtain might differ from those shown in Figure 8.10.

The black curves show the overall defect rate for each factor fixed at the X axis value while all other factors vary.

Consider the overall curve for SILICA. As silica varies, the defect rate goes from the lowest rate of 0.001 when silica is about 1 and increases quickly up to a defect rate of nearly 1 as silica increases or decreases from 1. However, SILICA is itself random. If you integrate the density curve of SILICA, you would estimate the average defect rate to be about 0.03, which is shown as the Mean for SILICA. This estimate of the overall defect rate estimated by the simulation is shown in the defect table under the simulation histograms. The Mean value for the overall defect rate for all factors are similar.

The Defect Profiler also includes an estimate of the standard deviation of the defect rate with respect to the variation in each factor. This value (labeled SD) is 0.057 for SILICA. The standard deviation is related to the sensitivity of the defect rate with respect to the distribution of that factor. Comparing the SD values across the three factors, the SD for SULFUR is higher than the SD values for SILICA and SILANE. This indicates that to improve the defect rate, shifting the distribution in SULFUR should have the greatest effect. A distribution can be shifted by changing its mean, changing its standard deviation, or by truncating the distribution by rejecting inputs that do not meet certain specification limits.

2. Click the Simulator red triangle and select Defect Parametric Profile.
Figure 8.11  Defect Parametric Profile

Consider SULFUR and note that the current defect rate (0.03) is represented in four ways corresponding to each of the four curves in the Parametric Profiler.

For the red curve, Mean Shift, the current rate is where the red curve intersects the vertical red dotted line. The Mean Shift curve represents the change in overall defect rate as the mean of SULFUR changes. One opportunity to reduce the defect rate is to shift the mean slightly to the left. If you use the crosshair tool on this plot, you see that a shift down in the mean reduces the defect rate to about 0.02.

For the blue curve, Std Narrow, the current defect rate is where the blue curve intersects the two dotted blue lines. The Std Narrow curves represent the change in defect rate as the standard deviation changes. The dotted blue lines represent one standard deviation below and above the current mean. The blue curve is drawn symmetrically around the center. At the center, the blue curve reaches a minimum, representing the defect rate for a standard deviation of zero. That is, if we totally eliminate variation in SULFUR, the defect rate is about 0.003. This is much lower than the current rate of 0.03. If you look at the other defect parametric profile curves, you can see that this is better than reducing variation in the other factors, something that we suspected by the SD value for SULFUR.

For the green curve, LSL Chop, there are no interesting opportunities for improvement in the defect rate. The green curve is above current defect rates for the entire range of the curve. This indicates that reducing the variation by rejecting parts with too-small values for SULFUR does not help reduce the defect rate.

The orange curve, USL Chop, suggests a way to improve the defect rate. Reading the curve from the right, the curve starts out at the current defect rate (0.03). Then as you start rejecting more parts by decreasing the USL for SULFUR, the defect rate improves. However, moving a spec limit to the center of the distribution is equivalent to throwing away half the parts, which might not be a practical solution.

Looking at all the opportunities over all factors, it now looks like there are two good options for further investigation. You could shift the mean of SILICA to about 1 or reduce the variation in SULFUR. Because it is generally easier in practice to change a process mean than a process variation, the best first adjustment might be to shift the mean of SILICA to 1.
3. In the Prediction Profiler, adjust the Mean of SILICA from 1.2 to 1.0.
4. Below the Defect Profiler, click **Rerun**.
   The Defect Profiler updates based on the adjusted SILICA value.

**Figure 8.12** Adjusted Defect Rates

By shifting the mean of SILICA from 1.2 to 1.0, the defect rate has decreased from 0.03 to about 0.004, which is a good improvement. Investigating other defect reduction scenarios is easy to do by making changes to the distributions and rerunning the simulations.

**Example of Stochastic Optimization**

This example is adapted from Box and Draper (2007) and uses Stochastic Optimization.jmp. A chemical reaction converts chemical A into chemical B and B into C. The resulting amount of chemical B is a function of reaction time and reaction temperature. Use the profiler and simulator to explore factor settings to optimize the yield of B.
Figure 8.13 Chemical Reaction

For this reaction the yield of B can be computed using the Arrhenius laws. The column Yield contains the formula for yield. The formula is a function of Reaction Time (hours) and reaction rates $k_1$ and $k_2$. The reaction rates are a function of Reaction Temperature (degrees Kelvin) and known physical constants $\theta_1, \theta_2, \theta_3, \theta_4$. Therefore, Yield is a function of Reaction Time and Reaction Temperature.

Maximize Yield Using Desirability Function

1. Select Help > Sample Data Library and open Stochastic Optimization.jmp.
2. Select Graph > Profiler.
4. Click Expand Intermediate Formulas and then click OK.
   The Prediction Profiler with Desirability Functions enabled appears. For more information about Desirability Functions, see the “Desirability Profiling and Optimization” on page 51 in the “Profiler” chapter.
5. Click the Prediction Profiler red triangle and select Optimization and Desirability > Maximize Desirability.
   The Prediction Profiler maximizes Yield and sets the graphs to the optimum value of Reaction Time and Reaction Temperature.

Figure 8.14 Yield Maximum
The maximum Yield is approximately 0.62 at a Reaction Time of 0.115 hours and Reaction Temperature of 540 degrees Kelvin, or hot and fast. (Your results might differ slightly due to random starting values in the optimization process.)

**Simulate Defect Rate for Maximum Yield**

In a production environment, process inputs cannot always be controlled exactly. What happens to Yield if the inputs (Reaction Time and Reaction Temperature) have random variation? Furthermore, if Yield has a spec limit, what percent of batches are out of spec? The Simulator can help you investigate the variation and defect rate for Yield, given variation in Reaction Time and Reaction Temperature.

1. Click the Prediction Profiler red triangle and deselect **Optimization and Desirability > Desirability Functions**.
2. Click the Prediction Profiler red triangle and select **Simulator**.
3. Set the simulation parameters for Reaction Temperature to **Random > Normal Weighted** with Mean = 540 and SD = 1.
4. Set the simulation parameters for Reaction Time to **Random > Normal Weighted** with Mean = 0.115 and SD = 0.03.
5. Set the **N Runs** value to 15,000.

**Figure 8.15** Initial Simulator Settings
Yield has a lower spec limit of 0.55, set as a column property, and shows in Figure 8.15 as a dashed red line.

6. Click the **Simulate** button.

**Note:** Your numbers might differ from those shown in Figure 8.16 due to the random draws in the simulation.

**Figure 8.16** Simulation Results

The predicted **Yield** is 0.62 for Reaction Temperature of 540 and Reaction Time of 0.115. The simulation estimates an average defect rate of about 6% with a standard deviation of 0.03 given the assumed variation in the temperature and time. The defect rate of 6.0%, indicates that about 6.0% of batches would be out of specification.

Use the simulator to explore other settings of **Reaction Temperature** and **Reaction Time** that might maintain a high **Yield** but with a lower defect rate. Before changing settings, save these factor settings that give us the maximum **Yield** for later use.

7. Click the Prediction Profiler red triangle and select **Factor Settings > Remember Settings**.

8. Type “Max Yield” and click **OK**.

The settings are appended to the report window.
Figure 8.17  Remembered Settings for Maximum Yield

<table>
<thead>
<tr>
<th>Setting</th>
<th>Reaction Temperature</th>
<th>Reaction Time</th>
<th>Yield</th>
</tr>
</thead>
<tbody>
<tr>
<td>Max Yield</td>
<td>540</td>
<td>0.115468</td>
<td>0.6212525</td>
</tr>
</tbody>
</table>

9. Set the Mean value for Reaction Temperature to 535.

Using the dashed red line in the Reaction Time plot, you can explore and determine the approximate value that maximized Yield. This value should be around 0.16.

10. Set the Mean value of Reaction Time to 0.16.

11. Click Simulate.

Note: Your numbers might differ from those shown in Figure 8.18 due to the random draws in the simulation.

Figure 8.18  Defect Rate for Temperature of 535

By making slight changes to the input factor settings, the defect rate decreases to about 1.8% with a decrease of less than 0.01 in the predicted yield. The fixed (no variability) settings that maximize Yield are not the same settings that minimize the defect rate in the presence of factor variation.
Simulation Experiment

You can run a simulation experiment to find the settings of Reaction Temperature and Reaction Time that minimize the defect rate. To do this, simulate the defect rate at each point in an experimental design for Reaction Temperature and Reaction Time. Then fit a predictive model for the defect rate and find factor settings to minimize the defect rate.

1. Click the Simulator red triangle and select Simulation Experiment.

2. Set the number of experimental runs to 80 and the portion of the design space to 1 to use the whole factor space in the experiment.

3. Click OK.

   A Latin Hypercube design with 80 design points is generated within the specified factor space, and N Runs random draws are taken at each of the design points. The design points are the center of the random draws, and the shape and variance of the random draws come from the factor distribution settings.

   A data table is created with the results of the experiment. The Overall Defect Rate is given at each design point. You can now fit a model that predicts the defect rate as a function of Reaction Temperature and Reaction Time.

   **Note:** Do not close the Stochastic Optimization Profiler window. You come back to it later.

4. From the new data table, click the green triangle next to the Gaussian Process script.
5. To find the settings of Reaction Temperature and Reaction Time that minimizes the defect rate, click the Prediction Profiler red triangle and select **Optimization and Desirability > Maximize Desirability**.

The desirability function is already set up to minimize the defect rate.

**Note:** Your results might be slightly different due to the random draws in the simulation.
The settings that minimize the defect rate are approximately Reaction Temperature = 526 and Reaction Time = 0.3.

6. Click the **Transfer Factor Settings Back** button.
   
   This updates the original Profiler report to use the setting for Reaction Temperature and Reaction Time that minimize the defect rate.

7. Return to the original Profiler report window.

8. Click the Prediction Profiler red triangle and select **Factor Settings > Remember Settings**.

9. Type “Min Defect” and click **OK**.

10. With the new settings in place, click the **Simulate** button to estimate the defect rate at the new settings.
Figure 8.22 Lower Defect Rate

At the new settings the defect rate is 0.05%. This is much lower than the 6.0% for the settings that maximize Yield. That is a reduction of about 120x. Recall that the average Yield from the first settings is 0.62, and the new average is 0.59. The decrease in average Yield of 0.03 is the trade off for lowering the defect rate by 120x.

Because you saved the settings using Remember Settings, you can easily compare the old and new settings. The Differences report summarizes the difference.

11. Click the Remembered Settings radio buttons to view the profiler for each setting.
The chemist now knows what settings to use for a quality process. If the factors have no variation, the settings for maximum Yield are hot and fast. But, if the process inputs have variation similar to what we have simulated, the settings for maximum Yield produce a high defect rate. Therefore, to minimize the defect rate in the presence of factor variation, the settings should be cool and slow.

Example of Simulating General Formulas

Though the profiler and simulator are designed to work from formulas stored from a model fit, they work for any formula that is stored in a column. A typical application of simulation is to exercise financial models under certain probability scenarios to obtain the distribution of the objectives. This can be done in JMP. The key is to store the formulas into columns, set up ranges, and then conduct the simulation.

1. In the JMP Home Window, select **File > New > Script**. This opens a new script window.
2. Copy and paste the following JSL script into the new script window.
   ```jsl
   dt = New Table( "Sales Model" );
   dt << New Column( "Unit Sales", Values( {1000, 2000} ) );
   ```
dt << New Column( "Unit Price", Values( {2, 4} ) );
dt << New Column( "Unit Cost", Values( {2, 2.5} ) );
dt << New Column( "Revenue",
    Formula( :Unit Sales * :Unit Price )
);
dt << New Column( "Total Cost",
    Formula( :Unit Sales * :Unit Cost + 1200 )
);
dt << New Column( "Profit",
    Formula( :Revenue - :Total Cost ),
    Set Property( "Spec Limits", {LSL( 0 }) )
);
Profiler(
    Y( :Revenue, :Total Cost, :Profit ),
    Objective Formula( Profit )
);

3. Click the Run Script icon to run the script. Alternatively, you can select Ctrl-R.

   The script creates the data table in Figure 8.24 with some initial scaling data and stores formulas into the output variables. It also launches the Prediction Profiler.

**Figure 8.24** Data Table Created from Script

4. Click the Prediction Profiler red triangle and select the Simulator.

5. In the menus beneath Unit Sales and Unit Cost, select Random.

6. Fill in the factor parameters:
   - Unit Sales is Uniform with Lower limit 1000 and Upper limit 2000.
   - Unit Price is Fixed at 3.
   - Unit Cost is Normal with mean of 2.25 and standard deviation of 0.1.
7. Click the **Simulate** button.

**Note:** Your numbers might differ from those shown in Figure 8.26 due to the random draws in the simulation.

It appears that the models are unlikely to be profitable. By putting a lower specification limit of zero on Profit, the defect report tells you that the probability of being unprofitable is 62%.

8. Change the fixed value of Unit Price to 3.25.
9. Click the **Simulate** button.
Now the probability of being unprofitable is down to about 21%.

If unit price cannot be raised anymore, you should now investigate lowering your cost or increasing sales, if you want to further decrease the probability of being unprofitable.

Statistical Details for the Simulator

Normal Weighted Distribution

JMP uses the multivariate radial strata method for each factor that uses the Normal Weighted distribution. This seems to work better than a number of importance sampling methods and is accurate at estimating in the extreme tails.

First, define the number of strata. The strata are a net of hyperspheres that are centered around 0. For $d$ random factors, the strata are defined by their radial intervals. See Table 8.1.

<table>
<thead>
<tr>
<th>Strata Number</th>
<th>Inside Distance</th>
<th>Outside Distance</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>0</td>
<td>$\sqrt{d}$</td>
</tr>
<tr>
<td>1</td>
<td>$\sqrt{d}$</td>
<td>$\sqrt{d} + \sqrt{2d}$</td>
</tr>
<tr>
<td>2</td>
<td>$\sqrt{d} + \sqrt{2d}$</td>
<td>$\sqrt{d} + 2\sqrt{2d}$</td>
</tr>
<tr>
<td>$i$</td>
<td>$\sqrt{d} + (i-1)\sqrt{2d}$</td>
<td>$\sqrt{d} + i\sqrt{2d}$</td>
</tr>
<tr>
<td>$N_{\text{Strata}} - 1$</td>
<td>$\sqrt{d} + {(N_{\text{Strata}} - 1)\sqrt{2d}$</td>
<td>$\sqrt{d} + (N_{\text{Strata}} - 1)\sqrt{2d}$</td>
</tr>
</tbody>
</table>

The default number of strata is 16. To change the number of strata, a hidden command N Strata is available if you hold the Shift key down while clicking on the red triangle next to Simulator. Increase the sample size as needed to maintain an even number of strata.
For each simulation run, the following is done:

1. Select a strata as \( \text{mod}(i - 1, \ N_{\text{strata}}) \) for run \( i \).
2. Determine a random \( n \)-dimensional direction by scaling multivariate Normal \((0,1)\) deviates to unit norm.
3. Determine a random distance using a chi-square quantile appropriate for the strata of a random uniform argument.
4. Scale the variates so that the norm is the random distance.
5. Scale and re-center the variates individually to be as specified for each factor.

The resulting factor distributions are multivariate normal with the appropriate means and standard deviations when estimated with the right weights. Note that you cannot use the Distribution standard deviation with weights, because it does not estimate the desired value. However, multiplying the weight by a large value, like \( 10^{12} \), and using that as a Freq value results in the correct standard deviation.
The JMP Add-In for Excel uses the JMP Profiler to visualize models (or formulas) stored in Excel worksheets. You can install the Excel add-in when you install JMP.

Overview of the Excel Profiler

The JMP Add-In for Excel uses the JMP Profiler to visualize models (or formulas) stored in Excel worksheets. You can choose to install the Excel Add-In when you install JMP. Profiling in the Excel Add-In is a two-step process:

1. Click the **Create/Edit Model** button (Excel 2010 through 2016) to enter information about the model that JMP needs. This needs to be done only once per model. For more information, click **Help** in the Create/Edit Model window.

2. Click the **Run Model** button (Excel 2010 through 2016) to launch the JMP Profiler and run the Excel model. See “Run the JMP Profiler” on page 181.

Notes:

- The Preferences, Data Table, Graph Builder, Distribution, Fit Y by X, Fit Model, Time Series, and Control Chart buttons are not needed to profile an Excel model. For more information about these features, see *Using JMP*.

- A JMP ribbon is added to Microsoft Excel when the add-in is installed. If there is no JMP ribbon, install the add-in by double-clicking the JMP *setup.exe* file, selecting **Modify**, selecting **Excel Add-In**, and clicking **Next**.

Example of an Excel Model

An Excel model consists of one or more Excel formulas. Each formula must be a function of one or more other cells. This example uses the Demand.xls sample import data located in the Samples/Import Data folder.

**Figure 9.2** Demand Model in Excel
About the Demand.xls Sample Import Data

The formula in cell B8 is a calculation of the Overall Cost associated with having different amounts of product in stock. The formula, which is shown in the Formula Bar, is a function of four cells:

- **Amount Stocked** is the amount of product in stock.
- **Demand** is the customer demand for the product.
- **Air Freight** is the cost per unit to ship additional product by air when the demand exceeds the amount in stock.
- **Expiration Cost** is the cost per unit of disposing of unused product when the demand is less than the amount in stock.

The calculations of the formula depend on the relationship between **Amount Stocked** and **Demand**.

- If **Amount Stocked** is less than **Demand**, then the company has to ship additional units, at a cost of \((\text{Demand} - \text{Amount Stocked}) \times \text{Air Freight}\). For example, if the demand is 8, but the company has only 6 in stock, then it has to ship \(8 - 6 = 2\) units at a cost of \(2 \times 150 = 300\).
- If **Amount Stocked** is greater than **Demand**, then the company has to dispose of unused product, at a cost of \((\text{Amount Stocked} - \text{Demand}) \times \text{Expiration Cost}\). For example, if the demand is 5, but the company has 8 in stock, then it has to dispose of \(8 - 5 = 3\) units at a cost of \(3 \times 50 = 150\).
- If **Amount Stocked** is equal to **Demand**, then there is no shipping cost or disposal cost.
- There is never both a shipping cost and a disposal cost at the same time.

Create the Model in Excel

1. Select **Help > Sample Data Library** and navigate up one level to the Samples/Import Data folder.
2. Double-click **Demand.xls** to open the file in Microsoft Excel.
3. In Microsoft Excel, click the JMP ribbon.
4. Click the **Create/Edit Model** button.
   - The name of the workbook is displayed in the Model and Model Name fields.
   - The Inputs and Outputs fields are populated with data from the worksheet.
5. Enter Customer Demand in the Model Name field and click **Apply**.
   - The Model field is updated.
6. Select **Air Freight** in the Inputs box and then click the down arrow button.
   - Air Freight is moved to the bottom of the list because you want it displayed last in the Profiler.
7. Click **OK**.

The Excel model is saved to the worksheet.

**Notes:**

- If the fields in the Create/Edit Model window are not populated when you set up your model, click **Choose** and select the cell that contains the input or output name.
  - For inputs, specify the values and click **Apply**. Inputs must be values, not formulas.
  - For outputs, the specified cell must be a formula containing only information from the Input cells.
- You can create more than one model for a worksheet. In the Create/Edit Model window, click the plus button next to the Model name. In the Model Name field, change the name if necessary and click the **Apply** button. You can then change the inputs and outputs as necessary and click **OK**.
- You must define the entire model on one worksheet. A model cannot reference cells on another worksheet.

---

**Run the JMP Profiler**

Once you create the model using the Excel Add-In, you can run it in the JMP Profiler. From the Excel Add-In, perform the following actions:

1. In Microsoft Excel, click the JMP ribbon.
2. Click the **Run Model** button.
3. Select the model that you want to run.
4. Click **Profile in JMP**.
5. Use the JMP Profiler to simultaneously see the effect of all inputs on the output. You can also simulate a range of input combinations to see the resulting range of output values.

**Figure 9.3** Example of the Prediction Profiler Using Excel Models
Note: To ensure that your original Excel worksheet is not altered, JMP runs a hidden copy of Excel in the background that controls all of the Profiler calculations. Since the Excel worksheet and the Profiler are not dynamically linked, after you update a formula in the worksheet, you must relaunch the JMP Profiler to reflect the changes.

Use Linear Constraints

Within the JMP Profiler, you can alter the linear constraints in order to restrict the model input values. You are prompted to save the constraints to the Excel workbook. After constraints are saved to the Excel workbook, whenever the model is profiled from the Excel Add-In, the constraints are incorporated.

1. Click the Prediction Profiler red triangle and select Alter Linear Constraints.
2. Click Add Constraint.
3. Type in the constraining values.
4. Click OK.
5. Click the Prediction Profiler red triangle and select Save Linear Constraints.
   You are prompted to save the constraints to the Excel workbook.
6. Click Yes.

Note: When you save the .xls file, you might see a compatibility error. If so, click Continue to save the file.

The workbook opens in Excel. When you run the model, the constraints are reflected in the JMP Profiler. For more information about linear constraints, see “Linear Constraints” on page 34 in the “Introduction to Profilers” chapter.

Tip: To delete a linear constraint, set all constraint values to zero.

Resolution of Profile Lines

The Default N Levels option on the Prediction Profiler red triangle menu affects the resolution of the profile lines. Note the following information:

- This option defaults to 17 when the Profiler runs a model stored in Excel.
- This option defaults to 41 when the model is stored directly in JMP.
If the same model is stored in both Excel and JMP, then the profile lines can appear differently when the models are profiled. Increasing this value causes the Excel Profiler to run slower.

### Use the Excel Profiler from JMP

After you have defined model input and outputs in an Excel file, you can profile the model from within JMP.

1. Select **Graph > Excel Profiler**.
2. Locate the Excel file containing the model and then click **Open**.
3. If the Excel file contains multiple models, you are prompted to select the model that you want to profile.

Use the following code to script the Excel Profiler:

   ```
   Excel Profiler( "path to workbook", <"model name"> ) ;
   ```

If more than one model exists, and no model is specified, a window with the list of available models appears. For more information about scripting the Excel Profiler, see the *Scripting Guide*. 
Excel Profiler

Use the Excel Profiler from JMP

## 8 The Fit Definitive Screening Platform

### Analyze Data from Definitive Screening Experiments

- Overview of the Fit Definitive Screening Platform                        | 277  |
- Identification of Active Effects in DSDs                                 | 277  |
- Effective Model Selection for DSDs                                      | 277  |

### Example of the Fit Definitive Screening Platform

- Fit the Model                                                           | 278  |
- Examine Results                                                         | 279  |
- Reduce the Model                                                        | 280  |

### Launch the Fit Definitive Screening Platform                           | 282  |

### Fit Definitive Screening Report                                       | 282  |

- Stage 1 - Main Effect Estimates                                         | 283  |
- Stage 2 - Even Order Effect Estimates                                   | 284  |
- Combined Model Parameter Estimates                                      | 285  |
- Main Effects Residual Plots                                             | 285  |
- Prediction Profiler                                                     | 286  |

### Fit Definitive Screening Platform Options                             | 286  |

### Technical Details for the Fit Definitive Screening Platform           | 286  |

- The Effective Model Selection for DSDs Algorithm                        | 286  |

## 9 Screening Designs

The JMP DOE platforms help you to design, evaluate, and analyze experiments. Most of the platforms focus on constructing designs. Other platforms support the design effort. This section provides a quick overview of each of the platforms found under the DOE menu.

### Design Construction Platforms

**Custom Design** Constructs designs that fit a wide variety of settings. Custom designs tend to be more cost effective and flexible than approaches based exclusively on classical designs.

Custom designs accommodate various types of factors, constraints, and disallowed combinations. You can specify which effects are necessary to estimate and which are desirable to estimate, given the number of runs. You can specify a number of runs that matches the budget for your experimental situation. Custom designs also support hard-to-change and very-hard-to-change factors, allowing you to construct split-plot and related designs.

The Custom Design platform constructs many special design types:

- screening
- response surface
- mixture
- random block
- split-plot
- split-split-plot
- two-way split-plot

You can construct classical screening, response surface, and mixture designs using other platforms. However, the Custom Design platform gives you flexibility that is not available in the other platforms. Constructing designs for split-plot situations can be done only using the Custom Design platform.

**Definitive Screening Design** Constructs screening designs for continuous and two-level categorical factors. Definitive screening designs are useful if you suspect active interactions or curvature. Definitive screening designs enable you to identify the source of
strong nonlinear effects while avoiding complete confounding between any effects up through the second order.

Definitive screening designs are most appropriate for experimentation with four or more factors. Definitive screening designs support grouping runs into blocks. The number of blocks is user-specified.

**Screening Design** Constructs screening designs for continuous, discrete numeric, and categorical factors with an arbitrary number of levels. When standard designs exist, you have two options:

- Choose from a list of classical screening designs. These designs allow two-level continuous factors or two- or three-level categorical or discrete continuous factors.
- Generate a design that is orthogonal or nearly orthogonal for main effects. *Near-orthogonal designs* allow for categorical and discrete numeric factors with any number of levels, as well as two-level continuous factors. These designs focus on estimating main effects in the presence of negligible interactions.

For many screening situations, standard designs are not available. In these situations, you can construct near-orthogonal screening designs.

**Response Surface Design** Constructs designs that model a quadratic function of continuous factors. To fit the quadratic effects, response surface designs require three settings for each factor. JMP provides response surface designs for up to eight factors.

You can choose from a list of Central Composite or Box-Behnken designs. When appropriate, Central Composite designs that block orthogonally are included in the list. Various modifications to Central Composite designs are supported.

**Full Factorial Design** Constructs full factorial designs for any number of continuous or categorical factors, both with arbitrarily many levels. A full factorial design has a run at every combination of settings of the factors. Full factorial designs tend to be large. The number of runs equals the product of the numbers of factor levels.

**Mixture Design** Constructs designs that you use when factors are ingredients in a mixture. In a mixture experiment, a change in the proportion of one ingredient requires that one or more of the remaining ingredients change to maintain the sum. Choose from among several design types, including some classical mixture design approaches: optimal, simplex centroid, simplex lattice, extreme vertices, ABCD, and space filling. For optimal, extreme vertices, and space filling mixture designs, you can specify linear inequality constraints to limit the design space.

**Taguchi Arrays** Constructs designs that you use for signal-to-noise analysis. The designs are based on Taguchi’s inner and outer array approach. Control factor settings constitute the
inner array and noise factor settings form the outer array. The mean and signal-to-noise ratio are the responses of interest.

An alternative to using a Taguchi array is to construct a custom design that includes control factors, noise factors, and control-by-noise interactions. Such designs, called *combined arrays*, are generally more cost-effective and informative than Taguchi arrays.

**Choice Design** Constructs designs that you can use to compare prospective products. The factors in a choice design are product attributes. The design arranges product profiles, which are combinations of various attributes, in pairs or in groups of three or four. The experiment consists of having respondents indicate which profile in a pair of profiles that they prefer. You can generate a choice design that reflects prior information about the product attributes.

**MaxDiff** Constructs a design consisting of choice sets that can be presented to respondents as part of a MaxDiff study. Respondents report only the most and least preferred options from among a small set of choices. This forces respondents to rank options in terms of preference, which often results in rankings that are more definitive than rankings obtained using standard preference scales.

**Covering Array** Constructs combinatorial designs that you can use to test software, networks, and other systems. A strength \( t \) covering array has the property that every combination of levels of every \( t \) factors appears in at least one run. Covering arrays allow for any number of categorical factors, each with an arbitrary number of levels. Disallowed combinations can be specified.

**Space Filling Design** Constructs designs for situations where the system of interest is deterministic or near-deterministic. A standard application involves creating a simpler surrogate model of a highly complex deterministic computer simulation model.

In a deterministic system, there is no variation. The goal is to minimize the difference between the fitted model and the true model (bias). Space-filling designs attempt to meet this goal either by spreading the design points out as far from each other as possible or by spacing the points evenly over the design region.

JMP provides seven space-filling design approaches. One of these approaches, the fast flexible filling design, accommodates categorical factors with any number of levels and supports linear constraints.

**Accelerated Life Test Design** Constructs and augments designs useful for testing products at extreme conditions which are intended to accelerate failure time. Use experimental results to predict reliability under normal operating conditions.

The life distribution can be lognormal or Weibull. Designs can include one or two accelerating factors. If there are two accelerating factors, you can choose to include their interaction. You can specify prior distributions for the acceleration model parameters. D-optimal and two types of I-optimal designs are available.
Nonlinear Design   Constructs and augments designs that you use to fit models that are nonlinear in their parameters. You can construct a design using estimates from a model fit to existing data. You can also construct a design by applying prior knowledge if you do not have model-based estimates.

Balanced Incomplete Block Design   Constructs design for testing $a$ treatments in $b$ blocks where only $k$ treatments ($k < a$) can be run in any one block.

Group Orthogonal Supersaturated Design   Constructs supersaturated screening designs. They are appropriate in early stage work when the number of factors to be investigated is larger than the number of feasible runs. A group orthogonal supersaturated design is a special class of two-level supersaturated designs with properties that are desirable for model selection.

Supporting Platforms

Augment Design   Adds runs to existing designs in such a way that the resulting design is optimal. Augment Design enables you to conduct experiments in an iterative fashion. You can replicate the design, add center points, create a fold-over design, add axial points, add points to create a space-filling design, or augment the design with a specified number of runs. You can group runs into blocks to distinguish the original runs from the augmented runs. You can add model effects that were not in the original model and specify requirements for these effects.

Fit Definitive Screening Design   Analyzes definitive screening designs using a methodology called Effective Model Selection for DSDs. This methodology takes advantage of the special structure of definitive screening designs.

Fit Group Orthogonal Supersaturated   Analyzes group orthogonal supersaturated designs. This analysis technique takes advantage of the group orthogonal structure of group orthogonal supersaturated designs.

Evaluate Design   Provides diagnostics for an existing experimental design. The Evaluate Design platform provides various ways for you to assess the strengths and limitations of your design. The platform can be used with any data table, not only designs created using JMP.

Several diagnostics are provided:

- power analysis
- prediction variance plots
- estimation efficiency for parameters
- the alias matrix, showing the bias structure for model effects
- a color map showing absolute correlations among effects
- design efficiency values
**Compare Designs**  Compares up to four designs to a reference design. Use to explore, evaluate, and compare design performance. Diagnostics show how the designs perform relative to each other and how they perform in an absolute sense.

**Sample Size and Power**  Provides sample size and power calculations for a variety of testing situations: one or more sample means, a standard deviation, one or two proportions, counts per unit (Poisson mean), and sigma quality level. For these options, you specify two of three quantities to compute the third. These three quantities are the difference you want to detect, the sample size, and the power. If you supply only one of these values, a plot of the relationship between the other two values is provided.

You can compute the sample size required for a reliability test plan, where your goal is to estimate failure probabilities. You can also compute the sample size required for a reliability demonstration, where your goal is to demonstrate that a product meets or exceeds a specified standard.
A designed experiment is a controlled set of tests designed to model and explore the relationship between factors and one or more responses. JMP includes a variety of tools that enable you to create efficient experimental designs that work for your situation. In particular, these classes of designs are available:

- The Custom Design platform customizes a design for your unique situation. It constructs designs that accommodate any number of factors of any type and factors that are difficult to change (split plot situations). You control the number of runs.
- The Definitive Screening Design platform constructs an innovative class of screening designs where main effects are not aliased with each other or with two-way interactions. These designs also allow estimation of quadratic terms.

The Evaluate Design and Augment Design platforms provide tools for evaluating and augmenting existing design. The Sample Size and Power platform addresses sample size and power calculations for specialized situations.

This chapter presents an example that illustrates the JMP approach to DOE. This chapter also discusses the framework for DOE, the workflow that supports design creation, and principles that are fundamental to DOE.

Overview of Experimental Design and the DOE Workflow

A six-step framework provides the structure for designing an experiment, running the experimental trials, and analyzing the results. Sound engineering and process knowledge is critical to all of these steps.

Figure 3.2 Framework for Experimental Design

You perform the first three steps in the DOE platforms. The end result is a design that can be run in your work environment. For a detailed description of the workflow for these three steps, see “The DOE Workflow: Describe, Specify, Design” on page 59.

**Describe** Determine the goal of your experiment. Identify responses and factors.

Your goal might be to identify active factors, to find optimal factor settings, or to build a predictive model.

**Specify** Determine or specify an assumed model that you believe adequately describes the physical situation.

Your *assumed* model is an initial model that ideally contains all the effects that you want to estimate. In some platforms, you can explicitly build the model of interest. In others, the model is implicit in the choices that you make. For example, in the Screening Design platform, you might select a model with a given resolution. The resolution of the design determines which effects are confounded. Confounding of effects potentially leads to ambiguity about which effect is truly active.

**Design** Generate a design that is consistent with your assumed model. Evaluate this design to understand its strengths and limitations, and to ensure that it provides the information that you need, given your model and goals.

The Design Evaluation or Design Diagnostics outline in the design generation platform give you insight about the properties of your design.
The next step is the data collection phase, where the experiment is run under controlled conditions.

**Collect**  Conduct each of the trials and record the response values.

After you run your experiment, scripts in the generated data table help you fit a model using platforms such as Fit Model and Screening. Depending on your goal, the model can help you identify active effects or find optimal settings.

**Fit**  Fit your assumed model to the experimental data.

- Use the JMP modeling platforms to fit and refine your model. In some situations, you might need to augment the design and perform additional runs to resolve model ambiguity.

**Predict**  Use your refined model to address your experimental goals.

- Determine which effects are active, find factor levels to optimize responses, or build a predictive model.

Designed experiments are typically used sequentially to construct process knowledge. A design strategy often begins with a screening design to narrow the list of potentially active factors. Then the identified factors are studied in designs that focus on building a better understanding of interactions and quadratic effects. Sometimes there is a need to augment a design to resolve ambiguities relating to the factors responsible for effects. The steps outlined in this section relate to conducting and analyzing a single experiment. However, you may require a sequence of experiments to achieve your goals.

The example in “The Coffee Strength Experiment” on page 44 explicitly illustrates the steps in the DOE workflow process. It also shows how to use a data table script to analyze your experimental data. Many examples in the Design of Experiments Guide illustrate both the workflow that supports a good design and the analysis of the experimental data from the study.

---

**The Coffee Strength Experiment**

- “Define the Study and Goals”
- “Create the Design”
- “Run the Experiment”
- “Analyze the Data”
Define the Study and Goals

Your employer is a local mid-size coffee roaster. You need to address the strength of individually brewed twelve ounce cups of coffee. Your goal is to determine which factors have an effect on coffee strength and to find optimal settings for those factors.

Response

The response is coffee Strength. It is measured as total dissolved solids, using a refractometer. The coffee is brewed using a single cup coffee dripper and measured five minutes after the liquid is released from the grounds.

Previous studies indicate that a strength reading of 1.3 is most desirable, though the strength is still acceptable if it falls between 1.2 and 1.4.

Factors

Four factors are identified for the study: Grind, Temperature, Time, and Charge. Coffee is brewed at three stations in the work area. To account for variation due to brewing location, Station is included in the study as a blocking factor. The following describes the factors:

- Grind is the coarseness of the grind. Grind is set at two levels, Medium and Coarse.
- Temperature is the temperature in degrees Fahrenheit of the water measured immediately before pouring it over the grounds. Temperature is set at 195 and 205 degrees Fahrenheit.
- Time is the brewing time in minutes. Time is set at 3 or 4 minutes.
- Charge is the amount of coffee placed in the cone filter, measured in grams of coffee beans per ounce of water. Charge is set at 1.6 and 2.4.
- Station is the location where the coffee is brewed. The three stations are labeled as 1, 2, and 3.

Table 3.1 summarizes information about the factors and their settings. The factors and levels are also given in the Coffee Factors.jmp sample data table, located in the Design Experiment folder.

Table 3.1 Factors and Range of Settings for Coffee Experiment

<table>
<thead>
<tr>
<th>Factor</th>
<th>Role</th>
<th>Range of Settings</th>
</tr>

<td>195 - 205</td>
</tr>
<tr>
<td>Time</td>
<td>Continuous</td>
<td>3 - 4</td>
</tr>
<tr>
<td>Charge</td>
<td>Continuous</td>
<td>1.6 - 2.4</td>
</tr>
</tbody>
</table>
Note the following:

- Grind is categorical with two levels.
- Temperature, Time, and Charge are continuous.
- Station is a blocking factor with three levels.

All factors can be varied and reset for each run. There are no hard-to-change factors for this experiment.

The apparatus used in running the coffee experiment is shown in Figure 3.3. This is the setup at one of the three brewing stations. The two other stations have the same type of equipment.

**Table 3.1** Factors and Range of Settings for Coffee Experiment (Continued)

<th>Role</th>
<th>Range of Settings</th>
</tr>
</thead>
<tbody>
<tr>
<td>Station</td>
<td>Blocking</td>
<td>1, 2, 3</td>
</tr>
</tbody>
</table>

**Number of Runs**

Based on the resources and time available, you determine that you can conduct 12 runs in all. Since there are three stations, you conduct 4 runs at each station.
Create the Design

Create the design following the steps in the design workflow process outlined in *The DOE Workflow: Describe, Specify, Design*:

- Define Responses and Factors
- Specify the Model
- Generate the Design
- Evaluate the Design
- Make the Table

Define Responses and Factors

In the first outlines that appear, enter information about your response and factors.

Responses

1. Select **DOE > Custom Design**.
2. Double-click **Y** under Response Name and type **Strength**.
   
   Note that the default Goal is **Maximize**. Your goal is to find factor settings that enable you to brew coffee with a target strength of 1.3, within limits of 1.2 and 1.4.
3. Click the default Goal of **Maximize** and change it to **Match Target**.

   ![Figure 3.4 Selection of Match Target as the Goal](image)

4. Click under **Lower Limit** and type 1.2.
5. Click under **Upper Limit** and type 1.4.
6. Leave the area under **Importance** blank.

   Because there is only one response, that response is given Importance 1 by default.

The completed Responses outline appears in Figure 3.5.
Factors

Enter factors either manually or from a pre-existing table that contains the factors and settings. If you are designing a new experiment, you must first enter the factors manually. Once you have saved the factors to a data table using the Save Factors option, you can load them using the saved table.

For this example, you can choose either option. See “Entering Factors Manually” on page 48 or see “Entering Factors Using Load Factors” on page 49.

Entering Factors Manually

1. Click Add Factor > Categorical > 2 Level.
2. Type Grind over the default Name of X1.
   Note that Role is set to Categorical, as requested. The Changes attribute is set to Easy by default, indicating that Grind settings can be reset for every run.
3. Click the default Values, L1 and L2, and change them to Coarse and Medium.
4. Type 3 next to Add N Factors. Then click Add Factor > Continuous.
5. Type the factor names and values over the default entries:
   – Temperature (195 and 205)
   – Time (3 and 4)
   – Charge (1.6 and 2.4)
6. Click Add Factor > Blocking > 4 runs per block.
   Recall that your run budget allows for 12 runs. You want to balance these runs among the three stations.
7. Type Station over the default Name of X5.
   Notice that Role is set to Blocking and that only one setting for Values appears. This is because JMP cannot determine the number of blocks until the desired number of runs is specified. Once you specify the Number of Runs in the Design Generation outline, JMP updates the number of levels for Station to what is required.
8. Click **Continue**.

The following outlines are added to the Custom Design window:

- Define Factor Constraints (not used in this example)
- Model
- Alias Terms
- Design Generation

**Entering Factors Using Load Factors**

Enter factors using a table containing factor information:

1. Click the Custom Design red triangle and select **Load Factors**.
2. Select **Help > Sample Data Library** and open Design Experiment/Coffee Factors.jmp.

   After loading the factors, the Custom Design window is updated with additional outlines:
   - Define Factor Constraints (not used in this example)
   - Model
   - Alias Terms
   - Design Generation

**Define Factor Constraints**

The Define Factor Constraints outline appears once you have entered your factors manually and clicked Continue, or once you have loaded the factors from the factor table. Adding factor constraints, if you have any, is part of the Responses and Factors step. Since there are no constraints on factor settings for this design, leave this outline unchanged.
Specify the Model

Model Outline

Figure 3.7 shows the Model outline. The Model outline is where you specify your assumed model, which contains the effects that you want to estimate. See “Specify” on page 43. The list that appears by default shows all main effects as Necessary, indicating that the design is capable of estimating all main effects. Because your main interest at this point is in the main effects of the factors, you do not add any effects to the Model outline.

Figure 3.6 Model Outline with Main Effects Only

Steps to Duplicate Results (Optional)

Because the Custom Design algorithm begins with a random starting design, your design might differ from the one shown in Figure 3.8. To obtain a design with exactly the same runs, set the random seed and number of starts before generating your design:

1. Click the Custom Design red triangle and select Set Random Seed.
2. Type 569534903.
3. Click OK.
4. Click the Custom Design red triangle and select Number of Starts.
5. Type 100.
6. Click OK.

Note: Setting the Random Seed and Number of Starts reproduces the exact design shown in this example. However, the rows in the design table might be in a different order. In constructing a design on your own, these steps are not necessary.

Generate the Design

In the Design Generation outline, you can enter additional details about the structure and size of your design. The Default design is shown as having 12 runs. Recall that your design budget allows for 12 runs (“Number of Runs” on page 46).
Figure 3.7 Design Generation Outline

The Design and Design Evaluation outlines are added to the Custom Design window. The Output Options panel also appears.

The Design outline shows the design (Figure 3.8). If you did not set the random seed and number of starts as described in “Steps to Duplicate Results (Optional)” on page 50, your design might be different from the one in Figure 3.8. This is because the algorithm used to generate the design begins with a random starting design.

Figure 3.8 Design for Coffee Experiment

Evaluate the Design

The Design Evaluation outline provides various ways to evaluate your design. This is an important topic, but for simplicity, it is not covered in the context of this example. See the “Evaluate Designs” chapter on page 435.

Make the Table

Specify the order of runs in your data table using the Output Options panel. The default selection, Randomize within Blocks, is appropriate. This selection arranges the runs in a random order for each Station.
1. Click **Make Table**.

The data table shown in Figure 3.10 opens. Keep in mind that, if you did not set the random seed and number of starts as described in “Steps to Duplicate Results (Optional)” on page 50, your design table might be different. Your design table represents an alternative optimal design.

Note the asterisks in the Columns panel to the right of the factors and response. These indicate column properties that have been saved to the columns in the data table. These column properties are used in the analysis of the data. See “Factors” on page 89 and “Factor Column Properties” on page 95.
Run the Experiment

At this point, you perform the experiment. At each Station, four runs are conducted in the order shown in the design table. Equipment and material are reset between runs. For example, if two consecutive runs require water at 195 degrees, separate 12-ounce batches of water are heated to 195 degrees after the heating container cools. The Strength measurements are recorded.

Your design and the experimental results for Strength are given in the Coffee Data.jmp sample data table (Figure 3.11), located in the Design Experiment folder.

Figure 3.11 Coffee Design with Strength Results

Analyze the Data

The Custom Design platform facilitates the task of data analysis by saving a Model script to the design table that it creates (Figure 3.10). Run this script after you conduct your experiment and enter your data. The script opens a Fit Model window containing the effects that you specified in the Model outline of the Custom Design window.

Fit the Model

1. Select Help > Sample Data Library and open Design Experiment/Coffee Data.jmp.
   In the Table panel, notice the Model script created by Custom Design.
2. Click the green triangle next to the Model script.
   The Model Specification window shows the effects that you specified in the Model outline.
3. Select the **Keep dialog open** option.

4. Click **Run**.

**Analyze the Model**

The Effect Summary and Actual by Predicted Plot reports give high-level information about the model.
Figure 3.13  Effect Summary and Actual by Predicted Plot for Full Model

Note the following:

- The Actual by Predicted Plot shows no evidence of lack of fit.
- The model is significant, as indicated by the Actual by Predicted Plot. The notation $P = 0.0041$, shown below the plot, gives the significance level of the overall model test.
- The Effect Summary report shows that Charge, Station, and Time are significant at the 0.05 level.
- The Effect Summary report also shows that Temperature and Grind are not significant.

**Reduce the Model**

Because Temperature and Grind appear not to be active, they contribute random noise to the model. Refit the model without these effects to obtain more precise estimates of the model parameters associated with the active effects.

1. In the Model Specification window, select Temperature and Grind in the Construct Model Effects list.
2. Click **Remove**.
3. Confirm that the model **Emphasis** is set to **Effect Screening**.
   - The Effect Screening emphasis presents reports (such as the Prediction Profiler) that are useful for analyzing experimental designs.
4. Click **Run**.
Note the following:

- The Effect Tests report shows that all three effects remain significant.
- The Scaled Estimates report further indicates that the Station[1] and Station[3] means differ significantly from the average response of Strength.
- Note that the Estimates that appear in the Parameter Estimates report are identical to their counterparts in the Scaled Estimates report. This is because the effects are coded. See "Coding" on page 795 in the "Column Properties" appendix.
- The estimate of the Station[3] effect only appears in the Scaled Estimates report, where nominal factors are expanded to show estimates for all their levels.
- The Parameter Estimates report gives estimates for the model coefficients where the model is specified in terms of the coded effects.

**Explore the Model**

The Prediction Profiler appears at the bottom of the report.
Recall that, in designing your experiment, you set a response Goal of Match Target with limits of 1.2 and 1.4. JMP uses this information to construct a desirability function to reflect your specifications. See “Factors” on page 89.

Note the following in Figure 3.15:

- The first two plots in the top row of the graph show how Strength varies for one of the factors, given the setting of the other factor. For example, when Charge is 2, the line in the plot for Time shows how predicted Strength changes with Time.
- The values to the left of the top row of plots give the Predicted Strength (in red) and a confidence interval for the mean Strength for the selected factor settings.
- The right-most plot in the top row shows the desirability function for Strength. The desirability function indicates that the target of 1.3 is most desirable. Desirability decreases as you move away from that target. Desirability is close to 0 at the limits of 1.2 and 1.4.
- The plots in the bottom row show the desirability trace for each factor at the setting of the other factor.
- The value to the left of the bottom row of plots gives the Desirability of the response value for the selected factor settings.

Explore various factor settings by dragging the red dashed vertical lines in the columns for Time and Charge. Since there are no interactions in the model, the profiler indicates that increasing Charge increases Strength. Also, Strength seems to be more sensitive to changes in Charge than to changes in Time.

Since Station is a blocking factor, it does not appear in the Prediction Profiler. However, you might like to see how predicted Strength varies by Station. Include Station in the Prediction Profiler:

1. Click the Prediction Profiler red triangle and select **Reset Factor Grid**.
A Factor Settings window appears with columns for Time, Charge, and Station. Under Station, notice that the box corresponding to Show is not selected. This indicates that Station is not shown in the Prediction Profiler.

2. Select the box under Station in the row corresponding to Show.
3. Deselect the box under Station in the row corresponding to Lock Factor Setting.

Figure 3.16  Factor Settings Window

4. Click OK.

Plots for Station appear in the Prediction Profiler.

5. Click in either plot above Station to insert a dashed red vertical line.
6. Move the dashed red vertical line to Station 1.

Figure 3.17  Prediction Profiler Showing Results for Station 1

7. Move the dashed red vertical line to Station 3.
Figure 3.18 Prediction Profiler Showing Results for Station 3

The predicted Strength in the center of the design region for Station 1 is 1.44. For Station 3, the predicted Strength is about 1.18. The magnitude of the difference indicates that you need to address Station variability. Better control of Station variation should lead to more consistent Strength. Once Station consistency is achieved, you can determine common optimal settings for Time and Charge.

The process that you used to construct the design for the coffee experiment followed the steps in the DOE workflow. The next section describes the DOE workflow in more detail.

The DOE Workflow: Describe, Specify, Design

The DOE platforms are structured as a series of steps that present the workflow that is intrinsic to designing experiments. Once you complete each step, you click Continue to move to the next step. The elements described in this section are common to nine of the design of experiments platforms. These are the platforms that are addressed in this section:

- Custom Design
- Definitive Screening Design
- Screening Design
- Response Surface Design
- Full Factorial Design
- Mixture Design
- Covering Array
- Space Filling Design
- Taguchi Arrays
Three special-purpose platforms differ substantially: Choice Designs, Accelerated Life Test Design, and Nonlinear Design. These three platforms are not addressed in this section.

This section describes the steps in the DOE workflow. It also discusses their implementation in the various design platforms.

Define Responses and Factors

In the Describe step of the experimental design framework:

- You identify the responses and factors of interest.
- You determine your goals for the experiment. Do you want to maximize the response, or hit a target? What is that target? Or do you simply want to identify which factors have an effect on the response?
- You identify factor settings that describe your experimental range or design space.

When they open, most of the JMP DOE platforms display outlines where you can list your responses and your factors. The Responses outline is common across platforms. There you insert your responses and additional information, such as the response goal, lower limit, upper limit, and importance.

The Factors outline varies across platforms. This is to accommodate the types of factors and specific design situations that each platform addresses. In certain platforms, once responses and factors are entered, a Define Factor Constraints outline appears after you click Continue. In this outline, you can constrain the values of the factors that are available for the design.

Figure 3.19 shows the Responses and Factors outline using the Custom Design platform for constructing the design in the Box Corrosion Split-Plot.jmp sample data table, located in the Design Experiment folder. Also shown is the Define Factor Constraints outline, which appears once you click Continue. The Define Constraints outline enables you to specify restrictions that your factor settings must satisfy.
Specify the Model

Once you have completed filling in the Responses and Factors outlines, click the **Continue** button. This brings you to the next phase of design construction, where you either explicitly or implicitly choose an assumed model.

The Custom Design platform enables you to explicitly specify the model that you want to fit. The design that is generated is optimal for this model. The other design platforms do not allow you to explicitly specify your model. For example, in the screening platform, one option enables you to choose from a list of full factorial, fractional factorial, and Plackett-Burman designs. The aliasing relationships in these designs implicitly define the models that you can fit.

In Custom Design, when you click Continue after filling in the Responses and Factors, you see the Model outline. An example, for the design used in the *Box Corrosion Split-Plot.jmp* sample data table, is shown in Figure 3.20. The assumed model requires that the Furnace Temp and Coating main effects, and their interaction, be estimable. The design that is generated guarantees estimability of these effects.

In most other platforms, clicking Continue gives you a collection of designs to choose from. In Full Factorial, Continue takes you directly to Output Options, since the design is determined once the Factors outline is completed.
Figure 3.20 Model Outline for Box Corrosion Split-Plot Experiment

Generate the Design

Most of the DOE platforms give you some control over the size of the final design. In Custom Design, you can specify the number of runs and, when appropriate, the number of center points and replicate runs. In other platforms, you have various degrees of flexibility. Often you can specify the number of center points, replicate runs, or replications of the design.

Once you have specified your options in terms of the number of runs, click Make Design. The DOE window is updated to show your design in a Design outline.

The Design outline for a 24-run custom design for the Box Corrosion Split-Plot.jmp experiment is shown in Figure 3.21. Because Changes for Furnace Temp was specified as Hard, a Whole Plots factor is constructed to represent the random blocks of settings for Furnace Temp.

Figure 3.21 Design Outline for Box Corrosion Split-Plot Experiment
Note: For a custom design, once you have created your design, the controls in the Model and Alias Outlines are disabled. Use the Back button to change model or alias terms.

Evaluate the Design

When you click Make Design, in most platforms, a Design Evaluation outline appears. Here you can explore the design that you created in terms of its power to detect effects, its prediction variance, its estimation efficiency, its aliasing relationships, the correlations between effects, and other design efficiency measures. The Design Evaluation outline for a Custom Design is shown in Figure 3.22. Design Evaluation is covered in the “Evaluate Designs” chapter on page 435.

For some platforms, other types of design diagnostics are appropriate. For example, Space Filling Design provides a Design Diagnostics outline with metrics specific to space-filling designs. Covering Array provides a Metrics outline with measures that are specific to coverage.

Figure 3.22  Design Evaluation Outline in Custom Design

Make the Table

Most platforms provide an Output Options node or panel. Depending on the platform and the design, you can use the Output Options panel to specify additional design structure. For example, you can specify the number of runs, center points, replicates, or the order in which you want the design runs to appear in the generated data table.

The Output Options panel shown in Figure 3.23 is for the experiment in the Wine Data.jmp sample data table, located in the Design Experiment folder. In this example, you can choose various Run Order options and construct the design data table. Or, you can choose to go Back and restructure your design.
Principles and Guidelines for Experimental Design

Certain principles underlie the design of experiments and the analysis of experimental data. The principles of effect hierarchy, effect heredity, and effect sparsity relate primarily to model selection. These principles help you reduce the set of possible models in searching for a best model. See Hamada and Wu (1992), Wu and Hamada (2009), and Goos and Jones (2011).

- **“Effect Hierarchy”**
- **“Effect Heredity”**
- **“Effect Sparsity”**
- **“Center Points, Replicate Runs, and Testing”**

**Effect Hierarchy**

In regression modeling, the principle of effect hierarchy maintains that main (first-order) effects tend to account for the largest amounts of variation in the response. Second-order effects, that is, interaction effects and quadratic terms, are next in terms of accounting for variation. Then come higher-order terms, in hierarchical order.

Here are the implications for modeling: main effects are more likely to be important than second-order effects; second-order effects are more likely to be important than third-order effects; and so on, for higher-order terms.

**Effect Heredity**

The principle of effect heredity relates to the inclusion in the model of lower-order components of higher-order effects. The motivation for this principle is observational evidence that factors with small main effects tend not to have significant interaction effects.
**Strong effect heredity** requires that all lower-order components of a model effect be included in the model. Suppose that a three-way interaction (ABC) is in the model. Then all of its component main effects and two-way interactions (A, B, C, AB, AC, BC) must also be in the model.

**Weak effect heredity** requires that only a sequence of lower-order components of a model effect be included. If a three-way interaction is in the model, then the model must contain one of the factors involved and one two-way interaction involving that factor. Suppose that the three-way interaction ABC is in the model. Then if B and BC are also in the model, the model satisfies weak effect heredity.

For continuous factors, effect heredity ensures that the model is invariant to changes in the location and scale of the factors.

**Effect Sparsity**

The principle of **effect sparsity** asserts that most of the variation in the response is explained by a relatively small number of effects. Screening designs, where many effects are studied, rely heavily on effect sparsity. Experience shows that the number of runs used in a screening design should be at least twice the number of effects that are likely to be significant.

**Center Points, Replicate Runs, and Testing**

Several DOE platforms enable you to add center points (for continuous factors), replicate runs, or full replicates of the design, to your design. Here is some background relative to adding design points.

**Adding Center Points**

Center points for continuous factors enable you to test for lack of fit due to nonlinear effects. Testing for lack of fit helps you determine whether the error variance estimate has been inflated due to a missing model term. This can be a wise investment of runs.

You can replicate runs solely at center points or you can replicate other design runs. JMP uses replicate runs to construct a model-independent error estimate (pure-error estimate). This pure-error estimate enables you to test for lack of fit.

Be aware that center points do not help you obtain more precise estimates of model effects. They enable you to test for evidence of curvature, but do not identify the responsible nonlinear effects.

To identify the source of curvature, you must set continuous factors at a minimum of three levels. Definitive screening designs are three-level designs with the ability to detect and identify any factors causing strong nonlinear effects on the response. See Chapter 7, “Definitive Screening Designs”.
Adding Replicate Runs

If your run budget allows, you can either replicate runs or distribute new runs optimally within the design space. Adding replicate runs adds precision for some estimates and improves the power of the lack of fit test. However, for a given run budget, adding replicate runs generally lowers the ability of the design to estimate model effects. You are not able to estimate as many terms as you could by distributing the runs optimally within the design space.

Testing for Lack of Fit

Designed experiments are typically constructed to require as few runs as possible, consistent with the goals of the experiment. With too few runs, only extremely large effects can be detected. For example, for a given effect, the $t$ test statistic is the ratio of the change in response means to their standard error. If there is only one error degree of freedom (df), then the critical value of the test exceeds 12. So, for such a nearly saturated design to detect an effect, it has to be very large.

A similar observation applies to the lack-of-fit test. The power of this test to detect lack-of-fit depends on the numbers of degrees of freedom in the numerator and denominator. If you have only 1 df of each kind, you need an $F$ value that exceeds 150 to declare significance at the 0.05 level. If you have 2 df of each kind, then the $F$ value must exceed 19. In order for the test to be significant in this second case, the lack-of-fit mean square must be 19 times larger than the pure error mean square. It is also true that the lack-of-fit test is sensitive to outliers.

For more information about the Lack of Fit test, see Fitting Linear Models.

Determining the Number of Runs

In industrial applications, each run is often very costly, so there is incentive to minimize the number of runs. To estimate the fixed effects of interest, you need only as many runs as there are terms in the model. To determine whether the effects are active, you need a reasonable estimate of the error variance. Unless you already have a good estimate of this variance, consider adding at least 4 runs to the number required to estimate the model terms.
Use the Custom Design platform to construct optimal designs that are custom built for your specific experimental setting. Generally, a custom design is more cost-effective than a design obtained using alternative methods. You can perform the following tasks:

- Enter factors of many different types.
- Specify constraints on the design space.
- Indicate which effects are necessary to estimate and which are desirable to estimate, if possible, given the number of runs.
- Specify a number of experimental runs that matches your budget.

The Custom Design platform constructs a wide variety of designs, including these special design types: Screening, Response Surface, Mixture, Random Block, Split Plot, Split-Split-Plot, and Two-Way Split Plot.

This chapter contains a detailed example of how to use the Custom Design platform, followed by information about the platform. See also the “Examples of Custom Designs” chapter on page 135.

Overview of Custom Design

Use the Custom Design platform to construct an optimal design custom built for your specific experimental needs.

You can include a wide range of factor types, including the following:

- Continuous
- Discrete numeric (with any number of levels)
- Categorical (with any number of levels)
- Blocking (with a specified number of runs per block)
- Covariate
- Mixture
- Constant
- Uncontrolled

Specify the Region of Operability

You can restrict your experimental region to reflect your operating conditions using linear factor constraints or disallowed combinations. In particular, restrictions can be specified for categorical, continuous, and discrete numeric factors. See “Define Factor Constraints” on page 96.

Specify Factors with Hard-to-Change Levels

For continuous, discrete numeric, categorical, and mixture factors, you can indicate two levels of difficult-to-change factors. These difficulty levels are represented by whole plots or whole plots and split plots. You can also specify hard-to-change covariates.

Specify the Effects of Primary Interest

You can explicitly specify your assumed model. Your assumed model is an initial model that ideally contains all the effects that you want to estimate. Your model can contain any combination of main effects, interactions, response surface effects, and polynomial effects (up to the fifth power). You can specify the effects for which estimability is necessary and those for which estimability is desired. Custom Design uses a Bayesian optimality approach to estimate effects whose estimability is desired, subject to the number of runs. See “Model” on page 99.
Specify the Number of Runs

The Custom Design platform enables you to specify the number of runs that matches the budget for your experimental situation. The platform indicates the minimum number of runs that can be used to estimate the required effects and provides a default number of runs. These values can serve as a guide for determining a feasible number of runs. See “Design Generation” on page 102.

Construct the Appropriate Design Type

Custom Design can construct a wide variety of design types. These include classical designs and random block designs. For examples of different design types, see the “Examples of Custom Designs” chapter on page 135.

Construct an Optimal Design

Given your specific requirements, the Custom Design platform constructs a design that is optimal. The algorithm supports several optimality criteria:

- D optimality
- I optimality
- Bayesian D and I optimality (using If Possible effects)
- A optimality
- Alias optimality

See “Optimality Criteria” on page 128.

Designs are constructed using the coordinate-exchange algorithm (Meyer and Nachtsheim, 1995). See “Coordinate-Exchange Algorithm” on page 133.

Example of a Custom Design

Use the custom designer to design an experiment to investigate the effect of wine processing factors on wine taste. Your employer grows two varieties of Pinot Noir grapes that can be processed in different ways. Your goal is to determine which factors affect the taste of Pinot Noir wine. Before the grapes are processed, you set up your experimental design. Once processed, the wine samples are aged for 12 months, then filtered and bottled. At this point, the wine samples are rated for quality by expert wine tasters.
Response

Most of your vineyard’s product is sold to five large wine distributors. You arrange for a wine-tasting expert from each distributor to evaluate the wine samples for quality. To maximize the number of factors that you can study, you decide that each expert must rate eight different samples. This means that your design needs to have 40 wine samples, or runs.

The ratings follow a 0 – 20 scale, where 0 is the worst and 20 is the best. Rating, the variable consisting of the experts’ ratings, is the response of interest. You want to identify the wine-related factors that maximize the response.

Blocking Factor

A blocking factor is used to account for variation that is not necessarily of direct interest. A blocking factor is particularly effective when observations taken at one factor level are expected to be more similar than observations at different levels. In your experiment, ratings by one expert are likely to have similar characteristics and to differ from ratings by a different expert. Yet, you are interested in which properties of the wine lead to high ratings by all experts.

Because each rater tastes eight wines, Rater is a blocking factor with eight runs per block. For this experiment, only these five raters are of concern. You are not interested in generalizing to a larger population of raters.

Process Factors

You have identified nine process factors for the study. These include the grape variety, the field on which the grapes were grown, and seven other factors related to processing. You can experiment with any combination of these factors. Also, the factors can be varied at will as part of the experiment. Relative to the experiment, these factors are all “Easy” to change. For information about specifying factor changes, see “Changes and Random Blocks” on page 93.

The factors and their levels appear in Table 4.1. Note that all of these factors are categorical. The factors and their levels are also given in the factor table Wine Factors.jmp in the Design Experiment folder of Sample Data.

To experiment with all possible combinations of these factors would require a staggering $4 \times 2^8 = 1024$ runs. However, in this example, you are able to construct a compelling design in only 40 runs.

Now that the experimental goals, factors, and responses have been defined, you can build your custom design.

**Add Responses**

For this custom design example add your response, the response Goal, and, if appropriate, the Lower Limit, Upper Limit, and Importance. Here, the response is Rating.

1. Select **DOE > Custom Design**.
2. Double-click Y under Response Name and type Rating.
   
   Note that the default Goal is Maximize. Because you want to maximize the taste rating, do not change the goal.
3. Click under Lower Limit and type 0.
   
   The least desirable rating is 0.
4. Click under Upper Limit and type 20.
   
   The most desirable rating is 20.
5. Leave the area under Importance blank.
   
   Because there is only one response, that response is given Importance 1 by default.

*Figure 4.2* on page 74 shows the completed Responses outline.
Add Factors Manually or Automatically

For this custom design example, enter factors either manually or automatically using a pre-existing table that contains the factors and settings.

- If you are designing a new experiment, you must first enter the factors manually. See “Add Factors Manually” on page 73.
- Once you have saved the factors using the Save Factors option, you can load them automatically using the saved table. See “Add Factors Automatically Using Load Factors” on page 74.

Both methods add these four outlines to the Custom Design window: Define Factor Constraints, Model, Alias Terms, and Design Generation.

Add Factors Manually

1. First, add the blocking factor, Rater. Click Add Factor > Blocking > 8 runs per block.
2. Type Rater over the default Name of X1.

   Note that Role is set to Blocking. Note also that only one setting for Values appears. This is because the number of blocks cannot be determined until the desired number of runs is specified. Once you specify the Number of Runs in the Design Generation outline, the number of levels for Rater updates to what is required.

3. Click Add Factor > Categorical > 2 Level.
4. Type Variety over the default Name of X2.

   Note that Role is set to Categorical, as requested, and that Changes is set to Easy by default.

5. Click L1 and L2 and change them to Bernard and Dijon.
6. Click Add Factor > Categorical > 4 Level.
7. Type Field over the default Name of X3.
8. Click L1, L2, L3, and L4, and change them to 1, 2, 3, and 4.
9. Click Add Factor > Categorical > 2 Level.
10. Type De-Stem over the default Name of X4.
11. Click L1 and L2 and change them to No and Yes.
12. Type 6 next to Add N Factors, and then click Add Factor > Categorical > 2 Level. This adds six categorical two-level factors to your design.
13. Change the default factor names and values:
   - Yeast (Cultured and Wild)
   - Temperature (High and Low)
- Press (Hard and Soft)
- Barrel Age (New and Two Years)
- Barrel Seasoning (Air and Kiln)
- Filtering (No and Yes)

**Figure 4.2** Completed Responses and Factors Outlines

14. Click **Continue**.

The following outlines are added to the Custom Design window:

- Define Factor Constraints (not used in this example)
- Model
- Alias Terms
- Design Generation

**Add Factors Automatically Using Load Factors**

Enter factors using a table containing factor information:

1. Select **Help > Sample Data Library** and open **Design Experiment/Wine Factors.jmp**.
2. Click the Custom Design red triangle and select **Load Factors**.

After loading the factors, the Custom Design window automatically updates. The following outlines are added to the Custom Design window:

- Define Factor Constraints (not used in this example)
- Model
- Alias Terms
Design Generation

Define the Model

For this custom design example, the Model outline shows all main effects as Necessary, indicating that the design needs to be capable of estimating all main effects. Your assumed model reflects your interest in main effects only. However, if you wanted to estimate other effects, you could add them to the Model outline. For more information about models, see “Model” on page 99.

Figure 4.3 Model Outline

Define Alias Terms

The Alias Terms outline specifies the effects to be shown in the Alias Matrix, which appears later. The Alias Matrix shows the aliasing relationships between the Model terms and the effects listed in the Alias Terms outline. Open the Alias Terms outline node to verify that all two-factor interactions are listed. For more information about the alias matrix, see “Alias Matrix” on page 79.

Figure 4.4 Partial View of the Alias Terms Outline
Set Random Seed to Duplicate Design

The Custom Design algorithm begins with a random starting design. To duplicate a design such as in this example, or in a teaching setting, set the random seed used to define the staring design. If you want to obtain a design with exactly the same runs and run order as the one shown in Figure 4.5, set the random seed and number of starts:

1. Click the Custom Design red triangle and select Set Random Seed.
2. Type 100526291 (the random seed).
3. Click OK.
4. Click the Custom Design red triangle and select Number of Starts.
5. Type 2.
6. Click OK.

**Note:** Setting the Random Seed and Number of Starts reproduces the exact results shown in this example. In constructing a design on your own, these steps are not necessary.

Generate the Design

In the Design Generation outline, you can enter additional details about the structure and size of your design. In this example, the Default design shows 16 runs. But you have five raters, each of whom can sample eight wines. This means that you want a design with 40 runs. Change the number of design runs:

1. Under Number of Runs, type 40 in the User Specified box.
   - Because you do not want to replicate runs, leave the Number of Replicate Runs set to 0.
2. Click Make Design.

The Design and Design Evaluation outlines are added to the Custom Design window. The Output Options panel also appears.

Verify the Design

The Design outline shows the runs in the custom design that you have constructed. Later, you are able to randomize the order under Output Options. For now, verify that this design is appropriate for your experiment. For example, check that each of five Raters evaluates eight wines, that all necessary factors are shown, and that none of the settings represent infeasible combinations.

**Evaluate the Design**

The Design Evaluation outline provides different ways to evaluate your custom design. For this example, open the Design Evaluation outline, and examine the Color Map on Correlations, the Alias Matrix, and Design Diagnostics.

*Note:* For more information about the Design Evaluation outline, see the “Evaluate Designs” chapter on page 435.
**Color Map on Correlations**

The Color Map on Correlations shows the absolute value of the correlation between any two effects that appear in either the Model or the Alias Terms outline.

**Figure 4.6 Color Map on Correlations**

The main effects are represented by the 15 terms in the upper left corner of the map. The white corresponding to the correlations of main effects with other main effects indicate correlations of 0. This means that all main effects are orthogonal and can be estimated independently.

The only black in Figure 4.6 is on the main diagonal. Black indicates absolute correlations of one, reflecting that each term is perfectly correlated with itself. It follows that no main effect is completely confounded with any two-way interaction. In fact, the absolute values of the correlations of main effects with two-way interactions are fairly low. This means that estimates of main effects might be only slightly biased by the presence of active two-way interactions.

**Tip:** Hover over cells in the color map to see the absolute correlations between effects. Right-click below the legend to save the correlations to a data table.
Alias Matrix

In the Alias Matrix, model effects are listed in the column on the left. For a given model effect, a column entry indicates the degree to which the column effect (if active) biases the estimate of the model effect.

**Figure 4.7** Partial View of Alias Matrix

</table>

For example, consider the model effect Barrel Seasoning. If Variety*Press is active, then the expected value of the estimate for the Barrel Seasoning effect differs from an unbiased estimate of that effect. The amount by which it differs is equal to 0.4 times the effect of Variety*Press. Therefore, what appears to be a significant Barrel Seasoning estimated effect could in reality be a significant Variety*Press effect.

Design Diagnostics

The Design Diagnostics outline provides information about the efficiency of the design. Efficiency measures compare your design to a theoretically optimal design, which might not exist. The efficiency values are ratios, expressed as percents, of the efficiency of your design to the efficiency of this optimal design. For more information about the efficiency measures, see “Estimation Efficiency” on page 462 in the “Evaluate Designs” chapter.

**Figure 4.8** Design Diagnostics Outline
Notice that the D-, G-, and A-efficiency values are all 100%. Because your design is orthogonal for main effects, the design is optimal for the main effects model relative to all three efficiency criteria.

The first line in the Design Diagnostics outline indicates that your design was constructed to optimize the D-efficiency criterion. See the Optimality Criterion description in “Custom Design Options” on page 108. In this case, your design has D Efficiency of 100%.

**Specify Design Table Options**

The final steps of your custom design generation are to specify options for the design table and to make the table. Specify the order of runs in your data table using the Output Options panel. The default selection, **Randomize within Blocks**, is appropriate for this example. Simply click **Make Table**.

A Custom Design table is created and opens, similar to the one in Figure 4.9.

**Note:** Your table might look different because the algorithm that creates it uses a random starting design. To obtain the precise table shown in Figure 4.9, set the random seed and number of starts as described in “Set Random Seed to Duplicate Design” on page 76.

**Figure 4.9 Custom Design Table**
Note the following:

- In the Table panel, the Model, Evaluate Design, and DOE Dialog scripts are added during the design creation process. The Model script opens a Fit Model window containing the effects that you specified as Necessary in the Custom Design dialog window. The DOE Dialog script re-creates the window used to generate the design table.

- In the Columns panel, the asterisks to the right of the factors and response indicate column properties that have been saved to the columns in the data table. These column properties are used in the analysis of the data. For more information about column properties, see “Factors” on page 89 and “Factor Column Properties” on page 95.

**Analyze the Custom Design**

After running an experiment and compiling the data you are ready to analyze the results. Use the Rating column of your Custom Design table to record the Rating data.

1. Select Help > Sample Data Library and open Design Experiment/Wine Data.jmp.

   The Wine Data.jmp table is exactly the same as the Custom Design table shown in Figure 4.9, except that it contains your recorded experimental results.

2. In the Table panel, click the green triangle next to the Model script.

**Figure 4.10 Model Specification Window for the Wine Experiment**

Notice that Rater, the blocking factor, is added as a fixed effect, rather than as a random block effect. This is appropriate because the five raters were specifically chosen and are not a random sample from a larger population.
3. Click **Run**.

**Interpret the Full Model Results**

The model output from our custom design example is shown below.

**Figure 4.11** Partial Model Fit Results
Note the following:

- The Actual by Predicted Plot shows no obvious evidence of lack of fit.
- The model is significant, as indicated by the Actual by Predicted Plot and by the $p$-value beneath it.
- The Effect Tests report indicates that seven of the model terms are significant at the 0.05 level. Field, Temperature, and Barrel Age are not significant.
- The Effect Summary report lists these effects in decreasing order of significance. Larger LogWorth values correspond to smaller PValues and greater significance.

**Reduce the Model**

Reduce the model for the custom design results by removing the effects that you identified as inactive:

1. In the Effect Summary report, press Control and select Temperature, Field, and Barrel Age.
2. Click **Remove**.

The report updates to show the model fit with these three effects removed.

**Interpret the Model Results with the Profiler**

The Actual by Predicted Plot for the reduced model shows no lack of fit issues. The Effect Summary and the Effect Test report show that the remaining seven terms are significant at the 0.05 level. Use the prediction profiler to further explore your reduced model.

Figure 4.12 shows the Prediction Profiler. Recall that you specified a response goal of Maximize, with lower and upper limits of 0 and 20. Setting these limits caused a Response Limits column property to be saved to the Rating column in the Custom Design table. The Prediction Profiler uses the Response Limits information to construct a Desirability function, which appears in the right-most plot in the top row in Figure 4.12. The bottom row displays Desirability traces.

The first six plots in the top row show traces of the predicted model. For each factor, the line in the plot shows how Rating varies when all other factors are set at the values defined by the red dashed vertical lines. By default, the profiler appears with categorical factors set at their low settings. By varying the settings for the factors, you can see how the predicted Rating for wines changes. Notice that a confidence interval is given for the mean predicted Rating.

Observe that Rater is not included among the factors shown in the profiler. This is because Rater is a block variable. You included Rater to explain variation, but Rater is not of direct interest in terms of optimizing process factor settings. The predicted Rating for a wine with the given settings is the average of the predicted ratings for that wine by all raters.
**Optimize Factor Settings**

Use the prediction profiler to identify optimal settings based on your custom design results. You would like to identify settings that maximize Rating across raters.

1. Click the Prediction Profiler red triangle and select **Optimization and Desirability > Maximize Desirability**.

   The red dashed vertical lines in the Prediction Profiler update to show optimal settings for each factor. The optimal settings result in a predicted rating of 19.925. In general, there can be different sets of factor settings that result in the same optimal value.

**Figure 4.13 Prediction Profiler with Factor Settings Optimized**

2. To see predicted ratings for all runs, save the Prediction Formula. Click the Response Rating red triangle and select **Save Columns > Prediction Formula**.

   A column called Pred Formula Rating is added to the data table. Note that one of the runs, row 33, was given the maximum rating of 20 by Rater 5. The predicted rating for that run by Rater 5 is 19.550. But the row 33 trial was run at the optimal settings. The predicted
value of 19.925 given for these settings in the Prediction Profiler is obtained by averaging the predicted ratings for that run over all five raters.

**Lock a Factor Level**

You can lock factors in the profiler to explore optimization under specific conditions. When you maximized your design response, you learned that the optimal rating is achieved with the Dijon variety of grapes (Figure 4.13). Your manager points out that it would be cost-prohibitive to replant the fields that are growing Bernard grapes with young Dijon vines. Therefore, you need to find optimal process settings and the predicted rating for Bernard grapes.

1. In the Variety plot of the Prediction Profiler, drag the red dashed vertical line to Bernard.
2. Press Control and click in one of the Variety plots.
   The Factor Settings window appears.
3. Select **Lock Factor Setting** and click **OK**.
4. Click the Prediction Profiler red triangle and select **Optimization and Desirability > Maximize Desirability**.

**Figure 4.14** Prediction Profiler with Optimal Settings for Bernard Variety

The optimal settings are unchanged because the model contains no interaction terms. The predicted rating at these settings is 17.975.

**Add the Rater to the Profiler**

If you want to see the Profiler traces for the levels of Rater, perform the following steps:

1. Click the Prediction Profiler red triangle and select **Reset Factor Grid**.
A Factor Settings window appears with columns for all of the factors, including Rater. The box under Rater and next to Show is not checked. This indicates that Rater is not shown in the Prediction Profiler.

2. Check the box under Rater in the row corresponding to Show.

3. Deselect the box under Rater in the row corresponding to Lock Factor Setting.

4. Click OK.

The Profiler updates to show a plot for Rater.

5. Click in either plot above Rater.

**Figure 4.15** Profiler for Reduced Model Showing Rater

A dashed vertical red line appears. Drag this line to see the traces for each of the raters. Keep in mind that Variety is still locked at Bernard. To unlock Variety, press Control and click in one of the Variety plots. In the Factor Settings window that appears, deselect Lock Factor Setting.
Summary of Custom Design Example

In your wine tasting experiment, using only 40 runs, you have identified six (out of nine) factors that have an effect on ratings for Pinot Noir grapes. You found that you could achieve a predicted rating of 19.925 (out of a possible 20) at the optimal settings for those factors. You also identified optimal settings for both varieties of grapes.

In this section, you constructed a design using the outlines in the Custom Design window. The next section explains each outline and the design steps in more detail.

Build a Custom Design

Build a Custom Design by selecting DOE > Custom Design. First define your responses and factors. Next, continue to the design options, generation, and evaluation. The design process follows the flow in Figure 4.16.

Figure 4.16  Custom Design Flow

Responses

Use the Responses outline to specify one or more responses.

Tip: When you have completed the Responses outline, consider selecting Save Responses from the red triangle menu. This option saves the response names, goals, limits, and importance values in a data table that you can later reload in DOE platforms.

Figure 4.17  Responses Outline

Add Response  Enters a single response with a goal type of Maximize, Match Target, Minimize, None, or Functional. If you select Match Target, enter limits for your target value. If you select Maximize or Minimize, entering limits is not required but can be useful if you intend to use desirability functions.
**Functional** (Available only in JMP Pro.) Adds multiple Y columns with FDE column properties to the design data table. These columns can be used in the Functional Data Explorer platform with the DOE factors as supplementary factors.

**Remove** Removes the selected responses.

**Number of Responses** Enters additional responses so that the number that you enter is the total number of responses. If you have entered a response other than the default Y, the Goal for each of the additional responses is the Goal associated with the last response entered. Otherwise, the Goal defaults to Match Target. Click the Goal type in the table to change it.

The Responses outline contains the following columns:

**Response Name** The name of the response. When added, a response is given a default name of Y, Y2, and so on. To change this name, double-click it and enter the desired name.

**Goal, Lower Limit, Upper Limit** The Goal tells JMP whether you want to maximize your response, minimize your response, match a target, or that you have no response goal. JMP assigns a Response Limits column property, based on these specifications, to each response column in the design table. It uses this information to define a desirability function for each response. The Profiler and Contour Profiler use these desirability functions to find optimal factor settings. For further details, see the Profiler chapter in *Profilers* and “Response Limits” on page 784 in the “Column Properties” appendix.

- A Goal of Maximize indicates that the best value is the largest possible. If there are natural lower or upper bounds, you can specify these as the Lower Limit or Upper Limit.
- A Goal of Minimize indicates that the best value is the smallest possible. If there are natural lower or upper bounds, you can specify these as the Lower Limit or Upper Limit.
- A Goal of Match Target indicates that the best value is a specific target value. The default target value is assumed to be midway between the Lower Limit and Upper Limit.
- A Goal of None indicates that there is no goal in terms of optimization. No desirability function is constructed.

**Note:** If your target response is not midway between the Lower Limit and the Upper Limit, you can change the target after you generate your design table. In the data table, open the Column Info window for the response column (Cols > Column Info) and enter the desired target value.

**Importance** When you have several responses, the Importance values that you specify are used to compute an overall desirability function. These values are treated as weights for
the responses. If there is only one response, then specifying the Importance is unnecessary because it is set to 1 by default.

**Detection Limits**  The lower and upper detection limits are bounds beyond which the response cannot be measured. The detection limits are saved as a column property. You can use these limits to specify a censored response in the Generalized Regression platform. See the Generalized Regression chapter in *Fitting Linear Models*.

**Editing the Responses Outline**

In the Responses outline, note the following:

- Double-click a response to edit the response name.
- Click the goal to change it.
- Click on a limit or importance weight to change it.
- For multiple responses, you might want to enter values for the importance weights.

**Response Limits Column Property**

The Goal, Lower Limit, Upper Limit, and Importance that you specify when you enter a response are used in finding optimal factor settings. For each response, the information is saved in the generated design data table as a Response Limits column property. JMP uses this information to define the desirability function. The desirability function is used in the Prediction Profiler to find optimal factor settings. For further details about the Response Limits column property and examples of its use, see “Response Limits” on page 784 in the “Column Properties” appendix.

If you do not specify a Lower Limit and Upper Limit, JMP uses the range of the observed data for the response to define the limits for the desirability function. Specifying the Lower Limit and Upper Limit gives you control over the specification of the desirability function. For more details about the construction of the desirability function, see the Profiler chapter in *Profilers*.

**Factors**

Add factors to study in a custom design in the Factors outline.

**Tip:** When you have completed the Factors outline, consider selecting **Save Factors** from the red triangle menu. This saves the factor names, roles, changes, and values in a data table that you can later reload.
Figure 4.18  Factors Outline

Add Factor  Select the factor type. See “Factor Types” on page 91.

Remove  Removes the selected factors.

Note: If you attempt to remove all factors after clicking the Continue or Back button, one continuous factor remains. You can delete it after you add new factors.

Add N Factors  Adds multiple factors. Enter the number of factors to add, click Add Factor, and then select the factor type. Repeat Add N Factors to add multiple factors of different types.

Factors Outline

The Factors outline contains the following columns:

Name  The name of the factor. When added, a factor is given a default name of X1, X2, and so on. To change this name, double-click it and enter the desired name.

Role  Specifies the Design Role of the factor. The Design Role column property for the factor is saved to the data table. This property ensures that the factor type is modeled appropriately.

Changes  Indicates whether the factor levels are Easy, Hard, or Very Hard to change. Click the default value of Easy to change it. When you specify factors as Hard or Very Hard to change, your design reflects these restrictions on randomization. A factor cannot be designated as Very Hard unless the Factors list contains a factor designated as Hard. The Factor Changes column property is saved to the data table. See “Changes and Random Blocks” on page 93.

Values  The experimental settings for the factors. To insert Values, click the default values and enter the desired values.
Editing the Factors Outline

In the Factors outline, note the following:

- To edit a factor name, double-click the factor name.
- Categorical factors have a down arrow to the left of the factor name. Click the arrow to add a level.
- To remove a factor level, click the value, click Delete, and click outside the text box.
- To modify the entry under Changes, click the value in the Changes column and select the appropriate entry.
- To edit a value, click the value in the Values column.

Factor Types

To choose a factor type, click Add Factor in Custom Design.

**Note:** A Design Role column property containing each factor’s role is added to that factor’s column in the design table that is generated. The Design Role column property ensures that the factor is modeled correctly.

**Continuous**  Numeric data types only. A continuous factor is a factor that you can conceptually set to any value between the lower and upper limits you supply, given the limitations of your process and measurement system.

**Discrete Numeric**  Numeric data types only. A discrete numeric factor can assume only a discrete number of values. These values have an implied order.

The default values for a discrete numeric factor with \( k \) levels, where \( k > 2 \), are the integers 1, 2, ..., \( k \). The default values for a discrete numeric factor with \( k = 2 \) levels are -1 and 1. Replace the default values with the settings that you plan to use in your experiment.

**Note:** Not all levels of a discrete numeric factor appear in the design. The levels that appear are determined by your specifications in the Model outline. If you need all levels to appear in your design, consider using the Screening Design platform.

In the assumed model, the effects for a discrete numeric factor with \( k \) levels include polynomial terms in that effect through order \( k-1 \). For \( k \) greater than 6, powers up to the 5th level are included. The Estimability for polynomial effects (powers of two or higher) is set to If Possible. This allows the algorithm to use the multiple levels as permitted by the run size. If the polynomial terms are not included, then a main effects only design is
created. For more information about how discrete numeric factors are treated in the assumed model, see “Model” on page 99.

Fit Model treats a discrete numeric factor as a continuous predictor. The Model script that is saved to the design table does not contain any polynomial terms of order greater than two.

**Categorical** Either numeric or character data types. The data type in the resulting data table is categorical. The value order of the levels is the order of the values, as entered from left to right. This ordering is saved in the Value Order column property after the design data table is created.

**Blocking** Either numeric or character data types. A blocking factor is a special type of categorical factor that can enter the model only as a main effect. When you define a blocking factor, you specify the number of runs per block. The RunsPerBlock column property is saved to the design table. The Default run size always assumes that there are at least two blocks. If you specify a run size that is not an integer multiple of the number of runs per block, JMP tries to balance the design to the extent possible. In balancing the design, JMP ensures that there are at least two runs per block.

**Covariate** Either numeric or character data types. The values of a covariate factor are measurements on experimental units that are known in advance of an experiment. Covariate values are selected to ensure the optimality of the resulting design relative to the optimality criterion. See “Changes and Random Blocks” on page 93 and “Covariates with Hard-to-Change Levels” on page 127.

JMP obtains the covariate factors and their values from an open data table that contains the measured covariates for the available experimental units. Make this data table your current data table. Use Add Factors or click Select Covariate Factors in the Covariate Candidate Runs outline to add covariates. When you add a covariate, a list of columns in the current data table opens, and you select the columns containing covariates from this list. The addition of covariate factors loads a table with the candidate rows into the Covariate Candidate Runs outline. Once loaded, you can select rows to force into the design. To force selected covariate rows into your design, use the Design Generation option Include all selected covariate rows in the design.

If the design has fewer runs than the number of covariate rows, then the design table includes a Covariate Row Index column. This column indicates the row from the covariate table that corresponds to each experimental run.

In some situations, you might want to select a small set of design points from a larger set of candidate settings. For example, you might have multiple measurement columns (factors) for a large batch of units. You want to treat the measurements for each unit as a candidate run. From these candidate runs, you want to select a small but optimal collection for which you measure a response. In this case, make the data table of all candidate runs the active table, select Add Factor > Covariate, and enter all of your
measurement columns as covariates. Specify your desired run size. The Custom Design platform identifies an optimal collection of design settings.

**Note:** When you have covariates, the Design Generation outline contains two options. The first option allows you to specify that selected rows in your covariate table are included in the design. The second option allows covariate rows to be repeated in the design.

**Mixture** Continuous factors that represent ingredients in a mixture. The values for a mixture factor must sum to a constant. By default, the values for all mixture factors sum to one. To set the sum of the mixture components to some other positive value, select Advanced Options > Mixture Sum from the red triangle menu. The Mixture column property is saved to the data table.

**Constant** Either numeric or character data types. A constant factor is a factor whose values are fixed during an experiment. Constant factors are not included in the Model outline or in the Model script that is saved to the data table.

**Uncontrolled** Either numeric or character data types. An uncontrolled factor is one whose values cannot be controlled during production, but it is a factor that you want to include in the model. It is assumed that you can record the factor’s value for each experimental run.

An empty column with a Continuous Modeling Type is created in the design table. You can change the column’s Data Type and Modeling Type in the Column Info window if required. Enter your data in this column. Uncontrolled factors are included in the Model outline and the Model script that is saved to the data table.

**Changes and Random Blocks**

Specifying the relative difficulty of changing a factor from run to run is useful in industrial experimentation. It is often convenient to make several runs while keeping factors that are hard-to-change fixed at some setting. A Changes value of Hard results in a split-plot design. A Changes value of Very Hard results in a split-split-plot design or a two-way split-plot design.

You can set Changes for Continuous, Discrete Numeric, Categorical, and Mixture factors to Hard and Very Hard. To set a factor to Very Hard, the list must contain another factor that is set to Hard.

You can set Changes for a Covariate factor to Hard. In this case, all other covariates are also set to Hard and the remaining factors are set to Easy. The algorithm requires a combination of row exchange and coordinate exchange. For this reason, even moderately sized designs might take some time to generate.
For designs with Hard or Very Hard to change factors, Custom Design strives to find a design that is optimal, given your specified optimality criterion. See “Optimality Criteria” on page 128. For more information about the methodology used to generate split-plot designs, see Jones and Goos (2007). For more information about designs with hard-to-change covariates, see Jones and Goos (2015).

Figure 4.19 shows a split-split-plot scenario, using the factors from the Cheese Factors.jmp sample data table (located in the Design Experiment folder).

Figure 4.19 Factors and Design Generation Outline for a Split-Split-Plot Design

If you assign Changes as Hard for one or more factors, but no factors are assigned Changes that are Very Hard, a categorical factor called Whole Plots is added to the design. This situation results in a split-plot design:

- Each level of Whole Plots corresponds to a block of constant settings of the hard-to-change factors.
- The Model script in the design table applies the Random Effect attribute to the factor Whole Plots.
- The factor Whole Plots is assigned the Design Role column property with a value of Random Block.
When you designate Changes as both Hard and Very Hard, categorical factors called Subplots and Whole Plots are added to the design. This situation results in a split-split-plot design:

- Each level of Subplots corresponds to a block of constant settings of the hard-to-change factors.
- Each level of Whole Plots corresponds to a block of constant settings of the very-hard-to-change factors.
- The Model script in the design table applies the Random Effect attribute to the Whole Plots and Subplots effects.
- The levels of the hard-to-change factor are assumed to be nested within the levels of the very-hard-to-change factor by default.
- In the design table, both of the factors Whole Plots and Subplots are assigned the Design Role column property with a value of Random Block.

To construct a two-way split-plot design, select the Hard to change factors can vary independently of Very Hard to change factors option under Design Generation. The option crosses the levels of the hard-to-change factor with the levels of the very-hard-to-change factor. See “Two-Way Split-Plot Designs” on page 124.

Use the Number of Whole Plots and Number of Subplots text boxes to specify values for the numbers of whole plots or subplots. These boxes are initialized to suggested numbers of whole plots and subplots. For information about how these values are obtained, see “Numbers of Whole Plots and Subplots” on page 127.

For more information and scenarios that illustrate random block split-plot, split-split-plot, and two-way split-plot designs, see “Designs with Randomization Restrictions” on page 118. For more information about designs with hard-to-change covariates, see “Covariates with Hard-to-Change Levels” on page 127.

**Factor Column Properties**

For each factor, various column properties are saved to the data table. You can find more information about these column properties and related examples in Appendix A, “Column Properties”.

**Design Role** Each factor is given the Design Role column property. The Role that you specify in defining the factor determines the value of its Design Role column property. When you add a random block under Design Generation, that factor is assigned the Random Block value. The Design Role property reflects how the factor is intended to be used in modeling the experimental data. Design Role values are used in the Augment Design platform. See “Design Role” on page 792 in the “Column Properties” appendix.

**Factor Changes** Each factor is assigned the Factor Changes column property. The value that you specify under Changes determines the value of its Factor Changes column property. The Factor Changes property reflects how the factor is used in modeling the experimental
data. Factor Changes values are used in the Augment Design and Evaluate Design platforms. See “Factor Changes” on page 808 in the “Column Properties” appendix.

**Coding**  If the Role is Continuous, Discrete Numeric, a continuous Covariate, or Uncontrolled, the Coding column property for the factor is saved. This property transforms the factor values so that the low and high values correspond to –1 and +1, respectively. See “Coding” on page 795 in the “Column Properties” appendix.

**Value Order**  If the Role is Categorical or Blocking, the Value Order column property for the factor is saved. This property determines the order in which levels of the factor appear. See “Value Order” on page 811 in the “Column Properties” appendix.

**Mixture**  If the Role is Mixture, the Mixture column property for the factor is saved. This property indicates the limits for the factor and the mixture sum. It also enables you to choose the coding for the mixture factors. See “Mixture” on page 803 in the “Column Properties” appendix.

**RunsPerBlock**  For a blocking factor, indicates the maximum allowable number of runs in each block. When a Blocking factor is specified in the Factors outline, the RunsPerBlock column property is saved for that factor. See “RunsPerBlock” on page 817 in the “Column Properties” appendix.

### Define Factor Constraints

Use Define Factor Constraints to restrict the design space. Unless you have loaded a constraint or included one as part of a script, the **None** option is selected. To specify constraints, select one of the other options:

**Specify Linear Constraints**  Specifies inequality constraints on linear combinations of factors. Available only for factors with a Role of Continuous or Mixture. See Specify Linear Constraints.

*Note:* When you save a script for a design that involves a linear constraint, the script expresses the linear constraint as a less than or equal to inequality ( \( \leq \)).

**Use Disallowed Combinations Filter**  Defines sets of constraints based on restricting values of individual factors. You can define both AND and OR constraints. See Use Disallowed Combinations Filter.

**Use Disallowed Combinations Script**  Defines disallowed combinations and other constraints as Boolean JSL expressions in a script editor box. See Use Disallowed Combinations Script.
Note: When you analyze a design that has factor constraints, the model profiler honors the constraints.

Specify Linear Constraints

In cases where it is impossible to vary continuous factors independently over the design space, you can specify linear inequality constraints. Linear inequalities describe factor level settings that are allowed.

Click **Add** to enter one or more linear inequality constraints.

**Add** Adds a template for a linear expression involving all the continuous factors in your design. Enter coefficient values for the factors and select the direction of the inequality to reflect your linear constraint. Specify the constraining value in the box to the right of the inequality. To add more constraints, click **Add** again.

Note: The Add option is disabled if you have already constrained the design region by specifying a Sphere Radius.

Remove Last Constraint  Removes the last constraint.

Check Constraints  Checks the constraints for consistency. This option removes redundant constraints and conducts feasibility checks. A JMP alert appears if there is a problem. If constraints are equivalent to bounds on the factors, a JMP alert indicates that the bounds in the Factors outline have been updated.

Use Disallowed Combinations Filter

This option uses an adaptation of the Data Filter to facilitate specifying disallowed combinations. For detailed information, see the JMP Reports chapter in *Using JMP*.

Select factors from the Add Filter Factors list and click **Add**. Then specify the disallowed combinations by using the slider (for continuous factors) or by selecting levels (for categorical factors).

The red triangle options for the Add Filter Factors menu are those found in the Select Columns panel of many platform launch windows. See the Get Started chapter in *Using JMP*.

When you click Add, the Disallowed Combinations control panel shows the selected factors and provides options for further control. Factors are represented as follows, based on their modeling types:

**Continuous Factors**  For a continuous factor, a double-ended slider that spans the range of factor settings appears. You can specify disallowed settings by dragging the slider ends or
by setting the endpoints by clicking on the text value under the slider. In the slider, a solid blue highlight represents the disallowed values.

**Categorical Factor**  For a categorical factor, the possible levels are displayed either as labeled blocks or, when the number of levels is large, as list entries. Select a level to disallow it. To select multiple levels, hold the Control key. The block or list entries are highlighted to indicate the levels that have been disallowed. When you add a categorical factor to the Disallowed Combinations panel, the number of levels of the categorical factor is given in parentheses following the factor name.

**Disallowed Combinations Options**

The control panel has the following controls:

- **Clear**  Clears all disallowed factor level settings that you have specified. This does not clear the selected factors.

- **Start Over**  Removes all selected factors and returns you to the initial list of factors.

- **AND**  Opens the Add Filter Factors list. Selected factors become an AND group. Any combination of factor levels specified within an AND group is disallowed.

To add a factor to an AND group later on, click the group’s outline to see a highlighted rectangle. Select AND and add the factor.

To remove a single factor, select **Delete** from its red triangle menu.

- **OR**  Opens the Add Filter Factors list. Selected factors become a separate AND group. For AND groups separated by OR, a combination is disallowed if it is specified in at least one AND group.

**Red Triangle Options for Factors**

A factor can appear in several OR groups. An occurrence of the factor in a specific OR group is referred to as an *instance* of the factor.

- **Delete**  Removes the selected instance of the factor from the Disallowed Combinations panel.

- **Clear Selection**  Clears any selection for that instance of the factor.

- **Invert Selection**  Deselects the selected values and selects the values not previously selected for that instance of the factor.

- **Display Options**  Available only for categorical factors. Changes the appearance of the display. Options include showing each level as a block, list, or single category, or adding a check box next to each value.

- **Find**  Available only for categorical factors. Provides a text box beneath the factor name where you can enter a search string for levels of the factor. Press the Enter key or click
outside the text box to perform the search. Once **Find** is selected, Find options appear in the red triangle menu, such as Does not contain, Match Case, Starts with or Ends with, or Clear Find.

**Use Disallowed Combinations Script**

Use this option to disallow particular combinations of factor levels using a JSL script. This option can be used with continuous factors or mixed continuous and categorical factors.

This option opens a script window where you insert a script that identifies the combinations that you want to disallow. The script must evaluate as a Boolean expression. When the expression evaluates as true, the specified combination is disallowed.

When forming the expression for a categorical factor, use the ordinal value of the level or the name of the level. If a factor’s levels are high, medium, and low, specified in that order in the Factors outline, their associated ordinal values are 1, 2, and 3. For example, suppose that you have two continuous factors, X1 and X2, and a categorical factor X3 with three levels: L1, L2, and L3, in order. You want to disallow levels where the following is true:

\[ e^{X_1} + 2X_2 < 0 \text{ and } X_3 = L2 \]

Enter the expression `(Exp(X1) + 2*X2 < 0) & (X3 == 2)` into the script window.

**Figure 4.20 Expression in Script Editor**

(In the figure, unnecessary parentheses were removed by parsing.) Notice that functions can be entered as part of the Boolean expression. The expression `(Exp(X1) + 2*X2 < 0) & (X3 == "L2")` is also valid.

**Model**

Specify your assumed model (which contains all the effects that you want to estimate) in the Model outline. For each effect that you specify, you can designate that effect’s Estimability. The Estimability value indicates whether it is Necessary to estimate that effect, or if you are content to estimate that effect If Possible.
The initial Model outline includes the main effects for all factors. If you have entered a discrete numeric factor with three or more levels, polynomial terms are also included in the initial model. The Estimability of second-and higher-order terms is set to If Possible. If you want to ensure that these terms are estimable, change their Estimability to Necessary.

**Note:** You can ensure that the estimability of discrete numeric polynomial terms is always set to Necessary. Select File > Preferences > Platforms > DOE. Check Discrete Numeric Powers Set to Necessary.

---

**Figure 4.21  Model Outline**

When you construct your design table, JMP saves a Model script to the data table. Except for discrete numeric factors, the Model script contains the effects shown in the Model outline. For a discrete numeric factor, the Model script contains only its main effect and quadratic term.

The Model outline contains the following buttons and fields:

**Main Effects**  Adds main effects for all factors in the model, and polynomial terms for discrete numeric factors.

**Interactions**  Adds interaction effects. If no factors are selected in the Factors outline, select 2nd, 3rd, 4th, or 5th to add all appropriate interactions up to that order. Add interactions up to a given order for specific factors by selecting the factor names in the Factors outline, selecting Interactions, and then specifying the appropriate order. Interactions between non-mixture and mixture factors, and interactions with blocking and constant factors, are not added.

**RSM**  Adds interaction and quadratic terms up to the second order (response surface model terms) for all continuous factors. Categorical factors are not included in RSM terms. Main effects for non-mixture factors that interact with all the mixture factors are removed.

**Cross**  Adds specific interaction terms. Select factor names in the Factors outline and effect names in the Model outline. Click Cross to add the crossed terms to the Model outline.

**Powers**  Adds polynomial terms. If no factor names are selected in the Factors outline, adds polynomial terms for all continuous factors. If factor names are selected in the Factors
outline, adds polynomial terms for only those factors. Select 2nd, 3rd, 4th, or 5th to add polynomial terms of that order.

**Scheffé Cubic**  (Available for mixture factors.) Adds Scheffé cubic terms for all mixture factors. These terms are used to specify a mixture model with third-degree polynomial terms.

**Remove Term**  Removes selected effects.

**Name**  The name of the effect.

**Estimability**  A designation of your need to estimate the effect.

- If Estimability is set to Necessary, the algorithm ensures that the effect is estimable.
- If Estimability is set to If Possible, the algorithm attempts to make that effect estimable, as permitted by the number of runs that you specify.

Except for polynomial terms for discrete numeric factors, all effects are specified as Necessary by default. Click an effect’s Estimability value to change it.

**Bayesian D-Optimality and Estimation of If Possible Effects**

The Bayesian D-Optimal design approach obtains precise estimation of all Necessary terms while providing omnibus detectability (and some estimability) for If Possible terms. For more detail, see “Response Surface Experiments” on page 159 in the “Examples of Custom Designs” chapter and “Bayesian D-Optimality” on page 129. If any main effect model term is set to If Possible, the Bayesian Information matrix is used for design diagnostic calculations.

**Alias Terms**

In the Alias Terms outline, add potentially active effects that are not in your assumed model but might bias the estimates of model terms. It is possible that effects not included in your assumed model are active. Once you generate your design, the Alias Matrix outline appears under Design Evaluation. The Alias Matrix entries represent the degree of bias imparted to model parameters by the effects that you specified in the Alias Terms outline. See the “The Alias Matrix” on page 823 in the “Technical Details” appendix.

By default, the Alias Terms outline includes all two-way interaction effects that are not in your Model outline (with the exception of terms involving blocking factors). Add terms using the buttons. For a description of how to use these buttons to add effects to the Alias Terms table, see “Model” on page 99.

**Note:**  For interaction terms, only interactions of the selected order are added. This differs from the Model outline where interactions of the selected order and all lower orders are added to the model.
For example, suppose that you specify a design with three continuous factors. Your assumed model, specified in the Model outline, contains only those three main effects. You can afford only six runs. You want to see how estimates of the main effects might be biased by active two-way interactions and the three-way interaction.

The Alias Terms table includes all two-way interactions by default. You can add the three-way interaction by selecting **Interactions > 3rd**.

![Figure 4.22 Alias Terms Outline](image)

![Figure 4.23 Alias Matrix](image)

The Alias Matrix indicates that each main effect is partially aliased with two of the interactions. See “Alias Matrix” on page 464 in the “Evaluate Designs” chapter and “The Alias Matrix” on page 823 in the “Technical Details” appendix.

### Design Generation

The Design Generation outline gives you choices relating to blocking, center points, replication, and the number of runs in your design. Typically, the input area has two parts:

- Design structure options
- Number of runs options
Design Structure Options

**Group runs into random blocks of size**  (Not available if a blocking factor is specified.) To construct a random block design, enter the number of runs that you want in each block. When you specify the sample size, a factor called Random Block is created. Its levels define blocks of a size that is consistent with the block size that you entered, given the specified number of runs. If the number of runs is an integer multiple of the block size, the block sizes equal your specified value.

**Number of Whole Plots**  Appears when you specify a hard or very-hard-to-change factor. The factor Whole Plots corresponds to the very-hard-to-change factors (split-split-plot design), if there are any, otherwise to the hard-to-change factors (split-plot design). JMP suggests a value for the number of whole plots that maximizes the information about the coefficients in the model. Or, you can enter a value for the number of whole plots. See “Numbers of Whole Plots and Subplots” on page 127.

**Number of Subplots**  Appears when you specify a very-hard-to-change factor. The factor Subplots corresponds to the hard-to-change factors in the split-split-plot design. JMP suggests values for the number of whole plots and subplots that maximize the information about the coefficients in the model. Or, you can enter a value for the number of subplots. See “Numbers of Whole Plots and Subplots” on page 127.

**Hard to change factors can vary independently of Very Hard to change factors**  Select this option to create a strip-plot (also known as two-way split-plot or split block) design. This option creates a design where the hard-to-change factors are randomized within the levels of the very-hard-to-change factors. They are *not* nested within the very-hard-to-change factors.

**Number of Center Points**  Appears only if the design contains factors with a Continuous or Mixture factor type. Specify how many additional runs you want to add as center points to the design. A center point is a run whose setting for each continuous factor is midway...
between the high and low settings. See “Center Points, Replicate Runs, and Testing” on page 65 in the “Starting Out with DOE” chapter.

If a design contains both continuous and other types of factors, center points might not be balanced relative to the levels of the other factors. Custom Design chooses the center points to maximize the D-, I-, or alias efficiency of the design.

**Number of Replicate Runs**  Specify the number of replicate trials that you want to add to the design. This does not replicate the entire design, but chooses the optimal design points to replicate. See “Center Points, Replicate Runs, and Testing” on page 65 in the “Starting Out with DOE” chapter.

**Number of Runs Options**

**Minimum**  A lower bound on the number of runs necessary to avoid failures in design generation. When you select Minimum, the resulting design is saturated. There are no degrees of freedom for error.

*Note:* If you select the Minimum number of runs, there will be no error term for testing. You will not be able to test parameter estimates. This choice is appropriate only when the cost of additional runs is prohibitive.

**Default**  Suggests the number of runs. This value is based on heuristics for creating a balanced design with at least four runs more than the Minimum number of runs.

**User Specified**  Specify the number of runs that you want. Enter that value into the Number of Runs text box. This option enables you to balance the cost of additional runs against the potential gain in information.

**Number of Runs**  This is the only option that appears when a covariate factor with Changes set to Easy is specified. The number of runs shown is the number of rows in the data table associated with your covariate or covariates. You can specify a smaller number of runs. In that case, the covariate runs that are selected optimize the design criterion.

**Make Design**

Once you have completed the Design Generation outline, click Make Design. Custom Design generates the design, presents it in the Design outline, and provides evaluation information in the Design Evaluation outline. Notice the controls in the Model and Alias Outlines are disabled. Use the Back button to change model or alias terms. The Output Options panel also appears, enabling you to create the design table.

*Note:* Sometimes several designs can optimize the optimality criterion. When this is the case, the design algorithm might generate different designs when you click the Back and Make Design buttons repeatedly.
Design

The Design outline shows the runs for the custom design. The design is optimal, given the conditions that you have specified. The runs might not appear to be randomized. You can select Run Order options in the Output Options panel before generating your design table.

Design Evaluation

The Design Evaluation red triangle menu and outlines provide a number of ways to evaluate the properties of the generated custom design.

Use Bayesian Information  Select to use the Bayesian Information matrix in the design diagnostic calculations for designs with If Possible model effects that are not estimable. For more information about the Bayesian Information adjustments see “Bayesian D-Optimality” on page 129.

**Note:** If all model effects are estimable, the Design Diagnostics are presented for all effects without making the Bayesian Information adjustment. If some terms are inestimable, only the Necessary model terms are presented unless the Use Bayesian Information option is selected.

Power Analysis  Enables you to explore your ability to detect effects of given sizes.

Prediction Variance Profile  Shows the prediction variance over the range of factor settings.

Fraction of Design Space Plot  Shows how much of the model prediction variance lies below (or above) a given value.

Prediction Variance Surface  Shows a surface plot of the prediction variance for any two continuous factors.

Estimation Efficiency  For each parameter, gives the fractional increase in the length of a confidence interval compared to that of an idealized (orthogonal) design, which might not exist. Also gives the relative standard error of the parameters.

Alias Matrix  Gives coefficients that indicate the degree by which the model parameters are biased by effects that are potentially active, but not in the model. You specify the terms representing potentially active effects in the Alias Terms table. See “The Alias Matrix” on page 823 in the “Technical Details” appendix.

Color Map on Correlations  Shows the absolute correlation between effects on a plot using an intensity scale.
Note: The default intensity scale is a gray scale. To change the color scale, click the Color Map on Correlations red triangle and select **Blue to Gray to Red**. For a custom color scale, right-click in the plot and select **Color Theme**.

**Design Diagnostics**  Indicates the optimality criterion used to construct the design. Also gives efficiency measures for your design. See Optimality Criterion in “Custom Design Options” on page 108 and “Optimality Criteria” on page 128.

Note: The Design Diagnostics outline does not provide the following statistics when the model includes factors with Changes set to Hard or Very Hard or with Estimability set to If Possible: D Efficiency, G Efficiency, A Efficiency.

For more information about the Design Evaluation outline, see “Design Evaluation” on page 451 in the “Evaluate Designs” chapter.

**Output Options**

Use the Output Options panel to save your custom design X Matrix, simulate responses, or customize your design data table. You can perform the following tasks:

- specify how you want the custom design data table to appear
- construct the design table
- return to a previous point in the Custom Design window

In most cases, the Output Options panel appears as shown in Figure 4.25.

**Figure 4.25  Output Options Panel**

The Output Options panel contains these options:

- “Data Table Options” on page 107
- “Run Order” on page 107
- “Make Table” on page 107
- “Back” on page 108
Data Table Options

The Data Table Options includes the Save X Matrix option ("Save X Matrix" on page 114), the Simulate Response option ("Simulate Responses" on page 112) as well as an Include Run Order Column option.

Include Run Order Column  Adds a column to the design data table that corresponds to the design order in the Design outline.

Tip: Use the Include Run Order Column when you save your data with a sorted run order. This provides a column of the randomized run order from the design outline.

Run Order

The Run Order options determine the order of the runs in the design table. Choices include the following:

Keep the Same  Rows in the design table are in the same order as in the Design outline.

Sort Left to Right  Columns in the design table are sorted from left to right.

Randomize  Rows in the design table are in random order.

Sort Right to Left  Columns in the design table are sorted from right to left.

Randomize within Blocks  Rows in the design table are in random order within the blocks.

Make Table

Click Make Table to construct the custom design data table. In the Custom Design table, the Table panel (in the upper left) can contain scripts, as appropriate given your design. The Model, Evaluate Design, and DOE Dialog scripts are always provided. To run a script, click the green triangle next to the script name. If your design includes covariates, the design table includes a covariate row index column unless all covariate rows are used in the design.

Figure 4.26  Custom Design Table Showing Scripts
Possible scripts include the following:

**Model**  Runs the **Analyze > Fit Model** platform. The model described by the script is determined by your choices in the Model outline and by the type of design.

**Evaluate Design**  Runs the **DOE > Design Diagnostics > Evaluate Design** platform. The model described by the script is determined by your choices in the Model outline and by the type of design.

**Constraint**  Shows model constraints that you entered in the Define Factor Constraints outline using the **Specify Linear Constraints** option.

**Disallowed Combinations**  Shows model constraints that you entered in the Define Factor Constraints outline using the **Use Disallowed Combinations Filter** or the **Use Disallowed Combinations Script** options.

**DOE Dialog**  Re-creates the Custom Design window that you used to generate the design table. The script also contains the random seed used to generate your design.

**Back**

The Back button takes you back to where you were before clicking Make Design. You can make changes to the previous outlines and regenerate the design.

**Note:** If you attempt to remove all factors after clicking the Back button, one continuous factor remains. You can delete the continuous factor after new factors are added.

---

**Custom Design Options**

The Custom Design red triangle menu contains options for design setup and generation.

**Save Responses**  Saves the information in the Responses panel to a new data table. You can then quickly load the responses and their associated information into most DOE windows. This option is helpful if you anticipate reusing the responses.

**Load Responses**  Loads responses that you saved using the Save Responses option.

**Save Factors**  Saves the information in the Factors panel to a new data table. Each factor’s column contains its levels. Other information is stored as column properties. You can then quickly load the factors and their associated information into most DOE windows.
**Note:** It is possible to create a factors table by entering data into an empty table, but remember to assign each column an appropriate Design Role. Do this by right-clicking on the column name in the data grid and selecting **Column Properties > Design Role**. In the Design Role area, select the appropriate role.

**Load Factors**  Loads factors that you saved using the Save Factors option.

**Save Constraints**  (Unavailable for some platforms) Saves factor constraints that you defined in the Define Factor Constraints or Linear Constraints outline into a data table, with a column for each constraint. You can then quickly load the constraints into most DOE windows.

In the constraint table, the first rows contain the coefficients for each factor. The last row contains the inequality bound. Each constraint’s column contains a column property called **ConstraintState** that identifies the constraint as a “less than” or a “greater than” constraint. See “**ConstraintState**” on page 818 in the “Column Properties” appendix.

**Load Constraints**  (Unavailable for some platforms) Loads factor constraints that you saved using the Save Constraints option.

**Set Random Seed**  Sets the random seed that JMP uses to control actions that have a random component. These actions include one or more of the following:

- initializing search algorithms for design generation
- randomizing Run Order for design construction
- selecting a starting design for designs based on random starts

To reproduce a design, enter the random seed that generated the design before clicking **Make Design**.

**Note:** The random seed associated with a design is included in the DOE Dialog script that is saved to the design data table.

**Simulate Responses**  Adds response values and a column containing a simulation formula to the design table. Select this option before you click Make Table.

When you click Make Table, the following occur:

- A set of simulated response values is added to each response column.
- For each response, a new column that contains a simulation model formula is added to the design table. The formula and values are based on the model that is specified in the design window.
- A Model window appears where you can set the values of coefficients for model effects and specify one of three distributions: Normal, Binomial, or Poisson.
Note: Not all distributions are available for all design types.

– A script called **DOE Simulate** is saved to the design table. This script reopens the Model window, enabling you to re-simulate values or to make changes to the simulated response distribution.

Make selections in the Model window to control the distribution of simulated response values. When you click Apply, a formula for the simulated response values is saved in a new column called `<Y> Simulated`, where Y is the name of the response. Clicking Apply again updates the formula and values in `<Y> Simulated`.

For additional details, see “Simulate Responses” on page 112 in the “Custom Designs” chapter.

Note: **JMP Pro** You can use Simulate Responses to conduct simulation analyses using the JMP Pro Simulate feature. For more information and DOE examples, see the Simulate chapter in *Basic Analysis*.

**Save X Matrix** Saves the Moments Matrix and Model Matrix to table scripts in the design data table. These scripts contain the moments and design matrices. See “Save X Matrix” on page 114.

Caution: For a design with nominal factors, the Model Matrix saved by the Save X Matrix option is *not* the coding matrix used in fitting the linear model. You can obtain the coding matrix used for fitting the model by selecting the option Save Columns > Save Coding Table in the Fit Model report that you obtain when you run the Model script.

**Optimality Criterion** Changes the design optimality criterion. The default criterion, **Recommended**, specifies D-optimality for all design types, unless you added quadratic effects using the RSM button in the Model outline. For more information about the D-, I-, and alias-optimal designs, see “Optimality Criteria” on page 128.

Note: You can set a preference to always use a given optimality criterion. Select File > Preferences > Platforms > DOE. Check Optimality Criterion and select your preferred criterion.

**Number of Starts** Enables you to specify the number of random starts used in constructing the design. See “Number of Starts” on page 116.

**Design Search Time** Maximum number of seconds spent searching for a design. The default search time is based on the complexity of the design. See “Design Search Time” on page 117 and “Number of Starts” on page 116.

If the iterations of the algorithm require more than a few seconds, a Computing Design progress window appears. If you click **Cancel** in the progress window, the calculation
stops and gives the best design found at that point. The progress window also displays D-efficiency for D-optimal designs that do not include factors with Changes set to Hard or Very Hard or with Estimability set to If Possible.

**Note:** You can set a preference for Design Search Time. Select File > Preferences > Platforms > DOE. Check Design Search Time and enter the maximum number of seconds. In certain situations where more time is required, JMP extends the search time.

**Sphere Radius**  Constrained the continuous factors in a design to a hypersphere. Specify the radius and click OK. Design points are chosen so that their distance from 0 equals the Sphere Radius. Select this option before you click Make Design.

**Note:** Sphere Radius constraints cannot be combined with constraints added using the Specify Linear Constraints option. Also, the option is not available when hard-to-change factors are included (split-plot designs).

**Advanced Options > Mixture Sum**  Set the sum of the mixture factors to any positive value. Use this option to keep a component of a mixture constant throughout an experiment.

**Advanced Options > Split Plot Variance Ratio**  Specify the ratio of the variance of the random whole plot and the subplot variance (if present) to the error variance. Before setting this value, you must define a hard-to-change factor for your split-plot design, or hard and very-hard-to-change factors for your split-split-plot design. Then you can enter one or two positive numbers for the variance ratios, depending on whether you have specified a split-plot or a split-split-plot design.

**Advanced Options > Prior Parameter Variance**  (Available only when the Model outline is available.) Specify the weights that are used for factors whose Estimability is set to If Possible. The option updates to show the default weights when you click Make Design. Enter a positive number for each of the terms for which you want to specify a weight. The value that you enter is the square root of the reciprocal of the prior variance. A larger value represents a smaller variance and therefore more prior information that the effect is not active.

Bayesian D- or I-optimality is used in constructing designs with If Possible factors. The default values used in the algorithm are 0 for Necessary terms, 4 for interactions involving If Possible terms, and 1 for If Possible terms. See “The Alias Matrix” on page 823 in the “Technical Details” appendix and “Optimality Criteria” on page 128.

**Advanced Options > A- Optimality Parameter Weights**  (Use for A-Optimal designs.) Specify weights for the model parameters. This enables you to place more weight on the variance of the main effects over say 2nd order effects. For more information about parameter weights see Morgan and Stallings (2017).
Advanced Options > D Efficiency Weight  Specify the relative importance of D-efficiency to alias optimality in constructing the design. Select this option to balance reducing the variance of the coefficients with obtaining a desirable alias structure. Values should be between 0 and 1. Larger values give more weight to D-Efficiency. The default value is 0.5. This option has an effect only when you select Make Alias Optimal Design as your Optimality Criterion.

For the definition of D-efficiency, see “Optimality Criteria” on page 128. For more information about alias optimality, see “Alias Optimality” on page 132.

Save Script to Script Window  Creates the script for the design that you specified in the Custom Design window and places it in an open script window.

Simulate Responses

Use simulated responses for design exploration prior to data collection or in a classroom setting. When simulate responses is selected and you click Make Table to create your design table, the Simulate Responses option does the following for each response:

- It adds random response values to the response column in your design table.
- It adds a new a column containing a simulation model formula to the design table. The formula and values are based on the model that is specified in the design window.

A Model window appears where you can specify parameter values and select a response distribution for simulation. When you click Apply in the Model window, each column containing a simulation model formula is updated.

Control Window

Figure 4.27 shows the Model window for a design with one continuous factor (X1) and one three-level categorical factor (X2). Notice that X2 is represented by two model terms.

Figure 4.27  Simulate Responses Control Window
The initial window shows values for the coefficients of either 1 or -1, and a Normal distribution with error standard deviation equal to 1. If you have set Anticipated Coefficients as part of Power Analysis under Design Evaluation in the DOE window, then the default values in the Simulate Responses outline are the values that you specified as Anticipated Coefficients and Anticipated RMSE (Error Std) in the Power Analysis outline. If it is not possible to fit the model specified in the data table’s Model script, the intercept and coefficients have default values of 0.

**Simulate Responses**

To specify a model for simulated values, do the following:

1. For each term in the list of Effects, enter coefficients for the linear model used to simulate the response values. These define a linear function, \( L(\mathbf{x}, \beta) = \mathbf{x}'\beta \). See the Simulate Responses outline in Figure 4.27:
   - The vector \( \mathbf{x} \) consists of the terms that define the effects listed under Effects.
   - The vector \( \beta \) is the vector of model coefficients that you specify under Y.

2. Under Distribution, select a response distribution.

3. Click **Apply**. A <Y> Simulated column containing simulated values and their formula is added to the design table, where Y is the name of the response column.

**Distribution**

Choose from one of the available distributions in the Simulate Responses window:

**Normal** Simulates values from a normal distribution. Enter a value for Error \( \sigma \), the standard deviation of the normal error distribution. If you have designated factors to have Changes of Hard in the Factors outline, you can enter a value for Whole Plots \( \sigma \), the whole plot error. If you have designated factors to have Changes of Hard and Very Hard, you can enter values for both the subplot and whole plot errors. When you click Apply, random values and a formula containing a random response vector based on the model are entered in the column <Y> Simulated.

**Binomial** Simulates values from a binomial distribution. Enter a value for N, the number of trials. Random integer values are generated according to a binomial distribution based on N trials with probability of success \( \frac{1}{1 + \exp(-L(\mathbf{x}, \beta))} \). When you click Apply, random values and their formula are entered in the column <Y> Simulated. A column called N Trials that contains the value N is also added to the data table.

**Poisson** Simulates random integer values according to a Poisson distribution with parameter \( \exp((L(\mathbf{x}, \beta)) \). When you click Apply, random values and their formula are entered in the column <Y> Simulated.
**Note:** You can set a preference to simulate responses every time you click Make Table. To do so, select **File > Preferences > Platforms > DOE.** Select **Simulate Responses.**

## Save X Matrix

This option saves scripts called Moments Matrix and Model Matrix that contain the moments matrix and the model matrix to the design data table. The moments matrix and the model matrix are used to calculate the Average Variance of Prediction, which appears in the Design Diagnostics section of the Design Evaluation outline. See Goos and Jones (2011). If the design is a split-plot design, a V Inverse script is also saved. The V Inverse script contains the inverse of the covariance matrix of the responses.

**Caution:** For a design with nominal factors, the Model Matrix saved by the Save X Matrix option is *not* the coding matrix used in fitting the linear model. You can obtain the coding matrix used for fitting the model by selecting the option Save Columns > Save Coding Table in the Fit Model report that you obtain when you run the Model script.

**Note:** You can set a preference to always save the matrix script. Select **File > Preferences > Platforms > DOE.** Check Save X Matrix.

## Model Matrix

The *model matrix* describes the design for the experiment. The model matrix has a row for each run and a column for each term of the model specified in the Model outline. For each run, the corresponding row of the model matrix contains the coded values of the model terms:

- Continuous terms are coded to span the range from -1 to 1.
- Nominal terms are coded by applying the Gram-Schmidt orthogonalization procedure to the coding vectors used in fitting linear models.

For more information about the Gram-Schmidt orthogonalization procedure, see Horn and Johnson (2012).

**Note:** Coding for power analysis matches that of fitting linear models. For more information about the coding used for nominal terms in fitting linear models, see *Fitting Linear Models.*
Moments Matrix

The *moments matrix* is dependent upon the model effects but is independent of the design. It is defined as follows:

\[
M = \int_R f(x)f(x)'dx
\]

where \(f(x)\) denotes the model effects corresponding to factor combinations of the vector of factors, \(x\), and \(R\) denotes the design space. For more information about moments and design matrices, see Goos and Jones (2011) and Myers et al. (2009). Note that the moments matrix is called a matrix of region moments in Myers et al. (2009).

Scripts

From the Custom Design red triangle menu, select *Save X Matrix*. After the design and the table are created, in the Custom Design table, the Moments Matrix and Model Matrix scripts, and if the design is a split plot, the V Inverse script, are saved as table scripts.

- Right-click and Select *Edit* from either the Moments Matrix, Model Matrix, or V Inverse script. The script shows the corresponding matrix. You can copy this matrix into scripts that you write.
- When you run the Moments Matrix script, the log shows the number of rows in the moments matrix, called Moments.
- When you run the script Model Matrix, the log displays the number of rows in the model matrix, called X.
- When you run the script V Inverse, the log displays the number of rows in the inverse covariance matrix, called V Inverse.

Example

This example illustrates use of the model matrix script:

**Tip:** To see the log, select *View > Log* (*Window > Log* on macOS).

1. Select **DOE > Custom Design**.
2. Add 3 continuous factors and click **Continue**.
3. Click **Interactions > 2nd**.
4. Click the Custom Design red triangle and select **Save X Matrix**.
5. Using the Default Number of Runs (12), click **Make Design** and then **Make Table**.
6. In the Table panel, right-click the Moments Matrix script and select **Edit**.
The script appears in a script window. The script shows the moments matrix, which is called **Moments**.

**Figure 4.28** Moments Matrix Script

7. If it is not already open, select **View > Log (Window > Log)** on the macOS.

8. In the Table panel, click the green triangle next to the Moments Matrix script.

   The number of rows appear in the log as \(\text{N Row(Moments)} = 7\).

9. In the Table panel, right-click the Model Matrix script and select **Edit**.

   The script appears in a script window. The script shows the model matrix, which is called **X**.

10. Click **Run**.

    The number of rows appears in the log as \(\text{N Row(X)} = 12\).

11. To view the Model Matrix as a data table, add these lines to the script:

    ```
    dt = New Table( "Model Matrix" );
    dt << Set Matrix( X );
    ```

12. Click **Run**.

**Number of Starts**

The number of starts is the number of times that the coordinate-exchange algorithm initiates with a new design. See “Coordinate-Exchange Algorithm” on page 133. You can specify your own value using the **Number of Starts** option. Increasing the number of random starts tends to improve the optimality of the resulting design.

Unless you specify a value for Number of Starts and click OK, the number of starts is controlled by Design Search Time. To see how many starts were used to construct a design, click Make Design. Then select Number of Starts. The value in the text box is the number of starts used to construct the specific design.
In certain special cases, the globally optimal design is known from theory. If the coordinate-exchange algorithm detects that it has found an optimal design, it stops searching and returns that design.

**Tip:** To reproduce a specific design, you need to specify the Number of Starts and the Random Seed originally used to produce the design. Obtain these values from the red triangle options after you click Make Design.

In examples of custom designs in the documentation, the random seed and number of starts are often provided so that you can reconstruct the exact design being discussed.

**Design Search Time**

Design Search Time is the amount of time allocated to finding an optimal design. Custom Design’s coordinate-exchange algorithm consists of finding near-optimal designs based on random starting designs. See “Coordinate-Exchange Algorithm” on page 133. The Design Search Time determines how many designs are constructed based on random starting designs.

You can specify your own value using the Design Search Time option. Increasing the search time tends to improve the optimality of the resulting design.

Keep in mind that designs produced by rerunning the algorithm can differ. Even with the same random seed, the numbers of starting designs used to construct the final design might differ because of variations in computing speed and other factors.

**Note:** The number of starting designs is given by the value in the Number of Starts text box. However, this value is not updated until after you construct your design by clicking Make Design.

In certain special cases, the globally D-optimal design is known from theory. These cases include:

- Two-level fractional factorial designs or nonregular orthogonal arrays. These are globally D-optimal for all main effect and two-factor interaction models.
- Latin-square designs. These are D-optimal for main effect models assuming the right sample size and numbers of levels of the factors.
- Plackett-Burman designs. These are D-optimal for main effect models.

If the coordinate-exchange algorithm detects that it has found an optimal design, it stops searching and returns that design.

Designs with Randomization Restrictions

It is not always feasible to run a completely randomized design. Logistical or physical restrictions to randomization have to be considered when designing an experiment. This section describes how the Custom Design platform handles various types of designs where random assignment of experimental units to factor level settings is restricted. Random block designs and various types of split-plot designs are included.

Random Block Designs

A random block design groups the runs of an experiment into blocks that are considered to be randomly chosen from a larger population. Runs within a block of runs are usually more homogeneous than runs in different blocks. In these instances, you are often better able to discern other effects if you account for the variation explained by the blocking variables.

Scenario for a Random Block Design

Goos (2002) presents an example involving a pastry dough mixing experiment. The purpose of the experiment is to understand how certain properties of the dough depend on three factors: feed flow rate, initial moisture content, and rotational screw speed. Since it was possible to conduct only four runs a day, the experiment required several days to run. It is likely that random day-to-day differences in environmental variables have some effect on all of the runs that are performed on a given day. To account for the day-to-day variation, the runs were grouped into blocks of size four so that this variation would not compromise the information about the three factors.

The blocking factor, Day, consists of each day’s runs. The days on which the trials were conducted are representative of a large population of days with different environmental conditions. Day is a random blocking factor.
Setup for a Random Block Design

To create a random block design, use the Custom Design platform to enter responses and factors and define your model as usual. In the Design Generation outline, select the **Group runs into random blocks of size** option and enter the number of runs you want in each block. See “Design Structure Options” on page 103.

**Note:** To define a fixed blocking factor, enter a blocking factor in the Factors outline. To define a random blocking factor, do not enter a blocking factor in the Factors outline. Instead, select the **Group runs into random blocks of size** option under Design Generation.

Split-Plot Designs

Split-plot designs are used in situations where the settings of certain factors are held constant for groups of runs. In industry, these are usually factors that are difficult or expensive to change from run to run. Factors whose settings need to be held constant for groups of runs are classified as *hard-to-change* in JMP.

Because certain factors are hard-to-change, it is not practical to randomly allocate them to experimental units. Instead, they are allocated to groups of units. This imposes a restriction on randomization that must be considered in generating a design and in analyzing the results.

Scenario for a Split-Plot Design

Box et al. (2005) presents an experiment to study the corrosion resistance of steel bars. The bars are placed in a furnace for curing. Afterward, a coating is applied to increase resistance to corrosion. The two factors of interest are:

- **Furnace Temp** in degrees centigrade, with levels 360, 370, and 380
- **Coating**, with levels C1, C2, C3, and C4 depicting four different types of coating

**Furnace Temp** is a hard-to-change factor, due to the time it takes to reset the temperature in the furnace. For this reason, four bars are processed for each setting of furnace temperature. At a later stage, the four coatings are randomly assigned to the four bars.

The experimental units are the bars. **Furnace Temp** is a hard-to-change factor whose levels define whole plots. Within each whole plot, the **Coating** factor is randomly assigned to the experimental units to which the whole plot factor was applied.
The Factors outline for the corrosion experiment has Changes set to Hard for Furnace Temp and Easy for Coating. The 15-run design consists of five whole plots, within which the settings of Temperature are held constant.

Setup for a Split-Plot Design

In general, several factors can be applied to a processing step where settings are hard-to-change. In the furnace example, you might consider a furnace location factor, as well as temperature. In the Factors outline, under the Changes column, you would specify a Changes value of Hard for such factors.

When a custom design involves only easy-to-change and hard-to-change factors, the runs of the hard-to-change factors are grouped using a new factor called Whole Plots. The values of Whole Plots designate blocks of runs with identical settings for the hard-to-change factors. The Model script that is saved to the design table treats Whole Plots as a random effect. See “Changes” on page 90 and “Design Structure Options” on page 103.

For an example of creating a split-plot design and analyzing the experimental data, see “Split-Plot Experiment” on page 197 in the “Examples of Custom Designs” chapter.
Split-Split-Plot Designs

A split-split-plot design is used when there are two levels of factors that are hard-to-change. In industry, such designs often occur when batches of material or experimental units from one processing stage pass to a second processing stage. Factors are applied to batches of material at the first stage. Then those batches are divided for second-stage processing, where additional factors are studied. The first stage factors are considered very-hard-to-change, and the second-stage factors are considered hard-to-change. Additional factors can be applied to experimental units after the second processing stage. These factors are considered easy-to-change.

In a split-split-plot design, the batches are considered to be random blocks. Since the batches are divided for second-stage processing, the second-stage factors are nested within the first-stage factors.

Scenario for a Split-Split-Plot Design

Schoen (1999) presents an example of a split-split-plot design that relates to cheese quality. The factors are given in the Cheese Factors.jmp data table found in the Design Experiment folder. The experiment consists of three stages of processing:

- Milk is received from farmers and stored in a large tank.
- Milk from this tank is distributed to smaller tanks used for curd processing.
- The curds from each tank are transported to presses for processing individual cheeses.

The experiment consists of testing:

- Two factors that are applied when the milk is in the large storage tank.
- Five factors that are applied to the smaller curd processing tanks.
- Three factors that are applied to the individual cheeses from a curds processing tank.

Notice that the levels of factors applied to the curd processing tanks (subplots) are nested within the levels of factors applied to the milk storage tank (whole plots).

The Factors outline have Changes set as Very Hard, Hard, or Easy:

- Very Hard for the two storage tank factors.
- Hard for the five curd processing tank factors.
- Easy for the three factors that can be randomly assigned to cheeses.
The default number of whole plots is 5 and the default number of subplots is 10. The number of runs is set to 22. If only 10 subplots are used the design does not have enough whole plots to estimate the subplot variance. Change the number of subplots to 11 and click **Make Design** to see a 22-run design.
The five whole plots correspond to the storage factors; storage 1 and storage 2. The settings of the storage factors are constant within a whole plot. If consecutive whole plots have the same setting for a whole plot factor, the factor should be reset between the plots. For example, you should reset the level for storage 1 between runs 10 and 11 and between runs 14 and 15, and you should reset the level for storage 2 between runs 18 and 19. Resetting the factor between whole plots, even when the specified settings are the same, is required in order to capture whole plot variation.

The 11 subplots correspond to the curds factors. Within a subplot, the settings of the curds factors are constant. Each level of Subplots appears only within one level of Whole Plots, indicating that the levels of Subplots are nested within the levels of Whole Plots.

Levels of the cheese factors vary randomly from run to run.

**Setup for a Split-Split-Plot Design**

In a split-split-plot design, the Factors outline contains factors with Changes set to Very Hard and Hard. The design can also contain factors with Changes set to Easy. Two factors are created:

- A factor called Whole Plots represents the blocks of constant levels of the factors with Changes set to Very Hard.
- A factor called Subplots represents the blocks of constant levels of the factors with Changes set to Hard.
- The factor Subplots reflects the nesting of the levels of the factors with Changes set to Hard within the levels of the factors with Changes set to Very Hard.
• The levels of factors with Changes set to Easy are randomly assigned to units within subplots.

• The factors Whole Plots and Subplots are treated as random effects in the Model script that is saved to the design table.

See the Changes description under “Factors Outline” on page 90 and “Design Structure Options” on page 103.

Two-Way Split-Plot Designs

A two-way split-plot (also known as strip plot or split block) design consists of two split-plot components. In industry, these designs arise when batches of material or experimental units from one processing stage pass to a second processing stage. But, after the first processing stage, it is possible to divide the batches into sub-batches. The second-stage processing factors are applied randomly to these sub-batches. For a specific second-stage experimental setting, all of the sub-batches assigned to that setting can be processed simultaneously. Additional factors can be applied to experimental units after the second processing stage.

In contrast to a split-split-plot design, the second-stage factors are *not nested* within the first-stage factors. After the first stage, the batches are subdivided and formed into new batches. Therefore, both the first- and second-stage factors are applied to whole batches.

Although factors at both stages might be equally hard-to-change, to distinguish these factors, JMP denotes the first stage factors as *very-hard*-to-change, and the second-stage factors as *hard*-to-change. Additional factors applied to experimental units after the second processing stage are considered *easy*-to-change.

Scenario for a Two-Way Split-Plot Design

Vivacqua and Bisgaard (2004) describe an experiment to improve the open circuit voltage in battery cells. Two stages of processing are of interest:

• First stage: A continuous assembly process
• Second stage: A curing process with a 5-day cycle time

The engineers want to study six two-level factors:

• Four factors, X1, X2, X3, and X4, that are applied to the assembly process
• Two factors, X5 and X6, that are applied to the curing process

A full factorial design with all factors at two levels would require $2^6 = 64$ runs, and would require a prohibitive $64 \times 5 = 320$ days. Also, it is not practical to vary assembly conditions for individual batteries. However, assembly conditions can be changed for large batches, such as batches of 2000 batteries.
Both the first- and second-stage factors are hard-to-change. In a sense, there are two split-plot designs. However, the batches of 2,000 batteries from the first-stage experiment can be divided into four sub-batches of 500 batteries each. These sub-batches can be randomly assigned to the four settings of the two second-stage factors. All of the batches assigned to a given set of curing conditions can be processed simultaneously. In other words, the first- and second-stage factors are *crossed*.

To distinguish between the first- and second-stage factors, you designate the Changes for the first-stage factors as Very Hard, and the Changes for the second-stage factors as Hard (Figure 4.32). Also, under Design Generation, note the following option: **Hard to change factors can vary independently of Very Hard to change factors**. If this is not checked, the design is treated as a split-split-plot design, with nesting of factors at the two levels. Check this option to create a two-way split-plot design.

**Figure 4.32** Factors and Design Generation Outline for Two-Way Split Plot Design

The default number of whole plots is 7; the default number of subplots is 14. Click **Make Design** to see the 28-run design.
**Figure 4.33** Two-Way Split-Plot Design for Battery Cells

</table>

The seven whole plots correspond to the first-stage factors, X1, X2, X3, and X4. The settings of these factors are constant within a whole plot. The 14 subplots correspond to the second-stage factors, X5 and X6. For example, the sub-batches for runs 1 and 15 (from different whole plots) are subject to the same subplot treatment, where X5 is set at 1 and X6 at -1.

**Setup for a Two-Way Split-Plot Design**

A two-way split-plot design requires factors with Changes set to Very Hard and to Hard. As described in “Setup for a Split-Split-Plot Design” on page 123, factors called Whole Plots and Subplots are created. However, in a two-way split-plot design, Subplots does not nest the levels of factors with Changes set to Hard within the levels of factors with Changes set to Very Hard. Both Whole Plots and Subplots are treated as random effects in the Model script that is saved to the design table.

You need to ensure that the factor Subplots is *not nested* within the factor Whole Plots. Select the option **Hard to change factors can vary independently of Very Hard to change factor** in the Design Generation outline (Figure 4.32). See “Changes” on page 90 and “Design Structure Options” on page 103.

For an example of creating a split-plot design and analyzing the experimental data, see “Two-Way Split-Plot Experiment” on page 202 in the “Examples of Custom Designs” chapter.
Covariates with Hard-to-Change Levels

The Custom Design platform enables you to designate covariates as hard-to-change. Suppose that you have measurements on batches of material that are available for use in testing experimental factors. Or suppose that you have measurements on individuals who might be selected to participate in testing experimental factors. These measurements are known in advance of the experiment and are considered to be covariates.

The batches or individuals correspond to whole plots. You might want to use only some of these whole plots in your experiment. Because information about the whole plots in the form of covariates is available, the design should choose the whole plots in an optimal fashion.

The model, as given by the terms that you include in the Model outline, can include interactions and powers constructed using covariates and experimental factors.

**Note:** When you set Changes for a Covariate factor to Hard, all other covariates are also set to Hard. The remaining factors must be set to Easy. Because the algorithm requires a combination of row exchange and coordinate exchange, even moderately sized designs might take some time to generate.

Scenario for an Experiment with a Hard-to-Change Covariate

An experiment involving batches of polypropylene plates is discussed in Goos and Jones (2011, Chapter 9) and Jones and Goos (2015). Large batches of polypropylene plates are produced according to various formulations determined by several variables. Some plates are used immediately, and the remainder are stored for future experimental purposes. The compositions of these stored batches are known.

A customer has certain requirements regarding the plate formulation. Future experiments involve customizing the gas plasma treatment to the types of formulations required by the customer. The composition variables are considered hard-to-change covariates. Gas plasma treatment factors can be applied to sub-batches of plates with a given formulation.

The optimal design identifies the batches (defined by the covariates) to use, determines the number of plates from each batch to use, and provides settings for the gas plasma levels. Note that the optimal number of batches and plates from a given batch depend on the covariates.

An example is provided in the “Examples of Custom Designs” chapter on page 135.

Numbers of Whole Plots and Subplots

JMP suggests default values for the Number of Whole Plots and Number of Subplots. These values are based on heuristics for creating a balanced design that allows for estimation of the effects specified in the Model outline.
If you enter missing values for Number of Whole Plots or Number of Subplots, JMP chooses values that maximize the D-efficiency of the design. The algorithm uses the values specified in the Split Plot Variance Ratio option. See “Advanced Options > Split Plot Variance Ratio” on page 111. The D-efficiency is given by the determinant of $X'V^{-1}X$, where $V^{-1}$ is the inverse of the variance matrix of the responses. See Goos (2002).

If you enter values for the Number of Whole Plots and Number of Subplots, Custom Design attempts to maximize the optimality of the resulting design. For more information about split-plot designs, see Jones and Goos (2007). For more information about designs with hard-to-change covariates, see Jones and Goos (2015).

**Optimality Criteria**

Custom designs are created using search routines that depend on an optimality criteria. This section provides information about the optimality options for creating a custom design:

- “D-Optimality” on page 128
- “Bayesian D-Optimality” on page 129
- “I-Optimality” on page 130
- “Bayesian I-Optimality” on page 131
- “A-Optimality” on page 131
- “Alias Optimality” on page 132

**D-Optimality**

By default, the Custom Design platform optimizes the D-optimality criterion except when a full quadratic model is created using the RSM button. In that case, an I-optimal design is constructed.

The D-optimality criterion minimizes the determinant of the covariance matrix of the model coefficient estimates. It follows that D-optimality focuses on precise estimates of the effects. This criterion is desirable in the following cases:

- screening designs
- experiments that focus on estimating effects or testing for significance
- designs where identifying the active factors is the experimental goal

The D-optimality criterion is dependent on the assumed model. This is a limitation because often the form of the true model is not known in advance. The runs of a D-optimal design optimize the precision of the coefficients of the assumed model. In the extreme, a D-optimal design might be saturated, with the same number of runs as parameters and no degrees of freedom for lack of fit.
Specifically, a D-optimal design maximizes $D$, where $D$ is defined as follows:

$$D = \text{det}[X'X]$$

and where $X$ is the model matrix as defined in “Simulate Responses” on page 112.

D-optimal split-plot designs maximize $D$, where $D$ is defined as follows:

$$D = \text{det}[X' V^{-1} X ]$$

and $V^{-1}$ is the block diagonal covariance matrix of the responses (Goos 2002).

Since a D-optimal design focuses on minimizing the standard errors of coefficients, it might not allow for checking that the model is correct. For example, a D-optimal design does not include center points for a first-order model. When there are potentially active terms that are not included in the assumed model, a better approach is to specify If Possible terms and to use a Bayesian D-optimal design.

**Bayesian D-Optimality**

Bayesian D-optimality is a modification of the D-optimality criterion. The Bayesian D-optimality criterion is useful when there are potentially active interactions or non-linear effects. See DuMouchel and Jones (1994) and Jones et al (2008).

Bayesian D-optimality estimates a specified set of model parameters precisely. These are the effects whose Estimability you designate as Necessary in the Model outline. But at the same time, Bayesian D-optimality has the ability to estimate other, typically higher-order effects, as allowed by the run size. These are the effects whose Estimability you designate as If Possible in the Model outline. To the extent possible given the run size restriction, a Bayesian D-optimal design allows for detecting inadequacy in a model that contains only the Necessary effects.

The Bayesian D-optimality criterion is most effective when the number of runs is larger than the number of Necessary terms, but smaller than the sum of the Necessary and If Possible terms. When this is the case, the number of runs is smaller than the number of parameters that you would like to estimate. Using prior information in the Bayesian setting allows for precise estimation of all of the Necessary terms while providing the ability to detect and estimate some If Possible terms.

To allow for a meaningful prior distribution to apply to the parameters of the model, responses and factors are scaled to have certain properties (DuMouchel and Jones, 1994, Section 2.2).

Consider the following notation:

- $X$ is the model matrix as defined in “Simulate Responses” on page 112
- $K$ is a diagonal matrix with values as follows:
  - $k = 0$ for Necessary terms
– \( k = 1 \) for If Possible main effects, powers, and interactions involving a categorical factor with more than two levels
– \( k = 4 \) for all other If Possible terms

The prior distribution imposed on the vector of If Possible parameters is multivariate normal, with mean vector \( \mathbf{0} \) and diagonal covariance matrix with diagonal entries \( 1/k^2 \). Therefore, a value \( k^2 \) is the reciprocal of the prior variance of the corresponding parameter.

The values for \( k \) are empirically determined. If Possible main effects, powers, and interactions with more than one degree of freedom have a prior variance of 1. Other If Possible terms have a prior variance of 1/16. In the notation of DuMouchel and Jones (1994), \( k = 1/\tau \).

To control the weights for If Possible terms, select Advanced Options > Prior Parameter Variance from the red triangle menu. See “Advanced Options > Prior Parameter Variance” on page 111.

The posterior distribution for the parameters has the covariance matrix \((X'X + K^2)^{-1}\). The Bayesian D-optimal design is obtained by maximizing the determinant of the inverse of the posterior covariance matrix:

\[
\det(X'X + K^2)
\]

**I-Optimality**

I-optimal designs minimize the average variance of prediction over the design space. The I-optimality criterion is more appropriate than D-optimality if your primary experimental goal is not to estimate coefficients, but rather to do the following:

• predict a response
• determine optimum operating conditions
• determine regions in the design space where the response falls within an acceptable range

In these cases, precise prediction of the response takes precedence over precise estimation of the parameters.

The prediction variance relative to the unknown error variance at a point \( x_0 \) in the design space can be calculated as follows:

\[
\text{var}(\hat{Y}|x_0) = f(x_0)'(X'X)^{-1}f(x_0)
\]

where \( X \) is the model matrix as defined in “Simulate Responses” on page 112.
I-optimal designs minimize the integral $I$ of the prediction variance over the entire design space, where $I$ is given as follows:

$$I = \int_{\mathcal{R}} f(x)'(X'X)^{-1}f(x)dx = \text{trace}[(X'X)^{-1}M]$$

Here $M$ is the moments matrix:

$$M = \int_{\mathcal{R}} f(x)f(x)'dx$$

See “Simulate Responses” on page 112. For further information about simulating responses, see Goos and Jones (2011b).

The moments matrix does not depend on the design and can be computed in advance. The row vector $f(x)'$ consists of a 1 followed by the effects corresponding to the assumed model. For example, for a full quadratic model in two continuous factors, $f(x)'$ is defined as follows:

$$f(x)' = (1, x_1, x_2, x_1x_2, x_1^2, x_2^2)$$

A-Optimality

The A-optimality criterion minimizes the trace of the covariance matrix of the model coefficient estimates. The trace is the sum of the main diagonal elements of a matrix. An A-optimal design minimizes the sum of the variances of the regression coefficients.

Bayesian I-Optimality

The Bayesian I-optimal design minimizes the average prediction variance over the design region for Necessary and If Possible terms.

Consider the following notation:

- $X$ is the model matrix, defined in “Simulate Responses” on page 112
- $K$ is a diagonal matrix with values as follows:
  - $k = 0$ for Necessary terms
  - $k = 1$ for If Possible main effects, powers, and interactions involving a categorical factor with more than two levels
  - $k = 4$ for all other If Possible terms

The prior distribution imposed on the vector of If Possible parameters is multivariate normal, with mean vector $0$ and diagonal covariance matrix with diagonal entries $1/k^2$. (For more information about the values $k$, see “Bayesian D-Optimality” on page 129.)
The posterior variance of the predicted value at a point $x_0$ is as follows:

$$\text{var}(\hat{Y} | x_0) = f(x_0)'(X'X + K^2)^{-1}f(x_0)$$

The Bayesian I-optimal design minimizes the average prediction variance over the design region, as follows:

$$I_B = \text{trace}[(X'X + K^2)^{-1}M]$$

where $M$ is the moments matrix. See “Simulate Responses” on page 112.

**Alias Optimality**

Alias optimality seeks to minimize the aliasing between effects that are in the assumed model and effects that are not in the model but are potentially active. Effects that are not in the model but that are of potential interest are called alias effects. For more information about alias-optimal designs, see Jones and Nachtsheim (2011b).

Specifically, let $X_1$ be the model matrix corresponding to the terms in the assumed model, as defined in “Simulate Responses” on page 112. The design defines the model that corresponds to the alias effects. Denote the matrix of model terms for the alias effects by $X_2$.

The alias matrix is the matrix $A$, defined as follows:

$$A = (X_1'X_1)^{-1}X_1'X_2$$

The entries in the alias matrix represent the degree of bias associated with the estimates of model terms. See “The Alias Matrix” on page 823 in the “Technical Details” appendix for the derivation of the alias matrix.

The sum of squares of the entries in $A$ provides a summary measure of bias. This sum of squares can be represented in terms of a trace as follows:

$$\text{trace}(A'A)$$

Designs that reduce the trace criterion generally have lower D-efficiency than the D-optimal design. Consequently, alias optimality seeks to minimize the trace of $A'A$ subject to a lower bound on D-efficiency. For the definition of D-efficiency, see “Optimality Criteria” on page 128. The lower bound on D-efficiency is given by the D-efficiency weight, which you can specify under Advanced Options. See “Advanced Options > D Efficiency Weight” on page 112.
D-Efficiency

Let $X$ denote the design, or model, matrix for a given assumed model with $p$ parameters. For the definition of the model matrix, see “Simulate Responses” on page 112. Let $X_D$ denote the model matrix for a D-optimal design for the assumed model. Then the D-efficiency of the design given by $X$ is as follows:

$$D\text{-Efficiency} = \left[ \frac{\det(X'X)}{\det(X_D'X_D)} \right]^{1/p}$$

Coordinate-Exchange Algorithm

The Custom Designer constructs a design that seeks to optimize one of several optimality criteria. (See “Optimality Criteria” on page 128.) To optimize the criterion, Custom Design uses the coordinate-exchange algorithm (Meyer and Nachtsheim, 1995). The algorithm begins by randomly selecting values within the specified design region for each factor and each run to construct a starting design.

Suppose your study requires continuous factors, no factor constraints, and a main-effects model. An iteration consists of testing each value of the model matrix, as follows:

- The current value of each factor is replaced by its two most extreme values.
- The optimality criterion is computed for both of these replacements.
- If one of the values increases the optimality criterion, this value replaces the old value.

The process continues until no replacement occurs for an entire iteration.

Appropriate adjustments are made to the algorithm to account for polynomial terms, nominal factors, and factor constraints.

The design obtained using this process is optimal in a large class of neighboring designs. But it is only locally optimal. To improve the likelihood of finding a globally optimal design, the coordinate-exchange algorithm is repeated a large number of times. Goos and Jones (2011, p. 36) recommend using at least 1,000 random starts for all but the most trivial design situations. The number of starting designs is controlled by the Number of Starts option. See “Number of Starts” on page 116. Custom Design provides the design that maximizes the optimality criterion among all the constructed designs.
Use the Custom Design platform as your primary tool for constructing a wide range of experimental designs. You can construct a variety of design types and fine tune them to your specific experimental needs and resource budget.

Custom Design provides more options and control than the Screening, Response Surface, Full Factorial, and Mixture Design platforms. The designs that you construct are created specifically to meet your goals. This eliminates the struggle to find a classical design that only comes close to meeting your goals.

The flexible special-purpose designs that you can construct using Custom Design include:

- Screening designs, including supersaturated screening designs
- Response surface designs, including those with categorical factors
- Mixture designs, including those with process factors, and mixture of mixture designs
- Designs that include covariates or that are robust to linear time trends
- Fixed and random block designs
- Split-plot, split-split-plot, and two-way split-plot (strip-plot) designs

In this chapter you construct most of these design types within the Custom Design platform. In many cases, you also analyze the experimental results. For help with using the Custom Design platform, see the “Custom Designs” chapter on page 67.

Screening Experiments

In the early stages of studying a process, you identify a list of factors that potentially affect your response or responses. You are interested in identifying the active factors, that is, the factors that actually do affect your response or responses. A screening design helps you determine which factors are likely to be active. Once the active factors are identified, you can construct more sophisticated designs, such as response surface designs, to model interactions and curvature.

Screening designs constructed using the Custom Design platform are often equivalent to the classical designs provided in the Screening Design platform. However, Custom Design can construct designs for cases where classical screening designs are not available.

The Custom Design platform constructs screening designs using either the D-optimality or Bayesian D-optimality criterion. The D-optimality criterion minimizes the determinant of the covariance matrix of the model coefficient estimates. It follows that D-optimality focuses on precise estimates of the effects. See “Optimality Criteria” on page 128 in the “Custom Designs” chapter.

- “Design That Estimates Main Effects Only”
- “Design That Estimates All Two-Factor Interactions”
- “Design That Avoids Aliasing of Main Effects and Two-Factor Interactions”
- “Supersaturated Screening Designs”
- “Design for Fixed Blocks”

Design That Estimates Main Effects Only

Note: For more information about main effects only screening designs, see the “Screening Designs” chapter on page 291.

In this example, you are interested in studying the main effects of six factors. You construct a screening design where all of the main effects are orthogonal. However, the main effects are aliased with two-factor interactions.

1. Select DOE > Custom Design.
2. In the Factors outline, type 6 next to Add N Factors.
3. Click Add Factor > Continuous.
4. Click Continue.

The Model outline appears. It includes only main effects with Estimability designated as Necessary. This means that all main effects are estimable in the design that is generated.
Figure 5.2  Custom Design Window Showing Model Outline

Keep the default of 12 runs.

**Note:** Setting the Random Seed in step 5 and Number of Starts in step 6 reproduces the exact results shown in this example. When constructing a design on your own, these steps are not necessary.

5. (Optional) Click the Custom Design red triangle, select **Set Random Seed**, type 12345, and click **OK**.

6. (Optional) Click the Custom Design red triangle, select **Number of Starts**, type 1, and click **OK**.

7. Click **Make Design**.
8. Open the Design Evaluation > Color Map on Correlations outline.

Notice the following:

– The main effects are represented by the six terms in the upper left corner of the map.
– The white coloring corresponding to the correlations of the six main effects with other main effects indicates correlations of 0. This means that all main effects are orthogonal and can be estimated independently of each other.
– The light gray color in the squares corresponding to some two-way interactions indicates that the corresponding effects are correlated. This means that these effects cannot be estimated independently of other effects. Hover over these squares to see the exact correlation.
Notice that no effects are completely confounded with each other. The black squares, indicating absolute correlations of 1, are only on the main diagonal.

**Figure 5.5 Alias Matrix**

The Alias Matrix shows how the coefficients of the main effect terms in the model are biased by potentially active two-factor interaction effects. The column labels identify interactions. For example, in the X1 row, the column X2*X3 has a value of -0.33 and the column X2*X4 has a value of 0.333. This means that the expected value of the main effect of X1 is the sum of the main effect of X1 plus -0.33 times the effect of X2*X3, plus 0.333 times the effect of X2*X4, and so on, for the rest of the X1 row. In order for the estimate of the main effect of X1 to be meaningful, you must assume that these interactions are negligible in size compared to the effect of X1.

**Tip:** The Alias Matrix is a generalization of the confounding pattern in fractional factorial designs.

### Design That Estimates All Two-Factor Interactions

The Alias Matrix in Figure 5.5 shows partial aliasing of effects. In other cases, main effects might be fully aliased, or confounded, with two-factor interactions. In both of these cases, strong two-factor interactions can confuse the results of main effects only experiments. To avoid this risk, create a design that resolves all two-factor interactions.

In this example, you create a resolution V screening design. Two-factor interactions are orthogonal, but they are confounded with three-factor interactions.

1. Select DOE > Custom Design.
2. Type 5 next to Add N Factors.
3. Click Add Factor > Continuous.
4. Click Continue.
5. In the Model outline, select Interactions > 2nd.
6. Click **Minimum** to accept 16 for the number of runs.

   **Note:** Setting the Random Seed in step 7 and Number of Starts in step 8 reproduces the exact results shown in this example. In constructing a design on your own, these steps are not necessary.

7. (Optional) Click the Custom Design red triangle, select **Set Random Seed**, type 12345, and click **OK**.

8. (Optional) Click the Custom Design red triangle, select **Number of Starts**, type 1, and click **OK**.

9. Click **Make Design**.

   Figure 5.7 shows the runs of the design. All main effects and two-factor interactions are estimable because their Estimability was designated as Necessary (by default) in the Model outline.
Figure 5.7 Design to Estimate All Two-Factor Interactions

The Color Map indicates that the five main effects and the ten two-way interactions are all mutually orthogonal.

10. Open the Design Evaluation > Color Map on Correlations outline.

Figure 5.8 Color Map on Correlations

The Color Map indicates that the five main effects and the ten two-way interactions are all mutually orthogonal.
Design That Avoids Aliasing of Main Effects and Two-Factor Interactions

Suppose that your primary interest is in estimating the main effects of six continuous factors. However, you want to do this in a way that minimizes aliasing of main effects with potentially active two-factor interactions.

Your budget allows for only 16 runs. With six factors, there are 15 possible two-factor interactions. The minimum number of runs required to fit the constant, the six main effects, and the 15 two-factor interactions is 22.

In this example, you find a compromise between an 8-run main effects only design (see “Design That Estimates Main Effects Only” on page 137) and a 22-run design capable of fitting all the two-factor interactions. You use Alias Optimality as the optimality criterion to achieve your goal.

1. Select DOE > Custom Design.
2. Type 6 next to Add N Factors.
3. Click Add Factor > Continuous.
4. Click Continue.
   
The model includes the main effect terms by default. The default estimability of these terms is Necessary. In the Alias Terms outline, notice that second-order interactions are added. By default, all two-way interactions not included in the assumed model are added to the Alias Terms list.
5. Click the Custom Design red triangle and select Optimality Criterion > Make Alias Optimal Design.
   
The Make Alias Optimal Design selection tells JMP to generate a design that balances reduction in aliasing with D-efficiency. See “Alias Optimality” on page 132 in the “Custom Designs” chapter.
6. Click User Specified and change the number of runs to 16.
**Figure 5.9  Factors, Model, Alias Terms, and Number of Runs**

![Custom Design interface](image)

**Note:** Setting the Random Seed in step 7 and Number of Starts in step 8 reproduces the exact results shown in this example. In constructing a design on your own, these steps are not necessary.

7. (Optional) Click the Custom Design red triangle, select **Set Random Seed**, type 12345, and click **OK**.

8. (Optional) Click the Custom Design red triangle, select **Number of Starts**, type 10, and click **OK**.

9. Click **Make Design**.
10. Open the **Design Evaluation > Alias Matrix** outline.

**Figure 5.10** Alias Matrix

![Alias Matrix](image)

All rows contain only zeros, which means that the Intercept and main effect terms are not biased by any two-factor interactions.

11. Open the **Design Evaluation > Color Map on Correlations** outline.

**Figure 5.11** Color Map on Correlations

![Color Map on Correlations](image)

The Color Map on Correlations shows that main effects can be estimated independently of two-way interactions. However, some two-way interactions are fully aliased with other two-way interactions. Hover over the off-diagonal red squares to see which two-way interactions are confounded.

It turns out that this particular design is a resolution IV orthogonal screening design. Main effects are not aliased with each other or with two-way interactions. But two-way interactions are fully aliased with other two-way interactions.
Supersaturated Screening Designs

It is common for brainstorming sessions to identify dozens of potentially active factors. Rather than reduce the list without the benefit of data, you can use a supersaturated design.

In a saturated design, the number of runs equals the number of model terms. In a supersaturated design, the number of model terms exceeds the number of runs (Lin, 1993). A supersaturated design can examine dozens of factors using fewer than half as many runs as factors. This makes it an attractive choice for factor screening when there are many factors and experimental runs are expensive.

Alternatively, use a group orthogonal supersaturated design for improved active effect identification over traditional supersaturated designs. See the “Group Orthogonal Supersaturated Designs” chapter on page 723.

Limitations of Supersaturated Designs

There are drawbacks to supersaturated designs:

- If the number of active factors is more than half the number of runs in the experiment, then it is likely that these factors will be impossible to identify. A general rule is that the number of runs should be at least four times larger than the number of active factors. In other words, if you expect that there might be as many as five active factors, you should plan on at least 20 runs.

- Analysis of supersaturated designs cannot yet be reduced to an automatic procedure. However, using forward stepwise regression is reasonable. In addition, the Screening platform (DOE > Classical > Two Level Screening > Fit Two Level Screening) offers a streamlined analysis.

Generate a Supersaturated Design

In this example, you want to construct a supersaturated design to study 12 factors in 8 runs. To create a supersaturated design, you set the Estimability of all model terms (except the intercept) to If Possible.

Note: This example is for illustration only. You should have at least 14 runs in any supersaturated design. If there are as many as four active factors, it is very difficult to interpret the results of an 8-run design. See “Limitations of Supersaturated Designs” on page 146.

1. Select DOE > Custom Design.
2. Type 12 next to Add N Factors.
3. Click Add Factor > Continuous.
4. Click Continue.
5. In the Model outline, select all terms except the Intercept.

6. Click Necessary next to any effect and change it to If Possible.

   Setting the effects to If Possible ensures that JMP uses the Bayesian D-optimality criterion to obtain the design.

**Figure 5.12** Factors, Model, and Number of Runs

7. In the Alias Terms outline, select all effects and click **Remove Term**.

   This ensures that only the main effects appear in the Color Map on Correlations. This plot is constructed once the design is created.
8. Click the Custom Design red triangle and select **Simulate Responses**.

   This option generates random responses that appear in your design table. You will use these responses to see how to analyze experimental data.

   Keep the Number of Runs set to the Default of 8.

   **Note:** Setting the Random Seed in step 9 and Number of Starts in step 10 reproduces the design shown in this example. In constructing a design on your own, these steps are not necessary. Your **Y Simulated** values may not be the same as those shown in Figure 5.13.

9. (Optional) Click the Custom Design red triangle, select **Set Random Seed**, type 12345, and click **OK**.

10. (Optional) Click the Custom Design red triangle, select **Number of Starts**, type 5, and click **OK**.

11. Click **Make Design**.

12. Click **Make Table**.

   Do not close your Custom Design window. You return to it later in this example.

The response columns, **Y** and **Y Simulated**, are initiated with the same simulated values. The values are random values from a \( N(0, s) \) distribution, where \( s \) is the RMSE from the power analysis dialog with a default of 1. The **Y Simulated** values are updated with randomly generated values using the model defined by the parameter values in the Simulate Responses window. The **Y** column is intended for your true responses after the experiment has be run.
The Simulate Responses window shows default coefficients of 0 for all terms, a Normal distribution selection and Error $\sigma$ of 1. The values in the Y and Y Simulated column currently reflect only random variation.

13. Change the values of the coefficients in the Simulate Responses window as shown in Figure 5.15.
Figure 5.15 Parameter Values for Simulated Responses

14. Click **Apply**.

The response values in the Y Simulated column change.

**Note:** The response values are randomly generated. Your values will not match those in Figure 5.16 exactly.

Figure 5.16 Y Simulated Response Column with X1 and X11 Active

In your simulation, you specified X1 and X11 as active factors with large effects relative to the error variation. For this reason, your analysis of the data should identify these two factors as active.
Analyze a Supersaturated Design Using the Screening Platform

The Screening platform provides a way to identify active factors. Use the screening platform to analyze the Y Simulated values in the design table (Figure 5.16). The Screening platform is located under the **DOE > Classical** menu.

**Note:** Your data table has slightly different Y Simulated values than those in this example. The exact values in your reports will differ from the results shown here.

1. Select **DOE > Classical > Two Level Screening > Fit Two Level Screening.**
2. Select Y Simulated and click **Y.**
3. Select X1 through X12, click **X** and click **OK.**

**Figure 5.17**  Screening Report for Supersaturated Design

The factors X1 and X11 have large contrast and Lenth t-Ratio values. Also, their Simultaneous p-Values are small. In the Half Normal Plot, both X1 and X11 fall far from the line. The Contrasts and the Half Normal Plot reports indicate that X1 and X11 are active. Although X12 has an Individual p-Value less than 0.05, its effect is much smaller than that of X1 and X11.

Because the design is supersaturated, *p*-values might be smaller than they would be in a model where all effects are estimable. This is because effect estimates are biased by other
potentially active main effects. In Figure 5.17, a note directly above the Make Model button warns you of this possibility.

You might also want to check whether the effects that appear active could be highly correlated with other effects. When this occurs, one effect can mask the true significance of another effect. The Color Map in Figure 5.19 displays absolute correlations between effects.

4. Click **Make Model**.

   The constructed model contains only the effects \(X_1\), \(X_{11}\), and \(X_{12}\).

5. Click **Run** in the Model Specification window.

**Figure 5.18** Parameter Estimates for Model

| Term     | Estimate | Std Error | t Ratio | Prob>|t|
|----------|----------|-----------|---------|------|
| Intercept| 10.03645 | 0.319502  | 31.38   | <0.001* |
| \(X_{11}\)| 11.34778 | 0.360447  | 31.48   | <0.001* |
| \(X_1\)  | 9.820584 | 0.319502  | 30.74   | <0.001* |
| \(X_{12}\)| -1.1329  | 0.360447  | -3.14   | 0.0347* |

Note that the parameter estimates for \(X_{11}\) and \(X_1\) are close to the theoretical values that you used to simulate the model. See Figure 5.15, where you specified a model with \(X_1 = 10\) and \(X_{11} = 10\). The significance of the factor \(X_{12}\) is an example of a false positive.

6. In your Custom Design window, open the **Design Evaluation > Color Map on Correlations** outline.

**Figure 5.19** Color Map on Correlations Outline
Hover over cells to see the absolute correlations. Notice that $X_1$ has correlations as high as 0.5 with other main effects ($X_4$, $X_5$, $X_7$). (Figure 5.19 uses JMP default colors.)

**Analyze a Supersaturated Design Using Stepwise Regression**

Stepwise regression is another way to identify active factors. The design table in Figure 5.16 contains three scripts. The Model script analyzes your data using stepwise regression in the Fit Model platform.

**Note:** Your data table has slightly different $Y$ Simulated values than those in this example. The exact values in your reports will differ from the results shown here.

1. In the Table panel of the design table, click the green triangle next to the **Model** script.
2. Change the **Personality** from **Standard Least Squares** to **Stepwise**.
3. Click **Run**.
4. In the Stepwise Fit for Y report, change the **Stopping Rule** to **Minimum AICc**.
   
   For designed experiments, BIC is typically a more lenient stopping rule than AICc as it tends to allow inactive effects into the model.
5. Click **Go**.
Figure 5.20 Stepwise Regression for Supersaturated Design

Figure 5.20 shows that the selected model consists of the two active factors, $X_1$ and $X_{11}$. The step history appears in the bottom part of the report. Keep in mind that correlations between $X_1$ and $X_{11}$ and other factors could mask the effects of other active factors (Figure 5.19).

Note: This example defines two large main effects and sets the rest to zero. Real-world situations can be less likely to have such clearly differentiated effects.

Design for Fixed Blocks

Traditional screening designs require block sizes to be a power of two. However, the Custom Design platform can create designs with fixed blocks of any size.
Suppose that you want to study three factors. You can run only three trials per day and you expect substantial day-to-day variation. Consequently, you need to block your design over multiple days. Also, in this study, you are interested in estimating all two-factor interactions. In this example, you construct a design with three runs per block.

1. Select **DOE > Custom Design**.
2. In the Factors outline, type 3 next to **Add N Factors**.
3. Click **Add Factor > Continuous**.
4. Click **Add Factor > Blocking > 3 runs per block**.
   The blocking factor X4 shows only one level under Values. This is because the run size is unknown at this point.

**Figure 5.21** Factors Outline Showing One Block for X4

5. Click **Continue**.
The Factors outline now shows an appropriate number of blocks, calculated as the Default run size divided by the number of runs per block. For this example, the default sample size of 9 requires three blocks. The Factors outline now shows that X4 has three values, indicating the three blocks.

**Note:** If you specify a different number of runs, the Factors outline updates to show the appropriate number of values for the blocking factor.

6. Select the three continuous factors, X1, X2, and X3, in the Factors outline.

7. In the Model outline, click **Interactions > 2nd**.
The Number of Runs panel now shows that 18 is the Default run size. The Factors outline now shows six values for X4, indicating six blocks.

**Note:** Setting the Random Seed in step 8 and Number of Starts in step 9 reproduces the exact results shown in this example. In constructing a design on your own, these steps are not necessary.

8. (Optional) Click the Custom Design red triangle, select **Set Random Seed**, type 12345, and click **OK**.

9. (Optional) Click the Custom Design red triangle, select **Number of Starts**, type 5, and click **OK**.

10. Click **Make Design**.
In the design, look at the blocking factor, \( X_4 \). The six blocks are represented. When you conduct your experiment, each day you will run three trials, where \( X_4 = 1 \) on the first day, \( X_4 = 2 \) on the second day, and so on. So you want the design table to randomize the trials within blocks. In the Output Options panel, the Randomize within Blocks option is already selected for Run Order.

11. Click **Make Table**.

The rows in the design table are grouped by each day’s runs. This design enables you to estimate the block effect, all main effects, and two-factor interactions.
Response Surface Experiments

Response surface experiments typically involve a small number (generally 2 to 8) of continuous factors that have been identified as active. The main goal of a response surface experiment is to develop a predictive model of the relationship between the factors and the response. Often, you use the predictive model to find better operating settings for your process. For this reason, your assumed model for a response surface experiment is usually quadratic.

Because a screening design is focused on identifying active effects, a measure of its quality is the size of the relative variance of the coefficients. You want these relative variances to be small. D-optimality addresses these relative variances.

In response surface experiments, the prediction variance over the range of the factors is more important than the variance of the coefficients. The prediction variance over the design space is addressed by I-optimality. An I-optimal design tends to place fewer runs at the extremes of the design space than does a D-optimal design. For more information about D- and I-optimality, see “Optimality Criteria” on page 128 in the “Custom Designs” chapter.

By default, Custom Design uses the Recommended option for the Optimality Criterion. Custom Design uses the I-optimality criterion as the Recommended criterion whenever you add quadratic effects using the RSM button in the Model outline. Otherwise, Custom Design uses the D-optimality criterion as the Recommended criterion. See “Optimality Criteria” on page 128 in the “Custom Designs” chapter.

- “Response Surface Design”
- “Response Surface Design with Flexible Blocking”
- “Comparison of a D-Optimal and an I-Optimal Response Surface Design”
- “Response Surface Design With Constraints and Categorical Factor”

Response Surface Design

This example contains these sections:

- “Construct a Response Surface Design” on page 160
- “Analyze the Experimental Results” on page 163
Construct a Response Surface Design

Construct a response surface design for three continuous factors that you have identified as active. You want to find process settings to maintain your response (Y) within specifications. The lower and upper specification limits for Y are 54 and 56, respectively, with a target of 55.

1. Select DOE > Custom Design.
2. In the Responses outline, click Maximize and select Match Target.
3. Type 54 as the Lower Limit and 56 as the Upper Limit.
4. Leave Importance blank.
   Because there is only one response, the Importance value is set to 1 by default.
5. Type 3 next to Add N Factors.
6. Click Add Factor > Continuous.
   This adds three continuous factors: X1, X2, and X3.
7. Click Continue.
8. In the Model outline, click the RSM button.
   This adds quadratic and interaction terms to the model. It also sets the value of the Recommended optimality criterion to I-optimality. You can verify this in the Design Diagnostics outline once you click Make Design.
   Leave the Default Number of Runs set to 16.

**Note:** Setting the Random Seed in step 9 and Number of Starts in step 10 reproduces the exact results shown in this example. In constructing a design on your own, these steps are not necessary.

9. (Optional) Click the Custom Design red triangle, select Set Random Seed, type 929281409, and click OK.
10. (Optional) Click the Custom Design red triangle, select Number of Starts, type 40, and click OK.
11. Click Make Design.
   The Design outline shows the design.
Figure 5.26  RSM Design

In order to estimate quadratic effects, a response surface design uses three levels for each factor. Note that the design in Figure 5.26 is a face-centered Central Composite Design with two center points.

Figure 5.27  Design Diagnostics Outline

The first line in the Design Diagnostics outline identifies the optimality criterion being used. This design is I-optimal.

Figure 5.28  Prediction Variance Profile
The vertical axis shows the relative prediction variance of the expected value of the response. The relative prediction variance is the prediction variance divided by the error variance. When the relative prediction variance is one, its absolute variance equals the error variance of the regression model.

The profiler shows values of the relative prediction variance over the design space. You can move the sliders to explore the prediction variance’s behavior. The prediction variance is smallest in the center of the design space. It is fairly constant, with values only slightly larger than 0.2, for factor settings between -0.5 and 0.5. The prediction variance increases as the settings approach the design space boundaries.

14. Click the Prediction Variance Profile red triangle and select **Maximize Variance**.

**Figure 5.29** Prediction Variance Profile with Relative Variance Maximized

The profiler shows that the maximum value of the relative prediction variance is 0.79569.

15. Open the **Design Evaluation > Fraction of Design Space Plot** outline.

**Figure 5.30** Fraction of Design Space Plot
The blue curve in the plot shows the relative prediction variance as a function of the fraction of design space. The red dashed cross hairs indicate that, for 50% of the design space, the prediction variance is about 0.32 or less. Use the cross hair tool to draw other inferences. For example, when the Fraction of Space is 0.95, the Prediction Variance is about 0.52. This means that for 95% of the design space, the relative prediction variance is below 0.52.

### Analyze the Experimental Results

The Custom RSM.jmp sample data table contains the results of the experiment. The Model script opens a Fit Model window showing all of the effects specified in the DOE window’s Model outline. This script was saved to the data table by the Custom Design platform.

1. Select **Help > Sample Data Library** and open Design Experiment/Custom RSM.jmp.
2. In the Table panel, click the green triangle next to the **Model** script.
3. Click **Run**.

   The Effect Summary report shows the LogWorth and PValue for each effect in the model. The vertical blue line in the plot is set at the value 2. A LogWorth that exceeds 2 is significant at the 0.01 level.

#### Figure 5.31 Effect Summary Report

The report shows that $X_1$, $X_2$, $X_1 \times X_1$, and $X_2 \times X_2$ are significant at the 0.01 level. None of the other effects are significant at even the 0.10 level. Reduce the model by removing these insignificant effects.

4. In the Effect Summary report, select $X_3$, $X_1 \times X_2$, $X_3 \times X_3$, $X_1 \times X_3$, and $X_2 \times X_3$. 
5. Click **Remove**.

The Fit Least Squares report is updated to show a model containing only the significant effects: $X_1$, $X_2$, $X_1 \times X_1$, and $X_2 \times X_2$.

Use the Prediction Profiler (at the bottom of the Fit Least Squares window) to explore how the predicted response ($Y$) changes as you vary the factors $X_1$ and $X_2$. Note the quadratic behavior of $Y$ across the values of $X_1$ and $X_2$.

Remember that you entered response limits for $Y$ in the Responses outline of the Custom Design window. As a result, the Response Limit column property is attached to the $Y$ column in the design table. The Desirability function for $Y$ (in the top plot at right) is based on the information contained in the Response Limit column property. JMP uses this function to calculate Desirability as a function of the settings of $X_1$ and $X_2$. The traces of the Desirability function appear in the bottom row of plots.

6. Click the Prediction Profiler red triangle and select **Optimization and Desirability > Maximize Desirability**.

**Figure 5.33** Prediction Profiler with Desirability Maximized
The predicted response achieves the target value of 55 at the process settings shown in red above \( X_1 \) and \( X_2 \). Figure 5.33 shows that a value of \( X_1 \) near –0.65 also achieves a predicted value of 55 when \( X_2 = -0.75062 \). In fact, your Prediction Profiler might show different settings as those that maximize desirability. This is because the predicted response is 55 for many settings of \( X_1 \) and \( X_2 \).

7. Click the Response Y red triangle and select **Factor Profiling > Contour Profiler**.

8. In the Contour Profiler report, type 55 as the value for **Contour**.

**Figure 5.34** Contour Profiler

![Contour Profiler](image)

The settings of \( X_1 \) and \( X_2 \) that correspond to the red contour have predicted response values of 55. You might want to select from among these process settings based on cost efficiency.

**Response Surface Design with Flexible Blocking**

When optimizing a process, you might need to include qualitative factors in your experiment as well as continuous factors. You might need to block by qualitative factors such as batch or day, or include qualitative factors such as machine or delivery mechanism. But the Response Surface Design platform supports only continuous factors. To obtain a response surface design with a qualitative factor, you can replicate the design over each level of the factor. However, this is inefficient. The Custom Design platform constructs an optimal design with fewer runs.
In this example, you construct a response surface design that accommodates two continuous factors and a blocking factor with four runs per block. You can include categorical or discrete numeric factors in a similar fashion.

1. Select **DOE > Custom Design**.
2. Type 2 next to **Add N Factors**.
3. Click **Add Factor > Continuous**.
4. Click **Add Factor > Blocking > 4 runs per block**.
   
   Notice that only one level appears under Values. This is because the number of blocks cannot be determined until the number of runs is determined.

**Figure 5.35**  Factors Outline with Two Continuous Factors and a Blocking Factor

5. Click **Continue**.

   The Default number of runs is 12. The Factors outline updates to show three levels for the Blocking factor, X3. Because you required X3 to have four runs per block, the 12 runs allow three blocks.

6. Click **RSM**.

   An informational JMP Alert window reminds you that the blocking factor cannot appear in interaction or quadratic terms. JMP adds only the appropriate RSM terms to the list.

7. Click **OK** to dismiss the message.

   Quadratic and interactions terms for X1 and X2 are added to the model. Because you added RSM terms, the Recommended optimality criterion changes from D-Optimal to I-Optimal. You can see this later in the Design Diagnostics outline.

**Figure 5.36**  Model Outline with Response Surface Effects
**Note:** Setting the Random Seed in step 8 and Number of Starts in step 9 reproduces the exact results shown in this example. In constructing a design on your own, these steps are not necessary.

8. (Optional) Click the Custom Design red triangle, select **Set Random Seed**, type 12345, and click **OK**.

9. (Optional) Click the Custom Design red triangle, select **Number of Starts**, type 5, and click **OK**.

10. Click **Make Design**.

11. Open the **Design Evaluation > Design Diagnostics** outline.

**Figure 5.37** Design Diagnostics Outline

The first line in the Design Diagnostics outline identifies the optimality criterion being used. This design is I-optimal.

12. Click **Make Table**.

**Figure 5.38** Design Table with Blocking Factor

Because the default Run Order was Randomize within Blocks, the levels of the blocking factor (X3) are sorted.

13. In the Table panel of the design table, click the green triangle next to the **Model** script.
Notice the following:
- The blocking factor (X3) is entered as an effect.
- No interactions involving X3 are included.
- The other five effects define a response surface model for X1 and X2.

**Comparison of a D-Optimal and an I-Optimal Response Surface Design**

In this example, you explore the differences between I-optimality and D-optimality in the context of a two-factor response surface design.

**I-Optimal Design**

1. Select **DOE > Custom Design**.
2. Type 2 next to **Add N Factors**.
3. Click **Add Factor > Continuous**.
4. Click **Continue**.
5. Click **RSM**.

Quadratic and interactions terms for X1 and X2 are added to the model. Because you added RSM terms, the Recommended optimality criterion changes from D-Optimal to I-Optimal. You can see this later in the Design Diagnostics outline.
**Note:** Setting the Random Seed in step 6 and Number of Starts in step 7 reproduces the exact results shown in this example. In constructing a design on your own, these steps are not necessary.

6. (Optional) Click the Custom Design red triangle, select **Set Random Seed**, type 383570403, and click **OK**.

7. (Optional) Click the Custom Design red triangle, select **Number of Starts**, type 8, and click **OK**.

8. Click **Make Design**.

In this I-optimal design, runs 1, 4, 7, and 10 are at the center point (X1 = 0 and X2 = 0). I-optimal designs tend to place more runs in the center (and consequently fewer runs at the extremes) of the design space than do D-optimal designs. You can compare this design to the D-optimal design shown in Figure 5.42.

9. Open the **Design Evaluation > Prediction Variance Profile** outline.

**Figure 5.41** Prediction Variance Profile for I-Optimal Model

The relative prediction variance of the expected response is smallest in the center of the design space.

10. Open the **Fraction of Design Space Plot** outline.
The Fraction of Design Space Plot appears on the left in Figure 5.44. When the Fraction of Space is 0.95, the vertical coordinate of the blue curve is about 0.5. This means that for about 95% of the design space, the relative prediction variance is below 50% of the error variance.

This Custom Design window contains your I-optimal design. Keep this window open. In the next section, you generate a D-optimal design, and compare the two.

D-Optimal Design

To compare Prediction Variance Profile and Fraction of Design Space plots for the I- and D-optimal designs:

1. In the Custom Design window containing your I-optimal design, click the Custom Design red triangle and select Save Script to Script Window.
   A window appears, showing a script that reproduces your work.
2. In this new script window, select Edit > Run Script.
   A duplicate Custom Design window appears, but with the Design Evaluation outlines closed.
3. In this new Custom Design window, click Back.
4. Click the Custom Design red triangle and select Optimality Criterion > Make D-Optimal Design.
5. (Optional) Click the Custom Design red triangle, select Set Random Seed, type 383570403, and click OK.
6. Click Make Design.
   You current Custom Design window contains your D-optimal design.

**Figure 5.42  D-Optimal Design**

In this D-optimal design, run 1 is the only run at the center point. D-optimal designs tend to place more runs at the extremes of the design space than do I-optimal designs. Recall that the I-optimal design had four center runs (Figure 5.40).

At the center of the design region, the relative prediction variance is 0.53562, as compared to 0.208333 for the I-optimal design (Figure 5.41). This means that the relative standard error is 0.732 for the D-optimal design and 0.456 for the I-optimal design. All else being equal, at the center of the design region, confidence intervals for the expected response based on the D-optimal design are about 60% wider than those based on the I-optimal design.

The Design outline shows that the D-optimal design has nine design points, one for every combination of $X_1$ and $X_2$ set to -1, 0, 1. The D-optimality criterion attempts to keep the relative prediction variance low at each of these design points. Explore the variance at the extremes of the design region by moving the sliders for $X_1$ and $X_2$ to -1 and 1. Note that the variance at these extreme points is usually smaller than the variance for the I-optimal design at these points.

8. Open the **Design Evaluation > Fraction of Design Space Plot** outline.

The Fraction of Design Space Plot appears on the right in Figure 5.44.

**Figure 5.44** Fraction of Design Space Plots (I-Optimal on left, D-Optimal on right)
The red cross-hairs in each plot indicate the maximum prediction variance for 50% of the design space. For 50% of the design space, the prediction variance for the I-optimal design falls below about 0.27. For the D-optimal design, the prediction variance is about 0.4.

9. Right-click in the Fraction of Design Space Plot for your I-optimal design. Select Edit > Copy Frame Contents.

10. Right-click in the Fraction of Design Space Plot for your D-optimal design. Select Edit > Paste Frame Contents.

Figure 5.45 Fraction of Design Space Plots Superimposed

The variance curve for the I-optimal design is below the curve for the D-optimal design over at least 90% of the design space. This reflects the fact that I-optimality attempts to minimize prediction variance over all of the design space. In contrast, D-optimality focuses on reducing prediction variance at the design points.

Response Surface Design With Constraints and Categorical Factor

In this example, you create a design to optimize the yield of a chemical reaction. Your experimental factors include a categorical factor at three levels, where constraints involve two of the levels. In this example, you will use the Disallowed Combinations Filter to enter the constraints.

Your response is Yield. You have three factors:

- **Time**: The range of interest is 500 to 560 seconds.
- **Temperature**: The range of interest is 350 to 750 degrees Kelvin.
- **Catalyst**: Three catalysts A, B, and C, must be tested.

Your design must allow for constraints on two of the levels of Catalyst:

- When catalyst B is used, the temperature must be above 400.
• When catalyst C is used, the temperature must be below 650.

Define the Response and Factors
1. Select **DOE > Custom Design**.
2. In the Response outline, double-click **Y** and change it to **Yield**.
   Because your goal is to maximize **Yield**, leave the **Goal** set to Maximize.
3. In the Factors outline, type 2 next to **Add N Factors**.
4. Click **Add Factor > Continuous**.
5. Click **Add Factor > Categorical > 3 Level**.
6. Rename the factors **Time**, **Temperature**, and **Catalyst**.
7. Change the **Values** for **Time** to 500 and 560.
8. Change the **Values** for **Temperature** to 350 and 750.
9. Change the **Values** for **Catalyst** to A, B, and C.

**Figure 5.46** Factor Settings

10. Click **Continue**.

Define the Constraints
1. Select **Use Disallowed Combinations Filter** in the Define Factor Constraints outline.
2. Select Temperature and Catalyst from the **Add Filter Factors** list.
3. Click **Add**.
4. Click 750 in the equation that appears above the Temperature slider and change it to 400.
   Press Enter (or click elsewhere).
   This disallows factor settings with Temperature values below 400.
5. Click the B block under Catalyst.
   Together with the constraint on Temperature, this disallows factor settings for which Catalyst is B and Temperature is below 400.
6. Click **OR**.
   This allows you to define your second constraint.
7. Select Temperature and Catalyst from the Add Filter Factors list. (Your earlier selection may have been retained.)

8. Click Add.

9. In the panel that appears beneath the word OR, click 350 in the equation that appears above the Temperature slider and change it to 650. Press Enter (or click elsewhere).
   This disallows factor settings with Temperature values above 650.

10. Click the C block under Catalyst.
    Together with the constraint on Temperature, this disallows factor settings for which Catalyst is C and Temperature is above 650.

**Figure 5.47** Constraints Defined

![](image)

**Note:** The (3) after Catalyst indicates the number of catalyst levels.

**Add Response Surface Terms and Make Design**

1. In the Model outline, select RSM.
   A JMP Alert informs you that only quadratic terms for continuous factors are being added to the model.

2. Click OK to dismiss the alert.
   JMP adds only the appropriate response surface terms to the model.
3. (Optional) Click the Custom Design red triangle, select **Set Random Seed**, type 654321, and click **OK**.

4. (Optional) Click the Custom Design red triangle, select **Number of Starts** and set it to 1000. Click **OK**.

5. Click **Make Design**.

**Figure 5.48** Design Satisfying Constraints

Because you added RSM terms to the Model outline, this is an I-optimal design. It satisfies your constraints:

- When catalyst B is used, the temperature must be above 400.
- When catalyst C is used, the temperature must be below 650.

**View the Design**

Recall that the design region consists of settings of **Time** between 500 and 560 and **Temperature** between 350 and 750. Generate a graph to obtain a geometric view of the design points within the design region:

1. Click **Make Table**.
2. Select **Graph > Graph Builder**.
3. Select **Time** and **Temperature** and drag them to the center of the template.
4. Deselect the **Smoother** icon. This is the second icon from the left above the template.
5. Select **Catalyst** and drag it to the **Group X** zone at the top of the template.
6. Double-click the Temperature axis.

7. Under Reference Lines, add two reference lines:
   - Next to Value, enter 350.
   - Click Add.
   - Next to Value, enter 750.
   - Click Add.

8. Click OK.
9. Double-click the Time axis.
10. Under Reference Lines, add two reference lines:
    – Next to Value, enter 500.
    – Click Add.
    – Next to Value, enter 560.
    – Click Add.
11. Click OK.
12. Click Done.

**Note:** The plot in Figure 5.51 is vertically resized.
Examples of Custom Designs

Chapter 5

Mixture Experiments

Mixture Experiments

Both the Custom Design and Mixture Design platforms construct designs for situations where all of your factors are ingredients in a mixture. However, mixture experiments can involve non-mixture process variables, or process factors. In addition to mixture only designs, the Custom Design platform can construct designs to accommodate both mixture and process factors. The Custom Design platform also allows the mixture components to sum to any positive number. See the Mixture description in “Factor Types” on page 91 in the “Custom Designs” chapter.

- “Mixture Design with Nonmixture Factors”
- “Mixture of Mixtures Design”

Mixture Design with Nonmixture Factors

In this example from Atkinson and Donev (1992), you create a design for an experiment involving both mixture factors and process factors. The design is an 18-run design that is balanced with respect to the levels of a categorical factor. The design enables you to fit a full response surface. You use Design Evaluation plots and results to examine the relative prediction variance of the design.
The design consists of a single response, three mixture factors, and a non-mixture factor:

- The response is Damping, which measures the electromagnetic damping of an acrylonitrile powder.
- The three mixture ingredients are:
  - CuSO4 (copper sulphate), ranging from 0.2 to 0.8
  - Na2S2O3 (sodium thiosulphate), ranging from 0.2 to 0.8
  - Glyoxal (glyoxal), ranging from 0 to 0.6
- The nonmixture environmental factor of interest is Wavelength (the wavelength of an electromagnetic wave) at three levels denoted L1, L2, and L3.
  
  Wavelength is a continuous variable. However, the researchers were interested only in predictions at three specific wavelengths. For this reason, you treat Wavelength as a categorical factor with three levels.

There are two parts to this example:

- “Create the Design” on page 179
- “Evaluate the Design” on page 181

Create the Design

1. Select DOE > Custom Design.
2. Double-click Y under Response Name and type Damping.
3. Click Maximize under Goal and change it to None.
   
   The goal is set to None because the authors of the study do not mention how much damping is desirable. Select Help > Sample Data Library and open Design Experiment/Donev Mixture Factors.jmp.
4. Click the Custom Design red triangle and select Load Factors.
   
   This loads the three mixture ingredients and the categorical environmental factor. Note that the bounds on the values of the three mixture factors are also loaded.
5. In the Model outline, click **Interactions > 2nd**.
   An informational JMP Alert window reminds you that JMP removes the main effect terms for non-mixture factors that interact with all the mixture factors. This means that the main effect of *Wavelength* is removed, but all two-way interactions of mixture factors with *Wavelength* are added.

6. Click **OK** to dismiss the message.

   The effects in the Model outline define a response surface model in the mixture ingredients along with the additive effect of the wavelength. See Scheffé (1958).

**Figure 5.53  Model and Design Generation Outlines**
7. Leave the default number of runs at 18.

The choice of 18 runs allows six runs for each of the three levels of the wavelength factor.

**Note:** Setting the Random Seed in step 8 and Number of Starts in step 9 reproduces the exact results shown in this example. In constructing a design on your own, these steps are not necessary.

8. (Optional) Click the Custom Design red triangle, select **Set Random Seed**, type 12345, and click **OK**.

9. (Optional) Click the Custom Design red triangle, select **Number of Starts**, type 5, and click **OK**.

10. Click **Make Design**.

**Figure 5.54** Design Outline Showing 18-Run Design

You can check that there are six runs for each level of Wavelength.

**Evaluate the Design**

1. Open the **Design Evaluation > Prediction Variance Profile** outline.

**Figure 5.55** Prediction Variance Profile for 18-Run Design
Move the slider for *Wavelength* to verify that the relative prediction variance profiles for the mixture factors do not change across the levels of *Wavelength*. Move the slider for any one of the mixture factors. The sliders for the other two mixture factors adjust to make the mixture ingredients sum to one. Notice that the smallest relative prediction variances occur near the center settings for the mixture factors.

2. Click the Prediction Variance Profile red triangle and select **Maximize Variance**.

Notice that the maximum relative prediction variance over the design space is 0.8 times the error variance.

3. Open the **Fraction of Design Space Plot** outline.

**Figure 5.56** Fraction of Design Space Plot for 18-Run Design

Over the entire design space, the relative prediction variance is below 0.8. The minimum relative prediction variance is about 0.32. As seen in Figure 5.55, the minimum occurs near the center settings for the mixture factors.

4. Open the **Design Diagnostics** outline.

**Figure 5.57** Design Diagnostics Outline for 18-Run Design

The design is optimal relative to the D-optimality criterion, even though its D-efficiency is very low (3.6%). Because mixture designs are far from orthogonal due to the mixture constraint, they typically have very low D-efficiencies. The Average (relative) Variance of Prediction is 0.412864. This is consistent with the Fraction of Design Space plot in Figure 5.56.
Mixture of Mixtures Design

In this example, construct a design for a mixture of mixtures situation.

Consider the ingredients that go into a cake. Dry ingredients include flour, sugar, and cocoa. Wet ingredients include milk, melted butter, and eggs. The wet and dry components of the cake are two mixtures that are first mixed separately and then blended together. Table 5.1 lists the factors and the ranges over which you vary them as part of your experiment.

<table>
<thead>
<tr>
<th>Mixture</th>
<th>Ingredient</th>
<th>Lower and Upper Levels</th>
</tr>
</thead>
<tbody>
<tr>
<td>Dry</td>
<td>Cocoa</td>
<td>0.1 - 0.2</td>
</tr>
<tr>
<td></td>
<td>Sugar</td>
<td>0 - 0.15</td>
</tr>
<tr>
<td></td>
<td>Flour</td>
<td>0.2 - 0.3</td>
</tr>
<tr>
<td>Wet</td>
<td>Butter</td>
<td>0.1 - 0.2</td>
</tr>
<tr>
<td></td>
<td>Milk</td>
<td>0.25 - 0.35</td>
</tr>
<tr>
<td></td>
<td>Eggs</td>
<td>0.05 - 0.20</td>
</tr>
</tbody>
</table>

The dry components (the mixture of cocoa, sugar, and flour) comprise 45% of the combined mixture. The wet components (butter, milk, and eggs) comprise 55%.

Note: With the constraints on the dry and wet ingredients, if you include all 6 factors in the mixture model, a model singularity exists.

The goal of your experiment is to optimize a Taste rating. Taste is rated on a scale of 1 to 10, with 10 representing the best taste.

You construct a 10-run design to fit a main effects model. Because of the constraint on the proportions of dry and wet ingredients, you need to include only five factors in the Model outline to avoid singularity. The choice of which factor not to include is arbitrary.

This example contains two parts:

- “Create the Design” on page 183
- “Analyze the Experimental Results” on page 186

Create the Design

1. Select DOE > Custom Design.

2. Double-click Y under Response Name and type **Taste**.
   Note that the default goal is Maximize. Because you want to maximize the Taste rating, do not change the goal.

3. Click under Lower Limit and type 0.
   The least desirable rating is 0.

4. Click under Upper Limit and type 10.
   The most desirable rating is 10.

5. Leave the area under Importance blank.
   Because there is only one response, that response is given Importance 1 by default.

6. Select **Help > Sample Data Library** and open **Design Experiment/Cake Factors.jmp**.

7. Click the Custom Design red triangle and select **Load Factors**.

**Figure 5.58** Completed Responses and Factors Outlines

Note that the factors are all mixture factors. The Values that define the range of settings for the experiment vary from factor to factor.

8. In the Define Factor Constraints outline, select **Specify Linear Constraints**.

9. In the Linear Constraints panel, click **Add** twice.

10. Enter the constraints shown in Figure 5.59.
Note that the second constraint is equivalent to specifying that the sum of Cocoa, Sugar, and Flour is greater than or equal to 0.45. The two constraints together imply that Cocoa, Sugar, and Flour comprise exactly 45% of the mixture, ensuring that the wet factors constitute the remaining 55%.

11. In the Model outline, select Eggs and click **Remove Term**.
   Because of the equality constraint, a model containing all six effects would be singular.

12. Type 10 next to **User Specified**.
   Your experiment requires baking 10 cakes.

   **Note:** Setting the Random Seed in step 13 and Number of Starts in step 14 reproduces the exact results shown in this example. In constructing a design on your own, these steps are not necessary.

13. (Optional) Click the Custom Design red triangle, select **Set Random Seed**, type 12345, and click **OK**.

14. (Optional) Click the Custom Design red triangle, select **Number of Starts**, type 40, and click **OK**.

15. Click **Make Design**.
   A JMP Alert informs you that your factor constraints include an equality constraint. This was what you intended, because the sum of the dry ingredient proportions is constrained to 45%.

16. Click **OK** to dismiss the JMP Alert.

17. Click **Make Table**.
The settings for the dry ingredients, Cocoa, Sugar, and Flour, sum to 45% of the mixture and the settings for the wet ingredients, Butter, Milk, and Eggs, sum to 55% of the mixture. The settings also conform to the upper and lower limits given in the Factors outline.

**Analyze the Experimental Results**

The Cake Data.jmp sample data table shows the results of the experiment. The design table contains a Model script that opens a Fit Model window showing the five main effects specified in the DOE window’s Model outline. Notice that the main effect of Eggs is not included in the Model outline for this design. The level of Eggs can be determined by the settings of the other 5 factors and the constraint on the dry ingredients. This script was saved to the data table when it was created by Custom Design.

1. Open the Cake Data.jmp sample data table, located in the Design Experiment folder.
2. In the Table panel of the design table, click the green triangle next to the Model script.

   The main effect due to Eggs is not included. To avoid model singularities, the Eggs effect was excluded from the Model outline in the Custom Design window. The five effects are designated as Response Surface and Mixture effects.

3. Click Run.

   A JMP Alert appears, notifying you that the Profiler cannot be shown because of the mixture of mixtures constraint on the subsets of factors.

4. Click OK to dismiss the JMP Alert.

   The Parameter Estimates report indicates that Sugar and Flour are significant at the 0.05 level.

**Figure 5.61 Parameter Estimates Report**
Experiments with Covariates

Sometimes measurements on the experimental units that are intended for an experiment are available. These measurements might affect the experimental response. It is useful to include these variables, called *covariates*, as design factors. Although you cannot directly control these values, you can ensure that the levels of the other design factors are chosen to yield the most precise estimates of all the effects.

The Custom Design platform constructs a design that selects covariate values in an optimal fashion. Covariate values are selected from an existing data table that provides covariate information about the potential experimental units. You can specify a number of runs that is smaller than the number of experimental units listed in your data table. You can also specify covariates that are hard-to-change. When you make your design and the design has fewer runs than the number of rows in the covariate table, the design table includes a Covariate Row Index column. This column indicates the row from the covariate table that corresponds to each experimental run.

**Note:** The number of rows in the covariate data table where covariate factors have nonmissing values must be greater than or equal to the specified Number of Runs.

- “Design with Fixed Covariates”
- “Design with Hard-to-Change Covariates”
- “Design with a Linear Time Trend”

**Design with Fixed Covariates**

In this example, you are interested in modeling the *Shrinkage* of parts produced by an injection molding process. The Thermoplastic.jmp sample data table in the Design Experiment folder lists 25 batches of raw (thermoplastic) material for potential use in your study. For each batch, material was removed to obtain measurements of Specific Gravity and Tensile Strength. A third covariate, Supplier, is also available.

You want to study the effects of three controllable factors, Temperature (mold temperature), Speed (screw speed), and Time (hold time), on Shrinkage. But you also want to study the effects of the covariates: Specific Gravity, Tensile Strength, and Supplier. Your resources allow for 12 runs.

**Create the Design**

1. Select **Help > Sample Data Library** and open Design Experiment/Thermoplastic.jmp.
2. Select **DOE > Custom Design**.
3. Double-click Y under Response Name and type Shrinkage.
4. Click **Maximize** under Goal and change it to **Minimize**.
5. Click **Add Factor** and select **Covariate**.
6. Select Specific Gravity, Tensile Strength, and Supplier from the list and click **OK**.
   These are covariates and cannot be controlled.
7. Type 3 next to **Add N Factors**.
8. Click **Add Factor > Continuous**.
9. Rename the three continuous factors Temperature, Speed, and Time.
   These are factors that can be controlled.

**Figure 5.62** Responses and Factors Outlines

10. Click **Continue**.
    The Number of Runs shows the number of rows with covariate values available. You have 25 batches with measured covariates.
11. Type 12 next to **Number of Runs**.

**Note:** Setting the Random Seed in step 12 and Number of Starts in step 13 reproduces the exact results shown in this example. In constructing a design on your own, these steps are not necessary.

12. (Optional) Click the Custom Design red triangle, select **Set Random Seed**, type 84951, and click **OK**.
13. (Optional) Click the Custom Design red triangle, select **Number of Starts**, type 40, and click **OK**.
14. Click **Make Design**.
Figure 5.63  Twelve-Run Optimal Design

This design is D-optimal, given the potential covariate values. It selects the best sets of covariate values and the best settings for the three controllable factors.

Evaluate the Design

The seven terms corresponding to main effects appear in the upper left corner of the color map. Notice that these seven terms are close to orthogonal. The largest absolute correlation is between Tensile Strength and Supplier 2. This absolute correlation of about 0.43 is a consequence of the available covariate values. (Figure 5.64 uses JMP default colors.)

**Design with Hard-to-Change Covariates**

In this example, you construct a design for developing a running shoe for serious runners that has good wear (Wear) properties. Your experiment includes four factors:

- sole thickness (Thickness)
- amount of gel cushioning (Gel)
- outsole material (Outsole)
- midsole material (Midsole)
To obtain generalizable conclusions, you need to test your shoes on a broad base of serious runners. To accommodate your experimental budget, each runner must test several experimental combinations.

Your company has collected data on 100 suitable runners willing to participate in your study. The concomitant variables (*covariates*) measured on these runners are average daily miles run (*Miles*), weight (*Weight*), and the foot’s strike point (*Strike Point*).

Create your design:

1. Select **Help > Sample Data Library** and open *Design Experiment/Runners Covariates.jmp*.
2. Select **DOE > Custom Design**.
3. Double-click **Y** under **Response Name** and type **Wear**.
4. Click **Maximize** under **Goal** and change it to **Minimize**.
5. Click **Add Factor** and select **Covariate**.
6. Select **Miles**, **Weight**, and **Strike Point** from the list and click **OK**.
   These are the hard-to-change covariates associated with the runners.
7. For one of the factors **Miles**, **Weight**, and **Strike Point**, under **Changes**, click **Easy** and change it to **Hard**.
   Note that **Changes** for all three covariates change to Hard.

To add the remaining factors manually, follow step 8 through step 16. Or, to load factors from a saved table, select **Load Factors** from the Custom Design red triangle. Open the *Runners Factors.jmp* sample data table, located in the Design Experiment folder. If you select **Load Factors**, skip step 8 through step 16.

8. Type 2 next to **Add N Factors**.
9. Click **Add Factor > Continuous**.
10. Rename the two factors **Thickness** and **Gel**.
11. Change the **Values** for **Thickness** to 5 and 20.
12. Change the **Values** for **Gel** to 1 and 10.
13. Type 2 next to **Add N Factors**.
14. Click **Add Factor > Categorical > 3 Level**.
15. Rename the two factors **Outsole** and **Midsole**.
   Keep the default **Values** for these factors.
16. Click **Continue**.

17. Select **Interactions > 2nd**.

   The specified model fits all two-factor interactions, including covariate by experimental factor interactions.

18. Set the Number of Whole Plots, or runners, to 32 (if it is not already set to that number).

19. Type 64 next to User Specified under Number of Runs (if it is not already set to that number).

**Note:** Setting the Random Seed in step 20 and Number of Starts in step 21 reproduces the exact results shown in this example. In constructing a design on your own, these steps are not necessary.

20. (Optional) Click the Custom Design red triangle, select **Set Random Seed**, type 12345, and click **OK**.

21. (Optional) Click the Custom Design red triangle, select **Number of Starts** and set it to 1 (if it is not already set to that number). Click **OK**.

22. Click **Make Design**.
Of the 100 runners, 32 are selected based on their covariate values. The rows corresponding to the selected runners are selected in the RunnersCovariates.jmp sample data table. Settings of the experimental factors Thickness, Gel, Insole, and Outsole are determined so that the design is optimal for the model described in the Model Outline.

23. With the RunnersCovariates.jmp sample data table as the active table, select Analyze > Distribution.

24. Select all three columns as Y, Columns.

25. Check Histograms Only.

26. Click OK.

Figure 5.67 Histograms for 100 Runners with Selected Runner Data Shaded
The histograms illustrate how the design selected runners to balance runs across the covariates. The distribution of selected runners is similar to the overall distribution of all runners for each covariate.

**Design with a Linear Time Trend**

Often, experiments conducted in a time sequence experience a linear drift in the response. If you randomize the order of the runs, then the drift’s effect does not generally bias the estimated factor effects. However, by accounting for the drift, you can reduce the variance of those effects.

Suppose that there is reason to suspect a strong linear trend in the response over time independent of the factor changes. Then you can construct a design that includes a linear covariate to account for the trend. The resulting design is optimal, given this trend covariate.

In this example, you design an experiment for 7 factors. You construct a 16-run design that is robust to linear trend.

1. Select **File > New > Data Table**.
2. Right-click Column1 and select **Column Info**.
3. Change the column name to **Run Order**.
4. From the list of **Initialize Data** options, select **Sequence Data**.
5. Type 16 next to **To**.
6. Click **OK**.

Consecutive integers from 1 to 16 have been entered in the data table.

7. Select **DOE > Custom Design**.
8. Click **Add Factor > Covariate**.
9. Select Run Order and click **OK**.
10. Type 7 next to **Add N Factors**.
11. Click **Add Factor > Continuous**.
12. Click **Continue**.

13. Open the **Alias Terms** outline.

14. Select all of the effects in the list and click **Remove Term**.

   This omits the interaction effects from the correlation color map, leaving only the main effects.

   **Note:** Setting the Random Seed in step 15 and Number of Starts in step 16 reproduces the exact results shown in this example. In constructing a design on your own, these steps are not necessary.

15. (Optional) Click the Custom Design red triangle, select **Set Random Seed**, type 1234, and click **OK**.

16. (Optional) Click the Custom Design red triangle, select **Number of Starts**, type , and click **OK**.

17. Click **Make Design**.

Figure 5.70  Color Map Showing Absolute Correlations with Run Order

The Color Map shows the following:

– The seven continuous factors, X2 through X8, are orthogonal to each other.
– Run Order, the linear time trend variable, has extremely low absolute correlation with X2 through X8.

The small absolute correlations of Run Order with X2 through X8 result in very small increases in confidence interval lengths, relative to an ideal orthogonal design. The increases in the lengths of confidence intervals for X2 through X8 are all less than about 0.1%.

In this example, the run order factor is nearly orthogonal to the factor effects. In some cases, your design might have more substantial correlations between the run order factor and other factors. Even in such a situation, including the run order as a factor accounts for any linear trend effect. Including the run order also allows for more precise estimation of the other factor effects.

Experiments with Randomization Restrictions

The Custom Design platform constructs split-plot, split-split-plot, and two-way split-plot (strip-plot) designs that are D-optimal or I-optimal. For more information about constructing these designs, see Goos (2002).

- “Split-Plot Experiment”
- “Two-Way Split-Plot Experiment”

Split-Plot Experiment

Split-plot designs originated in agriculture, but are commonplace in manufacturing and engineering studies. In a split-plot experiment, hard-to-change factors are reset only between one whole plot and the next whole plot. The whole plot is divided into subplots, and the levels of the easy-to-change factors are randomly assigned to each subplot.
The example in this section is adapted from Kowalski, Cornell, and Vining (2002). You are interested in the effects of five factors on the thickness of vinyl that is used to make automobile seat covers. The response and factors in the experiment are described below:

- The response is the thickness of the vinyl that is produced. You want to maximize thickness. A lower limit for thickness values is 10.
- The whole plot factors are the rate of extrusion (extrusion rate) and the temperature (temperature) of drying. These are process variables and are hard to change.
- The subplot factors are three plasticizers whose proportions (m1, m2, and m3) sum to one. These factors are mixture components.

Your experimental budget allows for running 7 settings of these whole plot factors. For each whole plot, you can conduct 4 runs of the subplot factors. This gives you a total of 28 runs.

**Create the Design**

1. Select **DOE > Custom Design**.
2. Double-click Y under Response Name and type thickness.
   - Keep the default goal set to Maximize.
3. Enter a Lower Limit of 10.

To add factors manually, follow step 4 through step 11. Or, to load factors from a saved table, select **Load Factors** from the Custom Design red triangle. Open the Vinyl Factors.jmp sample data table, located in the Design Experiment folder. If you select **Load Factors**, skip step 4 through step 11.

4. Type 2 next to **Add N Factors**.
5. Click **Add Factor > Continuous**.
6. Rename these factors extrusion rate and temperature.
   - Keep the default Values of –1 and 1 for these two factors.
7. Click **Easy** and select **Hard** for both extrusion rate and temperature.
   - This defines extrusion rate and temperature to be whole plot factors.
8. Type 3 next to **Add N Factors**.
9. Click **Add Factor > Mixture**.
10. Rename the three mixture factors m1, m2, and m3.
    - Keep the default Values of 0 and 1 for those three factors.
11. Click **Continue**.

12. Click **Interactions > 2nd**.

13. Click **OK** to dismiss the informative message.

   Note that 3 is the default value for the Number of Whole Plots.

14. Type 7 next to **Number of Whole Plots**.

15. Type 28 next to **User Specified**.

   **Note:** Setting the Random Seed in step 16 and Number of Starts in step 17 reproduces the exact results shown in this example. In constructing a design on your own, these steps are not necessary.

16. (Optional) Click the Custom Design red triangle, select **Set Random Seed**, type 12345, and click **OK**.

17. (Optional) Click the Custom Design red triangle, select **Number of Starts**, type 5, and click **OK**.

18. Click **Make Design**.
Note that the whole plot factors, extrusion rate and temperature, are reset seven times in accordance with the levels of the factor Whole Plots. Within each level of Whole Plots, the settings for the mixture ingredients, m1, m2, and m3, are assigned at random.

**Analyze the Results**

The Vinyl Data.jmp sample data table contains experimental results using a design created in a previous version of JMP.

1. Select Help > Sample Data Library and open Design Experiment/Vinyl Data.jmp.

   This sample data table contains 28 runs and response values. The design settings in the table that you created using the Custom Design platform might differ from those used in the Vinyl Data.jmp design.

2. In the Table panel, click the green triangle next to the Model script.
Notice the following in the Fit Model window:

- The factor **Whole Plots** has the Attribute called Random Effects (**&Random**). This specifies that the levels of **Whole Plots** are random realizations. They have an associated error term.

- The analysis method is **REML (Recommended)**. This method is specified precisely because the model contains a random effect. For more information about REML models, see *Fitting Linear Models*.

**Tip:** In the Fit Model window, JMP Pro users can change the Personality to Mixed Model.

3. Click **Run**.
The Parameter Estimates report shows that the three mixture ingredients, as well as the extrusion rate*temperature interaction, are significant at the 0.05 level.

The REML Variance Component Estimates report indicates that the variance component associated with Whole Plots is 2.476748. This is 38.838% of the total variation. It follows that the error term associated with whole plot replication is smaller than the residual (or within-plot) error term.

Two-Way Split-Plot Experiment

A two-way split-plot (also known as strip-plot or split-block) design consists of two split-plot components. In industry, these designs arise when batches of material or experimental units from one processing stage pass to a second processing stage. To use a two-way split-plot design, you must be able to reorder the units between stages.

After the first processing stage, you must be able to divide the batches into sub-batches. The second-stage processing factors are applied randomly to these sub-batches. For a specific second-stage experimental setting, all of the sub-batches assigned to that setting can be processed simultaneously. Additional factors can be applied to experimental units after the second processing stage.

In contrast to a split-split-plot design, the second-stage factors are not nested within the first-stage factors. After the first stage, the batches are subdivided and formed into new batches. Therefore, both the first- and second-stage factors are applied to whole batches.
Although factors at both stages might be equally hard-to-change, in order to distinguish these factors, JMP denotes the first stage factors as very-hard-to-change and the second-stage factors as hard-to-change. Additional factors applied to experimental units after the second processing stage are considered easy-to-change.

Scenario for a Two-Way Split-Plot Design

This example is based on an experiment to improve the open circuit voltage (OCV) in battery cells (Vivacqua and Bisgaard, 2004). You need to minimize the OCV in order to keep the cells from discharging on their own.

Battery cells move through two stages of processing:
- First stage: A continuous assembly process where batteries are processed in batches of 2000.
- Second stage: A curing process with a 5-day cycle time in a chamber that can accommodate 4000 batteries.

You want to study six two-level continuous factors:
- Four factors (A1, A2, A3, and A4) are applied to the assembly process. You can run 16 trials for the first-stage factors.
- Two factors (C5 and C6) are applied to the curing process. Because curing requires a 5-day cycle time, you can run only 6 cycles (30 days) for the second-stage factors. Using six curing cycles gives you partial replication of the curing settings, enabling you to test for curing effects.

Both the first- and second-stage factors are hard-to-change, suggesting two split-plots. However, the batches of 2,000 batteries from the first-stage experiment can be divided into sub-batches of 500 batteries each. Eight of these sub-batches can be randomly selected and processed simultaneously in the curing chamber.

The experiment has 48 experimental units. Note that the first- and second-stage factors are crossed.

Create the Design

To design a two-way split-plot experiment:
1. Select \textbf{DOE > Custom Design}.
2. Double-click \textit{Y} under Response Name and type \textit{OCV}.
3. Under Goal, click \textbf{Maximize} and select \textbf{Minimize}.
4. To add factors manually, follow step 5 through step 10. Or, to load factors from a saved table:
   a. Click the Custom Design red triangle and select \textbf{Load Factors}. 
b. Open the Battery Factors.jmp sample data table, located in the Design Experiment folder.

c. Proceed to step 11.

5. Type 6 next to **Add N Factors**.

6. Click **Add Factor > Continuous**.

7. Rename the factors A1, A2, A3, A4, C1, and C2.

   Keep the default Values of -1 and 1 for these factors.

8. For each of the factors A1, A2, A3, and A4, under Changes, click **Easy** and change it to **Very Hard**.

   To distinguish between the first- and second-stage factors, you designate the Changes for the first-stage factors as Very Hard, and the Changes for the second-stage factors as Hard.

9. For each of the factors C1 and C2, under Changes, click **Easy** and change it to **Hard**.

Figure 5.76  Responses and Factors Outlines

![Responses and Factors Outlines](image)

10. Click **Continue**.

11. Select **Interactions> 2nd** in the Model outline.

12. In the Design Generation outline, select the option **Hard to change factors can vary independently of Very Hard to change factors**.

   See Figure 5.77. Checking this option creates a two-way split-plot design. If this option is not checked, the design is treated as a split-split-plot design, with nesting of factors at the two levels.

13. Type 16 as the **Number of Whole Plots**.

   This is the number of trials that you can run for the first-stage factors.

14. Type 6 as the **Number of Subplots**.
This is the number of trials that you can run for the second-stage factors.

15. Under Number of Runs, type 48 next to User Specified.

This is the total number of experimental units.

**Figure 5.77  Design Generation Outline**

![Design Generation Outline](image)

**Note:** Setting the Random Seed in step 16 and Number of Starts in step 17 reproduces the exact results shown in this example. In constructing a design on your own, these steps are not necessary.

16. (Optional) Click the Custom Design red triangle, select Set Random Seed, type 1866762673, and click OK.

17. (Optional) Click the Custom Design red triangle, select Number of Starts, type 21, and click OK.

18. Click Make Design.

19. Click Make Table.

**Figure 5.78  Partial View of Design Table**

![Partial View of Design Table](image)
The design table shows 16 levels for Whole Plots. For each level of Whole Plots, the settings of the four assembly factors are constant. From each level of Whole Plots, three batches of 500 batteries (Subplots) are randomly assigned to settings of the curing factors. Two sets of curing conditions are replicated (C1 = -1, C2 = 1 and C1 = 1, C2 = 1). To see this, select columns C1 and C2, right-click in the header area, and select **Sort > Ascending**.

**Analyze the Results**

The Battery Data.jmp sample data table contains experimental results for the design that you generated.

1. Select **Help > Sample Data Library** and open Design Experiment/Battery Data.jmp.
2. In the Table panel, click the green triangle next to the **Model** script.

   Notice the following in the Fit Model window:

   - The factor Whole Plots has the Attribute called Random Effects (**&Random**). This specifies that the levels of Whole Plots are random realizations. They have an associated error term.
   - The factor Subplots also has the Random Effects Attribute (**&Random**).
   - The analysis Method is **REML (Recommended)**. This method is specified precisely because the model contains random effects. For more information about REML models, see *Fitting Linear Models*.

**Tip:** In the Fit Model window, JMP Pro users can change the Personality to Mixed Model.

3. Check the option to **Keep dialog open**.
4. Click **Run**.
The Parameter Estimates report indicates that four two-way interactions, $A_1C_1$, $A_1C_2$, $A_2C_1$, and $A_4C_2$, and two main effects, $A_1$ and $A_4$, are significant at the 0.05 level.

5. In the Table panel of Battery Data.jmp, click the green triangle next to the Reduced Model 1 script.

The script opens a Fit Model window where insignificant interactions have been removed. The remaining effects are all main effects and the four two-way interactions $A_1C_1$, $A_1C_2$, $A_2C_1$, and $A_4C_2$. You are reducing the model in a conservative fashion.

6. Click Run.
Notice that the main effect $C_2$ is now significant at the 0.05 level ($\text{Prob>|t|} = 0.0331$)

7. In the Fit Model window, remove $A_3$.

The main effect $A_3$ is the only main effect that is not significant and not involved in a two-way interaction.

8. Click **Run**.

The REML Variance Component Estimates report shows that the variance component associated with Whole Plots is about six times as large as the variance component for Subplots. This suggests that the assembly process is more variable than the curing process. Also, the within (Residual) error is larger than that for Subplots. Efforts to reduce variation should focus on the assembly process and on battery-to-battery differences.

9. Click the Response OCV red triangle and select **Factor Profiling > Profiler**.
10. Click the Prediction Profiler red triangle and select **Optimization and Desirability > Maximize Desirability**.

**Figure 5.82** Prediction Profiler with Settings That Minimize OCV

The profiler shows the five factors identified as active and settings that minimize OCV.

**Experiments for Robust Process and Product Design**

Often processes or products are impacted by noise factors. These are factors that are not easy or cost effective to control. Finding process or product settings of controllable factors that are least impacted by noise factors is desirable. Historically, Taguchi designs provided a method for experimenting in the presence of noise factors. Note that noise factors must be controlled during an experiment.
Alternatives to Taguchi designs include combined arrays and mixed resolution designs (Borror and Montgomery, 2000). The mixed resolution designs are used to obtain designs that contain both control and noise factors. The goal of such a design is to find robust settings for control variables. The key is the ability to estimate specific effects. In particular, one is interested in estimating main effects of the control variables, main effects of the noise variables, control by control interactions, noise by control interactions, and quadratic terms for the control variables.

Use the custom designer to generate a design for studying robust process settings.

In this example, you are interested in finding optimal settings for four control settings in the presence of three noise factors.

1. Select **DOE > Custom Design**.
2. In the Factors outline, type 4 next to **Add N Factors**.
3. Click **Add Factor > Continuous**.
4. In the Factors outline, type 3 next to **Add N Factors**.
5. Click **Add Factor > Continuous**.
6. Double-click **X5** and change it to **Z1** to designate a noise factor. Repeat to change **X6** and **X7** to **Z2** and **Z3**.

**Figure 5.83** Factor Outline for Design with 4 Control and 3 Noise Factors

7. Click Continue.

Next you set up the model that for exploring optimal settings for the control factors that are least impacted by the noise factors.

8. The model contains all main effects by default.
9. Click **Interactions > 2nd** to add all two-way interactions.

   This enters the control by control interactions, the control by noise interactions, and the noise by noise interactions. You do not want to estimate the interaction between noise factors.

10. Scroll to the bottom of the list, highlight **Z1*Z2**, **Z1*Z3**, and **Z2*Z3** and click Remove Term. This removes the noise by noise interactions.
11. In the Factors outline, select **X1**, **X2**, **X3**, and **X4**.
12. In the Model outline, click Powers > 2nd to add the control variable quadratic terms.

**Figure 5.84** Model Outline for Design with Noise Factors

</table>

13. Add two center points by entering 2 in the **Number of Center Points:** text box.
14. Click **Make Design.**

The result is a 36 run design that enables you to evaluate and optimize your control factors in the presence of your three noise factors. The goal of your analysis is to determine which effects are important and then to select settings for the control factors that are least impacted by the noise factors.
Augment Designs
Add Additional Runs to an Existing Design

Use the Augment Design platform to add runs to an existing experimental design. Experimentation is often a sequential process and augmenting a designed experiment can help resolve ambiguities that result from a single design.

For an existing design table, the Augment Design platform constructs additional runs that optimize the overall design. You can add runs to accomplish the following objectives:

- Replicate the design a specified number of times.
- Add center points.
- Create a foldover design.
- Add axial points together with center points to transform a screening design to a response surface design.
- Add space filling points to a design.
- Add runs to the design in order to fit a specific model.

For more information about augmenting designs see Goos and Jones (2011).

Example Using the Augment Design Platform

Use the Augment Design Platform to add additional runs to a design. This example demonstrates how to use the Augment Design platform to resolve ambiguities in the results of a screening design. In this study, a chemical engineer investigates the effects of five factors on the percent reaction of a chemical process. The original design was an 8-run design suitable for fitting main effects. This example augments the 8-run design such that all two-factor interactions can be estimated using a total of 16 runs.

1. Select Help > Sample Data Library and open Design Experiment/Reactor 8 Runs.jmp.
2. Select DOE > Augment Design.
3. Select Percent Reacted and click Y, Response.
4. Select Feed Rate, Catalyst, Stir Rate, Temperature, and Concentration, and click X, Factor.
5. Click OK.

Figure 6.2 Factors for the Reactor Example

Note: You can select Group new runs into separate block to add a blocking factor to any design. However, recall that this example estimates all two-factor interactions in 16 runs, and that cannot be done when there is an additional blocking factor in the model.

6. Click Augment.

The model shown in Figure 6.3 is defined using the Model script in the data table. With 8 runs, you can estimate up to 7 effects. The model in the script contains all 5 main effects and two interaction terms. All terms are defined as necessary for the model. For more information about effect estimability, see “Model” on page 99 in the “Custom Designs” chapter.
Figure 6.3 Initial Augment Design Platform

7. In the Model outline, select **Interactions > 2nd**.
   
   This adds all the two-factor interactions to the model. The minimum number of runs given for the specified model is 16, as shown in the Design Generation text edit box.

   **Note:** Setting the Random Seed in step 8 and Number of Starts in step 9 reproduces the exact results shown in Figure 6.4. When you are constructing a design on your own, these steps are optional.

8. (Optional) Click the Augment Design red triangle, select **Set Random Seed**, type 282322901, and click **OK**.

9. (Optional) Click the Augment Design red triangle, select **Number of Starts**, type 800, and click **OK**.

10. Click **Make Design**.

11. Click the **Design** disclosure icon to view the design.
Figure 6.4 16 Run Augmented Design

12. Click **Make Table** to generate a design table containing the original design with results and the augmented runs.

**Analyze the Augmented Design**

Continuing the augmented design example, suppose you have conducted the additional experimental runs and have recorded results to analyze.

1. Select **Help > Sample Data Library** and open Design Experiment/Reactor Augment Data.jmp.

   You want to maximize **Percent Reacted**. Note that the column’s Response Limits column property in this sample data table is set to **Maximize**. The lower and upper limits are set to 90 and 100, respectively.
Figure 6.5  Response Limits Column Property for the Percent Reacted Column

2. In the Table panel of the data table, click the green triangle next to the Model script.
   The Model script opens the Fit Model window with all main effects and two-factor
   interactions as effects.

3. Change the fitting personality from Standard Least Squares to Stepwise and then click Run.

4. In the Stepwise Regression Control panel, select P-value Threshold from the Stopping
   Rule menu and Mixed from the Direction menu. Enter 0.05 for the Prob to Enter and 0.05
   for the Prob to Leave.

5. In the Current Estimates panel, select the Entered check boxes for all the main effect terms
   (Feed Rate - Concentration).
6. Click **Go**.

   Stepwise regression, beginning with the main effects and using a $p$-value based search, results in a model with three main effects and two interaction terms. Click **Make Model** on the Stepwise Regression Control panel.

   This launches the Fit Model platform for the model built using the stepwise procedure.

7. Click **Run**.
Figure 6.7  Prediction Model Analysis of Variance and Lack of Fit Tests

The Actual by Predicted Plot indicates that the overall model is significant (PValue < .0001). Both the Actual by Predicted Plot and the Lack of Fit tests show no evidence of model misspecification. The Effect Summary report shows that Catalyst is the most significant effect.

8. Click the Prediction Profiler red triangle and select Optimization and Desirability > Maximize Desirability.
The prediction profile plot shows that the maximum percent reaction occurs at high Catalyst and Temperature and low Concentration. At these extreme settings, the estimate of Percent Reacted is 95.7. The desirability profiles flatten in regions where the predicted response falls outside of the response limits.

Launch the Augment Design Platform

Launch the Augment Design platform by selecting **DOE > Augment Design** from the data table that contains the design that you want to augment.

**Y, Response** Enter the numeric response column or columns. Entering a response is required.

**X, Factor** Enter the factor columns. Factors can be of any data type or modeling type.
Augment Design Window

The initial Augment Design window consists of the Factors and Define Factor Constraints outlines, and the Augmentation Choices panel.

Figure 6.10  Initial Augment Design Window Using Reactor 8 Runs.jmp

Factors

The factors are those you specified in the Augment Design launch window.

**Name**  Lists all factors listed as X, Factor in the Augment Design launch window except for factors with the Random Block design role column property.

**Role**  Specifies the Design Role of the factor specified in the column property. If the factor does not have a Design Role column property and is constant, then Constant appears in the Role column. Otherwise, the factor’s modeling type appears in the Role column.

**Changes**  Indicates whether the factor levels are Easy, Hard, or Very Hard to change as specified by the Factor Changes column property in the data table. If the factor does not have a Factor Changes column property, then Changes is specified as Easy.

**Note:** If a factor has a Factor Changes column property that is set to Hard or Very Hard, then the corresponding whole plot factor must be included in the X, Factor list in the Augment Design launch window.

**Values**  For continuous factors, shows the minimum and maximum values. For categorical factors, shows the levels.
Tip: Factors that have a role of Categorical or Constant appear in the Name column with a down arrow icon. Click the down arrow to add levels. If the factor is Constant and has a categorical modeling type, multiple levels can be added. If the factor is Constant and has a continuous modeling type, only one level can be added.

Group new runs into separate block  Adds a blocking factor to the design with a block for the original design and a block for the augmented runs.

Define Factor Constraints

If you augment a design using the Space Filling or Augment options, you can define restrictions on the design space for the added runs.

Use Define Factor Constraints to restrict the design space. Unless you have loaded a constraint or included one as part of a script, the None option is selected. To specify constraints, select one of the other options:

Specify Linear Constraints  Specifies inequality constraints on linear combinations of factors. Available only for factors with a Role of Continuous or Mixture. See Specify Linear Constraints.

Note: When you save a script for a design that involves a linear constraint, the script expresses the linear constraint as a less than or equal to inequality (≤).

Use Disallowed Combinations Filter  Defines sets of constraints based on restricting values of individual factors. You can define both AND and OR constraints. See Use Disallowed Combinations Filter.

Use Disallowed Combinations Script  Defines disallowed combinations and other constraints as Boolean JSL expressions in a script editor box. See Use Disallowed Combinations Script.

Note: When you analyze a design that has factor constraints, the model profiler honors the constraints.

Specify Linear Constraints

In cases where it is impossible to vary continuous factors independently over the design space, you can specify linear inequality constraints. Linear inequalities describe factor level settings that are allowed.
Click **Add** to enter one or more linear inequality constraints.

**Add**  Adds a template for a linear expression involving all the continuous factors in your design. Enter coefficient values for the factors and select the direction of the inequality to reflect your linear constraint. Specify the constraining value in the box to the right of the inequality. To add more constraints, click **Add** again.

**Note:** The Add option is disabled if you have already constrained the design region by specifying a Sphere Radius.

**Remove Last Constraint**  Removes the last constraint.

**Check Constraints**  Checks the constraints for consistency. This option removes redundant constraints and conducts feasibility checks. A JMP alert appears if there is a problem. If constraints are equivalent to bounds on the factors, a JMP alert indicates that the bounds in the Factors outline have been updated.

**Use Disallowed Combinations Filter**

This option uses an adaptation of the Data Filter to facilitate specifying disallowed combinations. For detailed information, see the JMP Reports chapter in *Using JMP*.

Select factors from the Add Filter Factors list and click **Add**. Then specify the disallowed combinations by using the slider (for continuous factors) or by selecting levels (for categorical factors).

The red triangle options for the Add Filter Factors menu are those found in the Select Columns panel of many platform launch windows. See the Get Started chapter in *Using JMP*.

When you click Add, the Disallowed Combinations control panel shows the selected factors and provides options for further control. Factors are represented as follows, based on their modeling types:

**Continuous Factors**  For a continuous factor, a double-ended slider that spans the range of factor settings appears. You can specify disallowed settings by dragging the slider ends or by setting the endpoints by clicking on the text value under the slider. In the slider, a solid blue highlight represents the disallowed values.

**Categorical Factor**  For a categorical factor, the possible levels are displayed either as labeled blocks or, when the number of levels is large, as list entries. Select a level to disallow it. To select multiple levels, hold the Control key. The block or list entries are highlighted to indicate the levels that have been disallowed. When you add a categorical factor to the Disallowed Combinations panel, the number of levels of the categorical factor is given in parentheses following the factor name.
Disallowed Combinations Options

The control panel has the following controls:

Clear  Clears all disallowed factor level settings that you have specified. This does not clear the selected factors.

Start Over  Removes all selected factors and returns you to the initial list of factors.

AND  Opens the Add Filter Factors list. Selected factors become an AND group. Any combination of factor levels specified within an AND group is disallowed.

To add a factor to an AND group later on, click the group’s outline to see a highlighted rectangle. Select AND and add the factor.

To remove a single factor, select **Delete** from its red triangle menu.

OR  Opens the Add Filter Factors list. Selected factors become a separate AND group. For AND groups separated by OR, a combination is disallowed if it is specified in at least one AND group.

Red Triangle Options for Factors

A factor can appear in several OR groups. An occurrence of the factor in a specific OR group is referred to as an *instance* of the factor.

Delete  Removes the selected instance of the factor from the Disallowed Combinations panel.

Clear Selection  Clears any selection for that instance of the factor.

Invert Selection  Deselects the selected values and selects the values not previously selected for that instance of the factor.

Display Options  Available only for categorical factors. Changes the appearance of the display. Options include showing each level as a block, list, or single category, or adding a check box next to each value.

Find  Available only for categorical factors. Provides a text box beneath the factor name where you can enter a search string for levels of the factor. Press the Enter key or click outside the text box to perform the search. Once **Find** is selected, Find options appear in the red triangle menu, such as Does not contain, Match Case, Starts with or Ends with, or Clear Find.

Use Disallowed Combinations Script

Use this option to disallow particular combinations of factor levels using a JSL script. This option can be used with continuous factors or mixed continuous and categorical factors.
This option opens a script window where you insert a script that identifies the combinations that you want to disallow. The script must evaluate as a Boolean expression. When the expression evaluates as true, the specified combination is disallowed.

When forming the expression for a categorical factor, use the ordinal value of the level or the name of the level. If a factor’s levels are high, medium, and low, specified in that order in the Factors outline, their associated ordinal values are 1, 2, and 3. For example, suppose that you have two continuous factors, X1 and X2, and a categorical factor X3 with three levels: L1, L2, and L3, in order. You want to disallow levels where the following is true:

\[ e^{X_1} + 2X_2 < 0 \text{ and } X_3 = L2 \]

Enter the expression \((\text{Exp}(X1) + 2*X2 < 0) \& (X3 == 2)\) into the script window.

**Figure 6.11** Expression in Script Editor

(In the figure, unnecessary parentheses were removed by parsing.) Notice that functions can be entered as part of the Boolean expression. The expression \((\text{Exp}(X1) + 2*X2 < 0) \& (X3 == "L2")\) is also valid.

**Augmentation Choices**

The Augment Design platform has the following choices for augmentation:

- **Replicate** Replicates the design a specified number of times. See “Replicate a Design” on page 231.

- **Add Centerpoints** Adds center points. Specify how many runs you want to add as center points to the design. A center point is a run whose setting for each continuous factor is midway between the high and low settings. See “Center Points, Replicate Runs, and Testing” on page 65 in the “Starting Out with DOE” chapter.

  If a design contains both continuous and other types of factors, center points might not be balanced relative to the levels of the other factors. Augment Design chooses the center points to maximize the D-, I-, or alias efficiency of the design.

  See “Add Center Points to a Design” on page 233.

- **Fold Over** Creates a foldover design. See “Create a Foldover Design” on page 233.
**Add Axial**  Adds axial points and center points to a design. Add Axial can be used to generate a central composite design from a screening design. See “Add Axial Points to a Design” on page 234.

**Space Filling**  Adds additional runs to any design consisting of continuous factors. Additional runs are constructed using the fast flexible filling methodology. See “Space Filling Augmentation” on page 236. Space Filling does not support grouping new runs in a separate block.

**Augment**  Adds runs to the design using a model. This model typically has more terms than the original model. See “Example Using the Augment Design Platform” on page 215.

---

**Augment Design Platform Options**

The Accelerated Life Test Plan red triangle menu contains the following options:

**Save Responses**  Saves the information in the Responses panel to a new data table. You can then quickly load the responses and their associated information into most DOE windows. This option is helpful if you anticipate reusing the responses.

**Load Responses**  Loads responses that you saved using the Save Responses option.

**Save Factors**  Saves the information in the Factors panel to a new data table. Each factor’s column contains its levels. Other information is stored as column properties. You can then quickly load the factors and their associated information into most DOE windows.

**Note:** It is possible to create a factors table by entering data into an empty table, but remember to assign each column an appropriate Design Role. Do this by right-clicking on the column name in the data grid and selecting **Column Properties > Design Role**. In the Design Role area, select the appropriate role.

**Load Factors**  Loads factors that you saved using the Save Factors option.

**Save Constraints**  (Unavailable for some platforms) Saves factor constraints that you defined in the Define Factor Constraints or Linear Constraints outline into a data table, with a column for each constraint. You can then quickly load the constraints into most DOE windows.

In the constraint table, the first rows contain the coefficients for each factor. The last row contains the inequality bound. Each constraint’s column contains a column property called ConstraintState that identifies the constraint as a “less than” or a “greater than” constraint. See “ConstraintState” on page 818 in the “Column Properties” appendix.
Load Constraints  (Unavailable for some platforms) Loads factor constraints that you saved using the Save Constraints option.

Set Random Seed  Sets the random seed that JMP uses to control actions that have a random component. These actions include one or more of the following:
- initializing search algorithms for design generation
- randomizing Run Order for design construction
- selecting a starting design for designs based on random starts
To reproduce a design, enter the random seed that generated the design before clicking Make Design.

Note: The random seed associated with a design is included in the DOE Dialog script that is saved to the design data table.

Simulate Responses  Adds response values and a column containing a simulation formula to the design table. Select this option before you click Make Table.

When you click Make Table, the following occur:
- A set of simulated response values is added to each response column.
- For each response, a new column that contains a simulation model formula is added to the design table. The formula and values are based on the model that is specified in the design window.
- A Model window appears where you can set the values of coefficients for model effects and specify one of three distributions: Normal, Binomial, or Poisson.

Note: Not all distributions are available for all design types.

- A script called DOE Simulate is saved to the design table. This script reopens the Model window, enabling you to re-simulate values or to make changes to the simulated response distribution.

Make selections in the Model window to control the distribution of simulated response values. When you click Apply, a formula for the simulated response values is saved in a new column called <Y> Simulated, where Y is the name of the response. Clicking Apply again updates the formula and values in <Y> Simulated.

For additional details, see “Simulate Responses” on page 112 in the “Custom Designs” chapter.

Note: You can use Simulate Responses to conduct simulation analyses using the JMP Pro Simulate feature. For more information and DOE examples, see the Simulate chapter in Basic Analysis.
**Save X Matrix**  Saves scripts called Moments Matrix and Model Matrix to the design data table. These scripts contain the moments and design matrices. See “Save X Matrix” on page 114 in the “Custom Designs” chapter.

**Caution:** For a design with nominal factors, the matrix in the Model Matrix script saved by the Save X Matrix option *is not* the coding matrix used in fitting the linear model. You can obtain the coding matrix used for fitting the model by selecting the option Save Columns > Save Coding Table in the Fit Model report that you obtain when you run the Model script.

**Optimality Criterion**  Changes the design optimality criterion. The default criterion, **Recommended**, specifies D-optimality for all design types, unless you added quadratic effects using the RSM button in the Model outline. For more information about the D-, I-, and alias-optimal designs, see “Optimality Criteria” on page 128 in the “Custom Designs” chapter.

**Note:** You can set a preference to always use a given optimality criterion. Select File > Preferences > Platforms > DOE. Select Optimality Criterion and choose your preferred criterion.

**Number of Starts**  Enables you to specify the number of random starts used in constructing the design. See “Number of Starts” on page 116 in the “Custom Designs” chapter.

**Design Search Time**  Maximum number of seconds spent searching for a design. The default search time is based on the complexity of the design. See “Design Search Time” on page 117 in the “Custom Designs” chapter and “Number of Starts” on page 116 in the “Custom Designs” chapter.

If the iterations of the algorithm require more than a few seconds, a Computing Design progress window appears. If you click **Cancel** in the progress window, the calculation stops and gives the best design found at that point. The progress window also displays D-efficiency for D-optimal designs that do not include factors with Changes set to Hard or Very Hard or with Estimability set to If Possible.

**Note:** You can set a preference for Design Search Time. Select File > Preferences > Platforms > DOE. Select Design Search Time and enter the maximum number of seconds. In certain situations where more time is required, JMP extends the search time.

**Sphere Radius**  Constrains the continuous factors in a design to a hypersphere. Specify the radius and click **OK**. Design points are chosen so that their distance from 0 equals the Sphere Radius. Select this option before you click Make Design.
Note: Sphere Radius constraints cannot be combined with constraints added using the Specify Linear Constraints option. Also, the option is not available when hard-to-change factors are included (split-plot designs).

Advanced Options

**Mixture Sum**  Sets the sum of the mixture factors to any positive value. Use this option to keep a component of a mixture constant throughout an experiment.

**Split Plot Variance Ratio**  Specifies the ratio of the variance of the random whole plot and the subplot variance (if present) to the error variance. Before setting this value, you must define a hard-to-change factor for your split-plot design, or hard and very-hard-to-change factors for your split-split-plot design. Then you can enter one or two positive numbers for the variance ratios, depending on whether you have specified a split-plot or a split-split-plot design.

**Prior Parameter Variance**  (Available only when the Model outline is available.) Specifies the weights that are used for factors whose Estimability is set to If Possible. The option is updated to show the default weights when you click Make Design. Enter a positive number for each of the terms for which you want to specify a weight. The value that you enter is the square root of the reciprocal of the prior variance. A larger value represents a smaller variance and therefore more prior information that the effect is not active.

Bayesian D- or I-optimality is used in constructing designs with If Possible factors. The default values used in the algorithm are 0 for Necessary terms, 4 for interactions involving If Possible terms, and 1 for If Possible terms. See “The Alias Matrix” on page 823 in the “Technical Details” appendix and “Optimality Criteria” on page 128 in the “Custom Designs” chapter.

**A- Optimality Parameter Weights**  (Use for A-Optimal designs.) Specifies weights for the model parameters. This enables you to place more weight on the variance of the main effects over say 2nd order effects. For more information about parameter weights see Morgan and Stallings (2017).

**D Efficiency Weight**  Specifies the relative importance of D-efficiency to alias optimality in constructing the design. Select this option to balance reducing the variance of the coefficients with obtaining a desirable alias structure. Values should be between 0 and 1. Larger values give more weight to D-Efficiency. The default value is 0.5. This option has an effect only when you select Make Alias Optimal Design as your Optimality Criterion.

For the definition of D-efficiency, see “Optimality Criteria” on page 128 in the “Custom Designs” chapter. For more information about alias optimality, see “Alias Optimality” on page 132 in the “Custom Designs” chapter.
Additional Examples of Augmentation Choices

- “Replicate a Design”
- “Add Center Points to a Design”
- “Create a Foldover Design”
- “Add Axial Points to a Design”
- “Space Filling Augmentation”

Replicate a Design

Augment a design with replication for a direct check on the assumption that the error variance is constant. Replication also reduces the variability of the regression coefficients in the presence of large process or measurement variability.

This example replicates an 8 run design.

1. Select Help > Sample Data Library and open Design Experiment/Reactor 8 Runs.jmp.
2. Select DOE > Augment Design.
3. Select Percent Reacted and click Y, Response.
4. Select Feed Rate, Catalyst, Stir Rate, Temperature, and Concentration and click X, Factor.
5. Click OK.

Figure 6.12  Choose an Augmentation Type

6. Select Group new runs into separate block to add a blocking variable to the design.
7. Click Replicate, enter 2, and then click OK.
**Note:** The replicate dialog box asks for the number of times each run is to be performed. Entering 2 specifies that you want each run to appear twice in the resulting design. This results in a single replicate of your original design.

**Figure 6.13** Reactor Data Design Augmented with a Replicate

</table>
The table includes the original design and results in Block 1. The augmented runs are in Block 2. The percent reacted values can be added to the table after the augmented runs have been measured.

**Add Center Points to a Design**

Augment a design with center points to check for curvature and reduce the prediction error in the center of the factor region. Center points are usually replicated points that allow for an independent estimate of pure error, which can be used in a lack-of-fit test.

This example adds two center points to an 8-run design.

1. Select Help > Sample Data Library and open Design Experiment/Reactor 8 Runs.jmp.
2. Select DOE > Augment Design.
3. Select Percent Reacted and click Y, Response.
4. Select Feed Rate, Catalyst, Stir Rate, Temperature, and Concentration and click X, Factor.
5. Click OK.
6. Select Group new runs into separate block to add a blocking variable to the design.
7. Click Add Centerpoints, enter 2, and then click OK.
8. Click Make Table.

**Figure 6.15** Design with Two Center Points Added

After data has been collected for the two center runs you can then test for curvature in your model.

**Create a Foldover Design**

Augment a design with a foldover to remove the confounding of two-factor interactions and main effects. A foldover design is especially useful as a follow-up to saturated or near-saturated fractional factorial or Plackett-Burman designs.
This example creates a foldover design of an 8-run design.

1. Select **Help > Sample Data Library** and open Design Experiment/Reactor 8 Runs.jmp.
2. Select **DOE > Augment Design**.
3. Select Percent Reacted and click **Y, Response**.
4. Select Feed Rate, Catalyst, Stir Rate, Temperature, and Concentration and click **X, Factor**.
5. Click **OK**.
6. Select **Group new runs into separate block** to add a blocking variable to the design.
7. Click **Fold Over** and then click **OK**.

In the fold over dialog box, if you select no factors, then all design factors are included in the fold over. If you choose a subset of factors to fold over, the remaining factors are replicates of the original runs.

**Figure 6.16** Foldover Design on All Factors

8. Click **Make Table**.

Each run in Block 2 can be obtained by changing the factor levels (from low to high or from high to low) of a run from Block 1.

### Add Axial Points to a Design

Augment a design with axial and center points to augment a screening design in order to obtain a response surface design. This enables you to fit a response surface model to your data to optimize the settings of your factors with respect to your response.

This example augments an 8 run screening design with axial and center points.

1. Select **Help > Sample Data Library** and open Design Experiment/Reactor 8 Runs.jmp.
2. Select **DOE > Augment Design**.
3. Select Percent Reacted and click **Y, Response**.
4. Select Feed Rate, Catalyst, Stir Rate, Temperature, and Concentration and click **X, Factor**.
5. Click **OK**.
6. Select **Group new runs into separate block** to add a blocking variable to the design.
7. Click **Add Axial**, enter 1 for axial value, 2 for number of center points, and then click **OK**.
8. Click **Make Table**.
9. From the Augmented Design table, select **Rows > Color or Mark by Column**.
10. Select **Block**, from Markers select **Standard**, and then click **OK**.
11. Select **Graph > Graph Builder**.
12. Drag **Feed Rate** to **Y** and drag **Catalyst** to **X**. Then click the smoother icon to remove.

**Figure 6.17**  Graphical View of the Augmented Design for Two Factors

The “+” points in the graph of Feed Rate versus Catalyst are the added axial and center points. The axial points are on the face of the design space. Increasing or decreasing the axial value in the augmentation of the design would move the axial points beyond or within the design space.
**Space Filling Augmentation**

Augment a design with space filling to add points to a design consisting of continuous factors. The Space Filling choice accommodates constraints on the design space. You can specify linear constraints or disallowed combinations. For more information about the algorithm used, see “Statistical Details” on page 237.

This example augments a design to explore a constrained area of the design space where the response, Depth, was maximized, with added constraints on both factors.

1. Select **Help > Sample Data Library** and open Design Experiment/DOE Example 1.jmp.
2. Select **DOE > Augment Design**.
3. Select Depth and click **Y, Response**.
4. Select Speed and Current, click **X, Factor**, and then click **OK**.
5. Open the Define Factor Constraints outline.
6. Select **Specify Linear Constraints** and click **Add**.
7. Enter 1 for Speed, select greater than or equal to, and then enter 4 for the lower bound on Speed.
8. Click **Add**.
9. Enter 1 for Current, select greater than or equal to, and then enter 155 for the lower bound on Current.
10. Click **Space Filling**.
11. Enter 10 and click **OK**.
12. Click **Make Table**.
13. From the Augmented Design table, select Graph Builder.
14. Drag Speed to the X drop zone and drag Current to the Y drop zone.
Figure 6.18  Space Filling Augmented Runs

The augmented runs fill the space in the upper right corner of the design space. This is the constrained design space.

Statistical Details

This section contains statistical details about the algorithm used to select points for the space-filling augmentation choice.

The algorithm that is used to augment designs begins by generating a large number of random points within the specified design region. These points are then clustered using a Fast Ward algorithm into a number of clusters that equals the Number of Additional Runs that you specify.

The final design points are obtained by optimizing the MaxPro (maximum projection) criterion over the existing and additional runs. For \( p \) factors and \( n \) equal to the number of existing and additional runs, the MaxPro criterion strives to find points in the clusters that minimize the following criterion:

\[
C_{MaxPro} = \sum_{i}^{n-1} \sum_{j=i+1}^{n} \left[ \frac{1}{p} \prod_{k=1}^{p} (x_{ik} - x_{jk})^2 \right]
\]
The MaxPro criterion maximizes the product of the distances between design points in a way that involves all factors. This supports the goal of providing good space-filling properties on projections of factors. See Joseph et al. (2015).
Definitive screening designs (DSD) are screening designs. They are appropriate for early stage experimentation work, typically with four or more factors. DSD can be used for combinations of continuous or two-level categorical factors. They work best when most of the factors are continuous. Each continuous factor has three levels allowing one to investigate quadratic model terms for continuous factors.

Here are areas where definitive screening designs are superior to standard screening designs:

- They help identify the causes of nonlinear effects by fielding each continuous factor at three levels. In standard screening designs, continuous factors have only two levels. You can add center points to screening designs, but these points establish only if curvature exists. They do not allow you to identify the factors responsible for quadratic effects.
- They avoid confounding between any effects up through the second order. For continuous factors, definitive screening designs have main effects that are orthogonal to each other and orthogonal to two-factor interactions and quadratic effects. Two-factor interactions are not completely confounded with each other. Confounding occurs in many standard screening designs with a similar number of runs.
- They avoid the need for costly additional experimentation to resolve ambiguity from the initial results of standard screening designs.

Overview of Definitive Screening Design

Investigators use screening designs when they want to identify the factors that have the most substantial effects on a response. A screening design enables you to study a large number of factors in a fairly small experiment.

Many standard screening designs focus on estimating main effects. Definitive screening designs offer advantages over standard screening designs. They avoid confounding of effects and can identify factors having a nonlinear effect on the response. For more information about the advantages and construction of definitive screening designs, see Jones and Nachtsheim (2011a).

For designs containing only continuous factors, compare these properties of definitive screening designs versus standard screening designs:

**Note:** When quadratic effects are mentioned, the standard screening designs are assumed to have center points.

- Main effects are orthogonal to two-factor interactions.
  - Definitive Screening Designs: Always
  - Standard Screening Designs: Only for Resolution IV or higher
- No two-factor interaction is completely confounded with any other two-factor interaction.
  - Definitive Screening Designs: Always
  - Standard Screening Designs: Only for Resolution V or higher
- All quadratic effects are estimable in models containing only main and quadratic effects.
  - Definitive Screening Designs: Always
  - Standard Screening Designs: Never

These properties are described more fully in the remainder of this section.

**Standard Screening Designs**

Standard screening designs, such as fractional factorial or Plackett-Burman designs, attempt to study many factors with a relatively small allocation of resources. However, standard screening designs have several undesirable features:

- They can alias some main effects with two-factor interactions. In Plackett-Burman designs, for example, main effects are correlated with several two-factor interactions. If one or more two-factor interaction effects are substantial, then the experimenter must perform additional runs to resolve the ambiguities.
• They can also confound some two-factor interactions with each other. Consequently, if a two-factor interaction effect is substantial, then the experimenter must perform additional runs to resolve the remaining ambiguities.

• Continuous factors are usually set at only two levels (low and high). However, engineers and scientists often prefer designs where continuous factors are set at three levels (low, middle, and high). This is because two levels are not sufficient to detect nonlinearity, which is common in physical systems. You can use a traditional screening design with added center points to detect nonlinearity, but such a design does not identify the responsible factors.

Definitive Screening Designs

Using definitive screening designs, you can do the following:

• Avoid model ambiguity, enabling you to identify important factors more quickly and efficiently.

• Identify the cause of nonlinear effects while avoiding confounding any terms up to second order. So not only can you detect nonlinearity, as you might with center points in a traditional screening design, but you can identify the responsible factors.

Definitive screening designs offer the following advantages:

• Definitive screening designs require only a small number of runs. For six or more factors, the minimum number of required runs is usually only a few more than twice the number of factors. For more detail on the number of runs, see “Conference Matrices and the Number of Runs” on page 271.

• Main effects are orthogonal to two-factor interactions. This means that estimates of main effects are not biased by the presence of active two-factor interactions, whether these interactions are included in the model or not. Note that resolution III screening designs confound some main and interaction effects. Also, Plackett-Burman designs produce biased main effect estimates if there are active two-factor interactions.

• No two-factor interaction is completely confounded with any other two-factor interaction. However, a two-factor interaction might be correlated with other two-factor interactions. Note that resolution IV screening designs completely confound some two-factor interaction effects.

• All quadratic effects are estimable in models comprised only of main effects and quadratic terms. This enables you to identify the factors that account for nonlinearity. Note that traditional screening designs with added center points do not allow estimation of all quadratic effects in models consisting of main and quadratic effects.

• Quadratic effects are orthogonal to main effects and not completely confounded with two-factor interactions. A quadratic effect might be correlated with interaction effects.

• For 6 through at least 30 factors, it is possible to estimate the parameters of any full quadratic model involving three or fewer factors with high precision.
For 18 factors or more, they can fit full quadratic models in any 4 factors. For 24 factors or more, they can fit full quadratic models in any 5 factors.

**Definitive Screening Design Platform**

The Definitive Screening Design platform enables you to construct definitive screening designs for continuous factors and for two-level categorical factors. It also enables you to construct blocked designs. You can add extra non-center runs that enhance the ability of the design to reliably detect effects when many effects are active.

To view the absolute values of the correlations among effects, use the Color Map on Correlations provided as part of the Design Evaluation outline in the Definitive Screening Design window. You can compare the aliasing structure of definitive screening designs to that of other designs by comparing their color maps on correlations. See “Color Map on Correlations” on page 465 in the “Evaluate Designs” chapter.

For more information about the structure of definitive screening designs, see “Structure of Definitive Screening Designs” on page 270. For information about definitive screening designs with blocks, see “Blocking in Definitive Screening Designs” on page 261. For suggestions on how to analyze data obtained using definitive screening designs, see “Analysis of Experimental Data” on page 272.

**Fit Definitive Screening Platform**

After you run a Definitive Screening Design (DSD), analyze your results using the Fit Definitive Screening platform. Standard model selection methods applied to DSDs can fail to identify active effects. To identify active main effects and second-order effects, the Fit Definitive Screening platform uses an algorithm called Effective Model Selection for DSDs. This algorithm leverages the special structure of DSDs. See Chapter 8, “The Fit Definitive Screening Platform”.

If you create your DSD in JMP, the design table contains a script called Fit Definitive Screening that automatically runs an analysis using the Effective Model Selection for DSDs methodology.

---

**Examples of Definitive Screening Designs**

- “Definitive Screening Design”
- “Comparison with a Fractional Factorial Design”
- “Definitive Screening Design with Blocking”
- “Comparison of a Definitive Screening Design with a Plackett-Burman Design”
Definitive Screening Design

Suppose that you need to determine which of six factors have an effect on the yield of an extraction process.

Create the Design

The factors and their settings are given in the data table Extraction Factors.jmp. You create a definitive screening design to investigate.

1. Select DOE > Definitive Screening > Definitive Screening Design.
2. Double-click Y under Response Name and type Yield.
4. Click the red triangle next to Definitive Screening Design and select Load Factors.
   The factor names and ranges are added to the Factors outline.

Figure 7.2 Responses and Factors for Extraction Design

5. Click Continue.
   The Design Options outline opens. Here you can specify a blocking structure. There is no need to block in this example, so you accept the default selection of No Blocks Required.
   You can also choose to add Extra Runs, which greatly enhance your ability to detect second-order effects. A minimum of four Extra Runs is highly recommended and is the default.
6. Click Make Design.
The Definitive Screening Design window updates to show a Design outline and a Design Evaluation outline.

**Figure 7.3 Design Outline**

7. Open the **Design Evaluation > Color Map on Correlations** outline.

The Color Map on Correlations assigns a color intensity scale to the absolute values of correlations among all main effects and two-factor interactions.

**Figure 7.4 Color Map on Correlations for Extraction Design**
Note the following:

- The solid white area shows that there is no correlation between main effects or between main effects and two-factor interactions.
- The shaded gray areas indicate that the absolute correlations between two-factor interactions are small.
- The black squares indicate absolute correlations of 1. These all appear on the diagonal, reflecting the expected correlation of an effect with itself.

In the Output Options panel, note that the Run Order is set to **Randomize**.

8. Click **Make Table** to obtain the data table shown in Figure 7.5.

**Note:** The runs in your design might appear in a different order than the order shown in Figure 7.5.

---

**Figure 7.5** Definitive Screening Design for Extraction Process

![Table of run 1 to 17 with factors and responses](image)

**Comparison with a Fractional Factorial Design**

Suppose that you had chosen a traditional screening design instead of the definitive screening design in “Definitive Screening Design” on page 244. This example compares the two designs in terms of confounding.

1. Select **DOE > Classical > Two Level Screening > Screening Design**.
2. Double-click Y under Response Name and type Yield.
3. Select **Help > Sample Data Library** and open Design Experiment/Extraction Factors.jmp.
4. Click the red triangle next to and select **Load Factors**.
   - The factor names and ranges are added to the Factors outline.
5. Click **Continue**.

6. Select **Choose from a list of fractional factorial designs**.

7. Click **Continue**.

**Figure 7.6** Screening Design List for Six Continuous Factors

</table>

8. Select the sixteen-run fractional factorial design with no blocks, shown highlighted in Figure 7.6.

9. Click **Continue**.

10. Open the **Display and Modify Design > Aliasing of Effects** outline.

**Figure 7.7** Aliasing of Effects for Fractional Factorial Design

The Aliasing of Effects outline for the 16-run fractional factorial design shows that every two-factor interaction is confounded with at least one other two-factor interaction. In this fractional factorial design, the Ethanol*Time interaction is confounded with Methanol*pH. To determine which interaction is active, you need to run additional trials. If the factors had been entered in a different order, the Ethanol*Time interaction might have been aliased with two other two-factor interactions.
In the section “Definitive Screening Design” on page 244, you constructed a 17-run definitive screening design. The Color Map on Correlations for this DSD (Figure 7.4) shows that no two-factor interactions are confounded with any other two-factor interactions. For the fractional factorial design, there are seven instances of confounded two-factor interactions. If you suspect that there are active two-factor effects, the DSD is the better choice.

You can conduct a more thorough comparison of the two designs using the Compare Designs platform (DOE > Design Diagnostics > Compare Designs). See Chapter 16, “Compare Designs”.

Definitive Screening Design with Blocking

Suppose that, due to raw material constraints, the extraction experiment requires that you run it using material from two separate lots. You can generate a definitive screening design with a blocking variable to account for the potential lot variation.

Create the Design

The extraction factors and their settings are given in the data table Extraction Factors.jmp. Generate a definitive screening design with a block:

1. Select DOE > Definitive Screening > Definitive Screening Design.
2. Double-click Y under Response Name and type Yield.
4. Click the red triangle next to Definitive Screening Design and select Load Factors.
   - The factor names and ranges are added to the Factors outline.
5. Click Continue.
   - The Design Options outline opens. Here you can specify a blocking structure.
6. Select Add Blocks with Center Runs to Estimate Quadratic Effects.
   - Leave Number of Blocks set at 2.
   - You are recreating the design for the Extraction2 Data.jmp sample data table, which was created without Extra Runs. Although four Extra Runs are strongly recommended, you will not add Extra Runs in this example.
7. Next to Number of Extra Runs, select 0.
8. Click Make Design.
   - The Definitive Screening Design window updates to show a Design outline and a Design Evaluation outline.
   - Check that Block has been added to the Factors outline and to the Design.
9. In the Factors outline, Double-click Block and type Lot.
In the Output Options panel, note that the Run Order is set to Randomize within Blocks.

10. Click **Make Table**.

**Note:** The runs in your design might appear in a different order than the order shown in Figure 7.8.

**Figure 7.8** Definitive Screening Design with Block for Extraction Process

Notice that run 1 is a center point run in Lot 1 and run 14 is a center point run in Lot 2.

**Analyze the Experimental Data**

At this point, you conduct your experiment and record your data in the **Yield** column of the design table (Figure 7.8). The Extraction2 Data.jmp sample data table contains your experimental results. The runs in the Extraction2 Data.jmp sample data table are in a different order than those in Figure 7.8.

To explore all second-order effects, one option is to use All Possible Models regression. Another option is to use forward stepwise regression. However, these standard methods often fail to identify active effects. For this reason, you use the Fit Definitive Screening platform.

1. Select **Help > Sample Data Library** and open Design Experiment/Extraction2 Data.jmp.
2. In the Table panel of the design table, click the green triangle next to the **Fit Definitive Screening** script.
The effects identified by Fit Definitive Screening as potentially active are listed in the Combined Model Parameter Estimates report.

3. Click the Run Model button at the bottom of the Combined Model Parameter Estimates report.

This fits a standard least squares model to the effects identified as potentially active.
The Actual by Predicted Plot shows no evidence of lack of fit. The Effect Summary report shows that Methanol*Ethanol and Methanol*Methanol are not significant. You decide to remove these effects from the model.

4. Select Methanol*Ethanol and Methanol*Methanol in the Effect Summary report and click **Remove**.

**Figure 7.11** Final Set of Active Effects

The remaining effects are all significant. You conclude that these are the active effects.
Comparison of a Definitive Screening Design with a Plackett-Burman Design

Plackett-Burman designs are an alternative to fractional factorials for screening. However, Plackett-Burman designs have complex aliasing of the main effects by two-factor interactions.

This example shows how to compare a definitive screening with a Plackett-Burman design using the Evaluate Design platform. For an extensive example using the Compare Designs platform, see “Designs of Same Run Size” on page 473 in the “Compare Designs” chapter.

The Definitive Screening Design

1. Select **DOE > Definitive Screening > Definitive Screening Design**.
2. Type **4** in the **Add N Factors** box and click **Continuous**.
3. Type **2** in the **Add N Factors** box and click **Categorical**.
   
   Your window should appear as shown in Figure 7.12.

Figure 7.12  Definitive Screening Dialog with 4 Continuous and 2 Categorical Factors

4. Click **Continue**.
   
   This example does not require a block. Under the Design Options Outline, check that the No Blocks Required option is selected.
   
   In order to compare designs of approximately equal sizes, do not add Extra Runs.
5. Next to **Number of Extra Runs**, select 0.
6. Click **Make Design**.
   The design that is generated has 14 runs.

7. Open the **Design Evaluation > Color Map On Correlations** outline.

**Figure 7.13** Color Map for Definitive Screening Design

Notice that the categorical main effects have small correlations with each other and with the continuous factors’ main effects. These correlations lead to a small reduction in the precision of the estimates.

8. Do not close your Definitive Design Screening window until you compare the color map with that of the Plackett-Burman design, below.

**The Plackett-Burman Design**

Now create a Plackett-Burman design using the same factor structure.

1. Select **DOE > Classical > Two Level Screening > Screening Design**.
2. Type 4 in the **Add N Factors** box and click **Continuous**.
3. Type 2 in the **Add N Factors** box and click **Categorical > 2 Level**.
4. Click **Continue**.
5. Select **Choose from a list of fractional factorial designs** and click **Continue**.
6. Select the 12 run Plackett-Burman design (Figure 7.14).
7. Click Continue.
   Compare the color map for the 12-run Plackett-Burman design to the color map for the 14-run definitive screening design.
Figure 7.15  Plackett-Burman Correlations (left) and Definitive Screening Correlations (right)

Figure 7.15 shows both color maps, but shows only the portion of the Plackett-Burman color map that involves main effects and two-way interactions. (To construct the color map for the Plackett-Burman design without the three-way interactions, construct the design. Then obtain the color map using Evaluate Design.)

In the color map for the Plackett-Burman design on the left, you see that most two-factor interactions are correlated with main effects. This means that any non-negligible two-factor interaction will bias several main effects. This can lead to a failure to identify an active main effect or the false conclusion that an inactive main effect is active.

Contrast this with the color map for the definitive screening design on the right. With only two additional runs, the definitive screening design trades off a small increase in the variance of the main effects for complete independence of main effects and two-factor interactions.

Definitive Screening Design Window

The definitive screening design window updates as you work through the design steps. See “The DOE Workflow: Describe, Specify, Design” on page 59 in the “Starting Out with DOE” chapter. The outlines, separated by buttons that update the outlines, follow the flow in Figure 7.16.
Figure 7.16 Definitive Screening Design Flow

Responses

Use the Responses outline to specify one or more responses.

Tip: When you have completed the Responses outline, consider selecting **Save Responses** from the red triangle menu. This option saves the response names, goals, limits, and importance values in a data table that you can later reload in DOE platforms.

Figure 7.17 Responses Outline

**Add Response**  Enters a single response with a goal type of Maximize, Match Target, Minimize, None, or Functional. If you select Match Target, enter limits for your target value. If you select Maximize or Minimize, entering limits is not required but can be useful if you intend to use desirability functions.

**Functional**  (Available only in JMP Pro.) Adds multiple Y columns with FDE column properties to the design data table. These columns can be used in the Functional Data Explorer platform with the DOE factors as supplementary factors.

**Remove**  Removes the selected responses.

**Number of Responses**  Enters additional responses so that the number that you enter is the total number of responses. If you have entered a response other than the default Y, the Goal for each of the additional responses is the Goal associated with the last response entered. Otherwise, the Goal defaults to Match Target. Click the Goal type in the table to change it.

The Responses outline contains the following columns:

**Response Name**  The name of the response. When added, a response is given a default name of Y, Y2, and so on. To change this name, double-click it and enter the desired name.

**Goal, Lower Limit, Upper Limit**  The Goal tells JMP whether you want to maximize your response, minimize your response, match a target, or that you have no response goal. JMP assigns a Response Limits column property, based on these specifications, to each
response column in the design table. It uses this information to define a desirability function for each response. The Profiler and Contour Profiler use these desirability functions to find optimal factor settings. For further details, see the Profiler chapter in Profilers and “Response Limits” on page 784 in the “Column Properties” appendix.

- A Goal of Maximize indicates that the best value is the largest possible. If there are natural lower or upper bounds, you can specify these as the Lower Limit or Upper Limit.

- A Goal of Minimize indicates that the best value is the smallest possible. If there are natural lower or upper bounds, you can specify these as the Lower Limit or Upper Limit.

- A Goal of Match Target indicates that the best value is a specific target value. The default target value is assumed to be midway between the Lower Limit and Upper Limit.

- A Goal of None indicates that there is no goal in terms of optimization. No desirability function is constructed.

Note: If your target response is not midway between the Lower Limit and the Upper Limit, you can change the target after you generate your design table. In the data table, open the Column Info window for the response column (Cols > Column Info) and enter the desired target value.

Importance When you have several responses, the Importance values that you specify are used to compute an overall desirability function. These values are treated as weights for the responses. If there is only one response, then specifying the Importance is unnecessary because it is set to 1 by default.

JMP PRO Detection Limits The lower and upper detection limits are bounds beyond which the response cannot be measured. The detection limits are saved as a column property. You can use these limits to specify a censored response in the Generalized Regression platform. See the Generalized Regression chapter in Fitting Linear Models.

Editing the Responses Outline
In the Responses outline, note the following:

- Double-click a response to edit the response name.
- Click the goal to change it.
- Click on a limit or importance weight to change it.
- For multiple responses, you might want to enter values for the importance weights.
Response Limits Column Property

The Goal, Lower Limit, Upper Limit, and Importance that you specify when you enter a response are used in finding optimal factor settings. For each response, the information is saved in the generated design data table as a Response Limits column property. JMP uses this information to define the desirability function. The desirability function is used in the Prediction Profiler to find optimal factor settings. For further details about the Response Limits column property and examples of its use, see “Response Limits” on page 784 in the “Column Properties” appendix.

If you do not specify a Lower Limit and Upper Limit, JMP uses the range of the observed data for the response to define the limits for the desirability function. Specifying the Lower Limit and Upper Limit gives you control over the specification of the desirability function. For more details about the construction of the desirability function, see the Profiler chapter in Profilers.

Factors

Add factors in the Factors outline.

**Figure 7.18  Factors Outline**

The factors outline contains the following buttons.

- **Continuous**  Enters the number of continuous factors specified in Add N Factors.
- **Categorical**  Enters the number of nominal factors specified in Add N Factors.
- **Remove**  Removes the selected factors.
- **Add N Factors**  Adds multiple factors of a given type. Enter the number of factors to add and click Continuous or Categorical. Repeat Add N Factors to add multiple factors of different types.

**Tip:** When you have completed your Factors panel, select Save Factors from the red triangle menu. This saves the factor names and values in a data table that you can later reload. See “Definitive Screening Design Options” on page 265.
The Factors outline contains the following columns:

**Name**  The name of the factor. When added, a factor is given a default name of X1, X2, and so on. To change this name, double-click it and enter the desired name.

**Role**  Specifies the Design Role of the factor. The Design Role column property for the factor is saved to the data table. This property ensures that the factor type is modeled appropriately.

**Values**  The experimental settings for the factors. To insert Values, click the default values and type the desired values.

**Editing the Factors Outline**

In the Factors outline, note the following:

- To edit a factor name, double-click the factor name.
- To edit a value, click the value in the Values column.

**Factor Types**

**Continuous**  Numeric data types only. A continuous factor is a factor that you can conceptually set to any value between the lower and upper limits you supply, given the limitations of your measurement system.

**Categorical**  Either numeric or character data types with two levels. For a categorical factor, the value ordering is the order of the values, as entered from left to right. This ordering is saved in the Value Order column property after the design data table is created.

**Factor Column Properties**

For each factor, various column properties are saved to the data table.

**Design Role**  Each factor is assigned the Design Role column property. The Role that you specify in defining the factor determines the value of its Design Role column property. When you add a block under Design Options, that factor is assigned the Blocking value. The Design Role property reflects how the factor is intended to be used in modeling the experimental data. Design Role values are used in the Augment Design platform.

**Factor Changes**  Each factor is assigned the Factor Changes column property with a setting of Easy. In definitive screening designs, it is assumed that factor levels can be changed for each experimental run. Factor Changes values are used in the Evaluate Design and Augment Design platforms.

**Coding**  If the Design Role is Continuous, the Coding column property for the factor is saved. This property transforms the factor values so that the low and high values correspond to –
1 and +1, respectively. The estimates and tests in the Fit Least Squares report are based on the transformed values.

**Value Order** If the Design Role is Categorical or Blocking, the Value Order column property for the factor is saved. This property determines the order in which levels of the factor appear.

**RunsPerBlock** Indicates the number of runs in each block. When a Block is selected in the Design Options outline and you then click Make Design, a factor with the default name Block is added to the Factors list. The RunsPerBlock column property is saved for that factor.

**Design Options**

The Design Options outline enables you to specify the blocking structure, the number of blocks, and the number of extra runs. Block effects are orthogonal to the main effects. Block sizes need not be equal.

The outline contains the following options:

**No Blocks Required** Indicates that the design will not contain a blocking factor. This is the default selection.

**Add Blocks with Center Runs to Estimate Quadratic Effects** Adds the number of blocks specified in the Number of Blocks text box. Constructs a design where block effects are orthogonal to main effects and where the model consisting of all main and quadratic effects is estimable. See “Add Blocks with Center Runs to Estimate Quadratic Effects” on page 261

**Add Blocks without Extra Center Runs** Adds the number of blocks specified in the Number of Blocks text box. Adds only as many center runs as required by the design structure. Constructs a design where block effects are orthogonal to main effects, but the model consisting of all main effects and quadratic effects might not be estimable. See “Add Blocks without Extra Center Runs” on page 262.

**Note:** Use the Add Blocks without Extra Center Runs option only if you can assume that not all quadratic effects are important.

**Number of Blocks** Indicates the number of blocks to add. The number of blocks that you can add ranges from two to the number of factors.

**Number of Extra Runs** Adds non-center runs that enable you to conduct effective model selection. See “Extra Runs” on page 271 and “Effective Model Selection for DSDs” on page 277 in the “The Fit Definitive Screening Platform” chapter.
Tip: Adding runs to your design with the Extra Runs option enhances your ability to detect effects in the presence of many active effects. The recommended number of Extra Runs is four, which dramatically improves the power of the design to identify active second-order effects.

Make Design  Generates the design, presents it in the Design outline, and provides evaluation information in the Design Evaluation outline. The Output Options panel also appears, enabling you to create the design table.

Blocking in Definitive Screening Designs

This section describes the two blocking options:

- “Add Blocks with Center Runs to Estimate Quadratic Effects” on page 261
- “Add Blocks without Extra Center Runs” on page 262

Add Blocks with Center Runs to Estimate Quadratic Effects

Note: For more information about the construction and properties of blocked designs that estimate quadratic effects, see Jones and Nachtsheim (2016). The paper also contains information about treating the blocks as random effects.

The Add Blocks with Center Runs to Estimate Quadratic Effects option constructs a design with these properties:

- Block effects are orthogonal to main effects.
- The model consisting of all main and quadratic effects is estimable.

If a design contains only continuous factors, a blocked design for \( k \) factors having these properties can be constructed:

- Remove the center run from the DSD design for \( k \) factors.
- Assign conference matrix foldover pairs to the same block.
- Add one center run to each block.

When some factors are categorical, the Add Blocks with Center Runs to Estimate Quadratic Effects option adds pairs of center runs within certain blocks. This structure ensures orthogonality and the ability to estimate all main and quadratic effects.

Because the only requirement on block size is that a block contains a foldover pair, the number of blocks can range from 2 to \( k \), if \( k \) is even and from 2 to \( k+1 \), if \( k \) is odd. See “Conference Matrices and the Number of Runs” on page 271. JMP attempts to construct blocks of equal size.
Add Blocks without Extra Center Runs

The **Add Blocks without Extra Center Runs** option constructs a design that has a single center run when all factors are continuous and two center runs when some factors are categorical. The resulting design has these properties:

- Block effects are orthogonal to main effects.
- Block effects might be confounded with a linear combination of quadratic effects. This implies that the model consisting of all main and quadratic effects might *not* be estimable.

For this reason, use this option only if you can assume that some quadratic effects are negligible.

Construct a blocked design for \( k \) factors without extra center runs:

- Assign conference matrix foldover pairs to the same block.
- If all factors are continuous, assign the single center run to a single block.
- If there are categorical factors, the unblocked definitive screening design requires the addition of two center runs to the foldover pairs defined by the conference matrix. See “Conference Matrices and the Number of Runs” on page 271. To construct the blocked design without extra center runs, these two center runs are added to a single block.

Because the only requirement on block size is that a block contains a foldover pair, the number of blocks can range from 2 to \( k \), if \( k \) is even and from 2 to \( k+1 \), if \( k \) is odd. See “Conference Matrices and the Number of Runs” on page 271. JMP attempts to construct blocks of equal size.

**Design**

The Design outline shows the runs for the definitive screening design. The runs are given in a standard order. To change the run order for your design table, you can select Run Order options in the Output Options panel before generating the table.

**Note:** Definitive screening designs for four or fewer factors are based on a five-factor design. See “Definitive Screening Designs for Four or Fewer Factors” on page 272.

**Design Evaluation**

**Note:** The Design Evaluation outline is not shown for Cotter designs.

The Design Evaluation outline provides a number of ways to evaluate the properties of the generated design. Open the Design Evaluation outline to see the following options:

- **Power Analysis** Enables you to explore your ability to detect effects of given sizes.
**Prediction Variance Profile**  Shows the prediction variance over the range of factor settings.

**Fraction of Design Space Plot**  Shows how much of the model prediction variance lies below (or above) a given value.

**Prediction Variance Surface**  Shows a surface plot of the prediction variance for any two continuous factors.

**Estimation Efficiency**  For each parameter, gives the fractional increase in the length of a confidence interval compared to that of an ideal (orthogonal) design, which might not exist. Also gives the relative standard error of the parameters.

**Alias Matrix**  Gives coefficients that indicate the degree by which the model parameters are biased by effects that are potentially active, but not in the model.

**Color Map on Correlations**  Shows the absolute correlation between effects on a plot using an intensity scale.

**Design Diagnostics**  Indicates the optimality criterion used to construct the design. Also gives efficiency measures for your design.

---

**Note:** The model used for the design diagnostics contains all main effects and two-factor interactions when all two-factor interactions are estimable. Otherwise, the model contains all main effects.

For more details about the Design Evaluation panel, see “Design Evaluation” on page 451 in the “Evaluate Designs” chapter.

### Output Options

Use the Output Options panel to perform the following tasks:

- specify the order for the runs in the design data table
- construct the design table
- return to a previous point in the Definitive Screening Design window

---

**Figure 7.19**  Output Options Panel

![Output Options Panel](image)

The Output Options panel contains these options:
Run Order

The Run Order options determine the order of the runs in the design table. Choices include the following:

- **Keep the Same**: Rows in the design table are in the same order as in the Design outline.
- **Sort Left to Right**: Columns in the design table are sorted from left to right.
- **Randomize**: Rows in the design table are in random order.
- **Sort Right to Left**: Columns in the design table are sorted from right to left.
- **Randomize within Blocks**: Rows in the design table are in random order within the blocks.

Make Table

Click Make Table to construct the Definitive Screening Design data table.

In the Definitive Screening Design table, the Table panel (in the upper left) contains the following scripts. To run a script, click the green triangle next to the script name.

- **Fit Definitive Screening**: Runs the DOE > Definitive Screening > Fit Definitive Screening platform. See Chapter 8, “The Fit Definitive Screening Platform”.

- **Evaluate Design**: Runs the DOE > Design Diagnostics > Evaluate Design platform. See Chapter 15, “Evaluate Designs”.

- **DOE Dialog**: Re-creates the Definitive Screening Design window that you used to generate the design table.
The Back button takes you back to where you were before clicking Make Design. You can make changes to the previous outlines and regenerate the design.

**Definitive Screening Design Options**

The red triangle menu in the Definitive Screening Design Design platform contains these options:

**Save Responses**  Saves the information in the Responses panel to a new data table. You can then quickly load the responses and their associated information into most DOE windows. This option is helpful if you anticipate reusing the responses.

**Load Responses**  Loads responses that you saved using the Save Responses option.

**Save Factors**  Saves the information in the Factors panel to a new data table. Each factor’s column contains its levels. Other information is stored as column properties. You can then quickly load the factors and their associated information into most DOE windows.
**Note:** It is possible to create a factors table by entering data into an empty table, but remember to assign each column an appropriate Design Role. Do this by right-clicking on the column name in the data grid and selecting **Column Properties > Design Role**. In the Design Role area, select the appropriate role.

**Load Factors**  Loads factors that you saved using the Save Factors option.

**Save Constraints**  (Unavailable for some platforms) Saves factor constraints that you defined in the Define Factor Constraints or Linear Constraints outline into a data table, with a column for each constraint. You can then quickly load the constraints into most DOE windows.

In the constraint table, the first rows contain the coefficients for each factor. The last row contains the inequality bound. Each constraint’s column contains a column property called **ConstraintState** that identifies the constraint as a “less than” or a “greater than” constraint. See “**ConstraintState**” on page 818 in the “Column Properties” appendix.

**Load Constraints**  (Unavailable for some platforms) Loads factor constraints that you saved using the Save Constraints option.

**Set Random Seed**  Sets the random seed that JMP uses to control actions that have a random component. These actions include one or more of the following:

- initializing search algorithms for design generation
- randomizing Run Order for design construction
- selecting a starting design for designs based on random starts

To reproduce a design, enter the random seed that generated the design before clicking **Make Design**.

**Note:** The random seed associated with a design is included in the DOE Dialog script that is saved to the design data table.

**Simulate Responses**  Adds response values and a column containing a simulation formula to the design table. Select this option before you click Make Table.

When you click Make Table, the following occur:

- A set of simulated response values is added to each response column.
- For each response, a new column that contains a simulation model formula is added to the design table. The formula and values are based on the model that is specified in the design window.
- A Model window appears where you can set the values of coefficients for model effects and specify one of three distributions: Normal, Binomial, or Poisson.
Note: Not all distributions are available for all design types.

A script called **DOE Simulate** is saved to the design table. This script reopens the Model window, enabling you to re-simulate values or to make changes to the simulated response distribution.

Make selections in the Model window to control the distribution of simulated response values. When you click Apply, a formula for the simulated response values is saved in a new column called \(<Y>\) Simulated, where \(Y\) is the name of the response. Clicking Apply again updates the formula and values in \(<Y>\) Simulated.

For additional details, see “Simulate Responses” on page 112 in the “Custom Designs” chapter.

**Note:** You can use Simulate Responses to conduct simulation analyses using the JMP Pro Simulate feature. For more information and DOE examples, see the Simulate chapter in *Basic Analysis*.

**Save X Matrix** Saves the Moments Matrix and Model Matrix to table scripts in the design data table. These scripts contain the moments and design matrices. See “**Save X Matrix**” on page 114 in the “Custom Designs” chapter.

**Caution:** For a design with nominal factors, the Model Matrix saved by the Save X Matrix option is *not* the coding matrix used in fitting the linear model. You can obtain the coding matrix used for fitting the model by selecting the option **Save Columns > Save Coding Table** in the Fit Model report that you obtain when you select run model from the definitive model fit.

**Save Script to Script Window** Creates the script for the design that you specified in the Definitive Screening Design window and saves it in an open script window.

**Simulate Responses**

When you click Make Table to create your design table, the Simulate Responses option does the following for each response:

- It adds random response values to the response column in your design table.
- It adds a new a column containing a simulation model formula to the design table. The formula and values are based on a main effects model.

A Model window opens where you can add and remove effects to define a model, specify parameter values, and select a response distribution for simulation. When you click Apply in the Model window, each column containing a simulation model formula is updated.
Control Window

Figure 7.21 shows the Model window for a design with two continuous factors (X1 and X2) and one two-level categorical factor (X3).

Figure 7.21  Simulate Responses Control Window

The window has three outlines:

- Factors
- Simulate Responses
- Distribution

The initial Simulate Responses outline shows terms for a main effects model with values of 1 for all coefficients. The Distribution outline shows a Normal distribution with error standard deviation equal to 1. If you have set Anticipated Coefficients as part of Power Analysis under Design Evaluation in the DOE window, then the initial values in the Simulate Responses outline are the values that you specified as Anticipated Coefficients and Anticipated RMSE (Error Std) in the Power Analysis outline.

Factors

Add terms to the simulation model using the Factors outline.

**Interactions**  Select factors in the list. Then select the interaction order from the Interactions menu. Those interactions are added to the list of Effects in the Simulate Responses outline.

**RSM**  Adds all possible response surface terms to the list of Effects in the Simulate Responses outline.
Powers  Select factors in the list. Then select the order from the Powers menu. Those powers are added to the list of Effects in the Simulate Responses outline.

Simulate Responses

To specify a model for simulated values, do the following:

1. For each term in the list of Effects, enter coefficients for the linear model used to simulate the response values. These define a linear function, \( L(x, \beta) = x'\beta \). See the Simulate Responses outline in Figure 7.21:
   - The vector \( x \) consists of the terms that define the effects listed under Effects.
   - The vector \( \beta \) is the vector of model coefficients that you specify under Y.

2. Under Distribution, select a response distribution.

3. Click Apply. A \( <Y> \) Simulated column containing simulated values and their formula is added to the design table, where \( Y \) is the name of the response column.

Reset coefficients  Sets all coefficients to 0.

Remove Term  Remove terms from the list of Effects. Select the effects to remove and click Remove Term. Note that you cannot remove main effects.

Distribution

Choose from one of the available distributions in the Simulate Responses window:

Normal  Simulates values from a normal distribution. Enter a value for Error \( \sigma \), the standard deviation of the normal error distribution. If you have designated factors to have Changes of Hard in the Factors outline, you can enter a value for Whole Plots \( \sigma \), the whole plot error. If you have designated factors to have Changes of Hard and Very Hard, you can enter values for both the subplot and whole plot errors. When you click Apply, random values and a formula containing a random response vector based on the model are entered in the column \( <Y> \) Simulated.

Binomial  Simulates values from a binomial distribution. Enter a value for \( N \), the number of trials. Random integer values are generated according to a binomial distribution based on \( N \) trials with probability of success \( 1/(1 + \exp(-L(x, \beta))) \). When you click Apply, random values and their formula are entered in the column \( <Y> \) Simulated. A column called N Trials that contains the value \( N \) is also added to the data table.

Poisson  Simulates random integer values according to a Poisson distribution with parameter \( \exp(L(x, \beta)) \). When you click Apply, random values and their formula are entered in the column \( <Y> \) Simulated.

Note: You can set a preference to simulate responses every time you click Make Table. To do so, select File > Preferences > Platforms > DOE. Select Simulate Responses.
Technical Details

- “Structure of Definitive Screening Designs”
- “Analysis of Experimental Data”

Structure of Definitive Screening Designs

Figure 7.22 shows an example of a definitive design with eight continuous factors and four Extra Runs that correspond to fake factors. Notice the following:

- Each pair of rows is a foldover pair; each even-numbered row is -1 times the previous row. The foldover aspect of the design removes the confounding of two-factor interactions and main effects.
- Each factor is set at its center value for three runs; this, together with the design’s construction, makes all quadratic effects estimable.
- Rows 17 through 20 are the Extra Runs that correspond to the fake factors.
- Adding the center run in the last row enables you to fit a model that includes an intercept and all main and quadratic effects.

This structure is typical of definitive screening designs for continuous factors.

Figure 7.22  Definitive Screening Design for Eight Continuous Factors

Conference Matrices and the Number of Runs

Definitive screening designs in JMP are constructed using conference matrices (Xiao et al., 2012). A conference matrix is an $m \times m$ matrix $C$ where $m$ is even. The matrix $C$ has 0s on the diagonal, off-diagonal entries equal to 1 or $-1$, and satisfies

$$C' C = (m-1)I_{mxm}.$$ 

Note: For certain even values of $m$, it is not known if a conference matrix exists.

Suppose that the number of factors, $k$, is five or larger. For the case of $k \leq 4$ factors, see “Definitive Screening Designs for Four or Fewer Factors” on page 272.

Consider the case of $k$ continuous factors and suppose that a conference matrix is available.

- When $k$ is even, the $k \times k$ conference matrix is used to define $k$ runs of the design. Its negative, $-C$, defines the foldover runs. A center point is added to the design to ensure that a model containing an intercept, main effects, and quadratic effects is estimable. So, for $k$ even, the minimum number of runs in the definitive screening design is $2k + 1$.

- When $k$ is odd, a $(k+1) \times (k+1)$ conference matrix is used, with its last column deleted. A center point is added. Thus, for $k$ odd, the minimum number of runs in the screening design is $2k + 3$.

A similar procedure is used when some factors are categorical and a conference matrix is available. See Jones and Nachtsheim (2013).

- Instead of a single center point, two additional runs are required. These two runs are center runs where all continuous factors are set at their middle values.

- When there are $k$ factors and $k$ is even, the number of runs in the design is $2k + 2$.

- When $k$ is odd, the number of runs is $2k + 4$.

For those values of $m$ for which a conference matrix is not available, a definitive screening design can be constructed using the next largest conference matrix. As a result, the required number of runs might exceed $2k + 3$, in the continuous case, and $2k + 4$, in the categorical case.

Extra Runs

Extra runs are constructed using fictitious, or fake, factors. Adding $f$ fake factors to a design results in $2^f$ additional runs.

Denote the number of factors in your experimental study by $k$. Four or eight extra runs can be added to a design. Extra runs are constructed by creating a design for $k + f$ factors, as described in “Conference Matrices and the Number of Runs” on page 271, and then dropping the last $f$ columns. As few as four extra runs can be highly beneficial in model selection.
For information about how extra runs are used, see “Effective Model Selection for DSDs” on page 277 in the “The Fit Definitive Screening Platform” chapter.

**Definitive Screening Designs for Four or Fewer Factors**

Definitive screening designs for four or fewer factors are constructed using the five-factor definitive screening design as a base. This is because designs for \( k \leq 4 \) factors constructed strictly according to the conference matrix approach have undesirable properties. In particular, it is difficult to separate second-order effects.

If you specify \( k \leq 4 \) factors, a definitive screening design for five factors is constructed and unnecessary columns are dropped. For this reason, the number of runs for an unblocked design with \( k \leq 4 \) factors is 13 if all factors are continuous or 14 if some factors are categorical.

**Analysis of Experimental Data**

In general, you want to fit a model that permits the possibility that two-way interactions are active. You also might want to include pure quadratic terms in your model. You might want to postulate a full second-order model, or you might want to specify an a priori model containing only certain second-order terms.

**Two-Way Interactions**

In fitting such a model, you need to be mindful of two facts:

- two-way interaction effects and quadratic effects are often correlated
- two-way interaction and quadratic effects cannot all be estimated simultaneously

Figure 7.23 shows a Color Map on Correlations for the design with eight continuous factors shown in Figure 7.22. The color map is for a full quadratic design. The eight pure quadratic effects are listed to the far right. You can construct this plot by using DOE > Design Diagnostics > Evaluate Design and entering the appropriate terms into the Alias Terms list. See “Alias Terms” on page 450 in the “Evaluate Designs” chapter.
Figure 7.23 Color Map on Correlations for Full Quadratic Model

Hover over the cells of the color map in order to see the absolute correlations between effects. You see that main effects are uncorrelated with all two-way interaction and pure quadratic effects. You also see that none of the effects are completely confounded with other effects because the only black cells are on the main diagonal. But note that some of the absolute correlations between two-factor interactions are substantial, with some at 0.75. Note also that absolute correlations between two-factor interactions and pure quadratic effects are either 0 or 0.3118.

If only main and pure quadratic effects are active, you can fit a saturated model that contains main effects and quadratic effects. This model will result in effect estimates that are unbiased, assuming no active three-way or higher order effects.

Because of the correlations involving second-order effects, you must be careful in fitting a model with two-way interactions. Analysis methodologies include the following, where the first is preferred:

- The method of Efficient Model Selection performs well, especially if many effects are likely to be active. See “Effective Model Selection for DSDs” on page 277 in the “The Fit Definitive Screening Platform” chapter.
- Forward stepwise or all possible subsets regression performs adequately if the following conditions hold:
  - The number of active effects is no more than half the number of runs.
There are at most two active two-way interactions or at most one active quadratic effect.

See “Forward Stepwise Regression or All Possible Subsets Regression” on page 274.

**Forward Stepwise Regression or All Possible Subsets Regression**

This method consists of first specifying a full response surface model. Then do one of the following:

- Use forward stepwise regression with the Stopping Rule set to Minimum AICc and the Rules set to Combine to ensure model heredity.
- Use All Possible Models regression, where you select the option that imposes the heredity restriction and use the AICc criterion for model selection.

You cannot fit the full response surface model because the number of runs is less than the number of parameters. So your analysis depends on the assumption of effect sparsity, where you assume that the number of active effects is less than the number of runs. This approach has some limitations:

- If the number of active effects exceeds half the number of runs, both stepwise and all possible models regression have difficulty finding the correct model.
- The power of tests to detect moderate quadratic effects is low. A quadratic effect must exceed three times the error standard deviation for the power to exceed 0.9.
- Because of effect confounding, several models might be equivalent. Additional runs will be necessary to resolve the confounding.
Use the Fit Definitive Screening platform to analyze definitive screening designs (DSDs) using a methodology called *Effective Model Selection for DSDs*. This methodology takes advantage of the unique structure of definitive screening designs.

Standard model selection methods applied to DSDs can fail to identify active effects. To identify active main effects and second-order effects, the Effective Model Selection for DSDs algorithm leverages the structure of DSDs.

**Figure 8.1** Fit Definitive Screening Results

| Term                  | Estimate | Std Error | t Ratio | Prob>|t| |

Overview of the Fit Definitive Screening Platform

The Fit Definitive Screening platform analyzes definitive screening designs (DSDs) using a methodology that takes advantage of their special structure. The methodology is called *Effective Model Selection for DSDs*. If you created your design in JMP, the design table contains a script called Fit Definitive Screening that automatically runs an analysis using the Effective Model Selection for DSDs methodology.

Identification of Active Effects in DSDs

DSDs are three-level designs that are valuable for identifying main effects and second-order effects in a single experiment. A minimum run-size DSD is capable of correctly identifying active terms with high probability if the number of active effects is less than about half the number of runs and if the effects sizes exceed twice the standard deviation.

However, by augmenting a minimum run-size DSD with four or more properly selected runs, you can identify substantially more effects with high probability. These runs are called *Extra Runs*, and correspond to fictitious inactive factors, called *fake factors*. For information about Extra Runs, see “Structure of Definitive Screening Designs” on page 270 in the “Definitive Screening Designs” chapter.

Extra Runs substantially increase the design’s ability to detect second-order effects. For this reason, Jones and Nachtsheim (2016) strongly encourage the inclusion of at least four Extra Runs.

Effective Model Selection for DSDs

When standard model selection methods are applied to DSDs, they can fail to identify active effects. See Errore et al. (2017). Also, standard selection methods do not leverage the structure of DSDs. The Fit Definitive Screening platform uses the Effective Model Selection for DSDs approach, which takes full advantage of the structure of the DSD.

Jones and Nachtsheim (2016) report on simulation studies using Effect Model Selection for DSDs as well as standard approaches. Denote by $c$ the sum of the number of factors and the number of fake factors in a DSD. In many situations, if the number of active main effects exceeds three, then up to $c/2$ active second-order effects can be reliably identified. Assuming strong effect heredity, if there are three or fewer active main effects, then all active second-order effects can be reliably identified. Reliable identification means that the ratio of the absolute value of the coefficient to the error standard deviation exceeds three and that the power to detect the effect exceeds 0.80.
The Fit Definitive Screening platform default settings assume strong effect heredity. Strong effect heredity means that the A*B interaction can only be considered for inclusion in the model if both A and B have been included. Strong effect heredity requires that all lower-order components of a model effect be included in the model. In identifying active second-order effects, the algorithm uses strong effect heredity and the results cited earlier about how many active second-order effects can be reliably identified.

In a DSD, main effects and second-order effects are orthogonal to each other. The Effective Model Selection for DSDs approach takes advantage of this fact. The linear space of the response is separated into the subspace spanned by the main effects and the orthogonal complement of this subspace. Miller and Sitter (2005) refer to the linear subspace spanned by the main effects as the odd space, because it contains all the information about odd effects: main effects, 3-factor effects, 5-factors effects, and so on. They refer to its orthogonal complement as the even space, because it contains all the information about even effects: the intercept, 2-factor effects, 4-factor effects, and so on.

Fit Definitive Screening follows this thinking. The subspace spanned by the main effects is the odd space. Its orthogonal complement, the even space, contains the second-order effects and the block variable, if one exists. For more information about the algorithm, see “The Effective Model Selection for DSDs Algorithm” on page 286 and Jones and Nachtsheim (2016).

Example of the Fit Definitive Screening Platform

The design in the sample data table Extraction 3 Data.jmp is a definitive screening design for six factors in two blocks. The Add Blocks with Center Runs to Estimate Quadratic Effects option was selected and 4 Extra Runs were added in the design generation. The resulting design has 18 runs. This design is used to explore the analysis of a definitive screening design.

- “Fit the Model”
- “Examine Results”
- “Reduce the Model”

Note: For an example of a design with continuous and categorical factors, open the sample data file Peanut Data.jmp and run the Fit Definitive Screening table script.

Fit the Model

1. Select Help > Sample Data Library and open Design Experiment/Extraction 3 Data.jmp.
2. Select DOE > Definitive Screening > Fit Definitive Screening.
3. Select Yield and click Y.
4. Select Lot through Time and click X.
5. Click OK.

The fit performs a two-stage analysis. For more information about the algorithm, see “Technical Details for the Fit Definitive Screening Platform” on page 286.

Examine Results

Stage 1: Main Effect Estimates

Stage 1 determines which main effects are likely to be active.

Figure 8.2  Stage 1 Report for Main Effects

Note: The fake factors do not appear in the design or as factors in the analysis.

A two-degree-of-freedom error sum of squares is computed from the four runs corresponding to the two fake factors. Because the fake factors are, by construction, inactive, this estimate of error variance is unbiased. For each main effect, the main effects response $Y_{ME}$ is tested against this estimate. In this example, three factors, Methanol, Ethanol, and Time, have $p$-values smaller than the threshold value and are retained as active. For more information about the threshold values, see “Stage 1 Methodology” on page 287.

The variability from the three inactive factors, Propanol, Butanol, and pH, is pooled with the fake factor sum of squares to produce the five-degree-of-freedom RMSE statistic shown in Figure 8.2.

Stage 2: Even Order Effect Estimates

Stage 2 uses guided subset selection to arrive at a list of second-order effects that are likely to be active. Interactions and quadratic terms are second-order or even order effects.
Because three main effects are identified as active in Stage 1, the guided subset selection procedure for active second-order effects can continue until all second-order effects are included. Because all six second-order effects are reported in Stage 2, it follows that the Stage 2 RMSE remained larger than the Stage 1 RMSE. See “Stage 2 Methodology” on page 288.

The two-degree-of-freedom RMSE given in the Stage 2 report is the error estimate obtained from the final subset of all six second-order effects.

**Combined Results**

The effects selected for the model are listed in the Combined Model Parameter Estimates report.

**Figure 8.4 Combined Model Parameter Estimates Report**

The RMSE and degrees of freedom given at the bottom of the report are the usual standard least squares quantities. Use these effects as potential factors for your final model.

**Reduce the Model**

The Make Model button enters the model for the listed terms in a Fit Model specification window. To run the model directly using standard least squares, click the Run Model button.

1. Click **Run Model**.
The Actual by Predicted Plot shows no lack of fit. The Effect Summary report suggests that you can reduce the model further.

**Figure 8.5** Actual by Predicted Plot and Effect Summary Report

2. Select Methanol*Ethanol in the Effect Summary report and click **Remove**.
   Methanol*Time has $p$-value 0.33750. Remove it next.

3. Select Methanol*Time in the Effect Summary report and click **Remove**.
   Ethanol*Ethanol has $p$-value 0.15885. Remove it next.

4. Select Ethanol*Ethanol in the Effect Summary report and click **Remove**.

**Figure 8.6** Effect Summary Report Showing Effects in Final Model

The remaining effects are significant. You conclude that these are the active effects.
Launch the Fit Definitive Screening Platform

To launch the Fit Definitive Screening platform, select **DOE > Definitive Screening > Fit Definitive Screening**. The launch window in Figure 8.7 uses Extraction3 Data.jmp.

**Note:** If you created your design in JMP, the design table contains a script called Fit Definitive Screening. Run this script to run the analysis directly.

![Figure 8.7 Fit Definitive Screening Launch Window](image)

**Y** One or more numeric response variables.

**X** Continuous or two-level categorical factors. Because the platform uses the unique features of a DSD in performing the analysis, these factors must define a DSD or a fold-over design.

**By** A column whose levels define separate analyses. For each level of the specified column, the corresponding rows are analyzed. The results appear in separate reports. If more than one By variable is assigned, a separate analysis is produced for each possible combination of the levels of the By variables.

For more information about the options in the Select Columns red triangle menu, see *Using JMP*.

Fit Definitive Screening Report

- “Stage 1 - Main Effect Estimates”
- “Stage 2 - Even Order Effect Estimates”
- “Combined Model Parameter Estimates”
- “Main Effects Residual Plots”
- “Prediction Profiler”
Stage 1 - Main Effect Estimates

The Main Effect Estimates report lists main effects that are identified as active. Main effects with $p$-values less than the threshold $p$-value are considered active.

- If fake factors or center point replicates are available, an estimator of error variance that is independent of the model is constructed. The main effects are tested against this estimate.
- If no fake factors or center point replicates are available, subsets of main effects are tested sequentially against an estimate of error variance constructed from the inactive main effects. For this procedure to be viable, at least one of the main effects must be inactive.

In either case, variability from the inactive main effects is pooled into the error variance used to test the main effects.

Figure 8.8 Stage 1 Report

| Term   | Estimate | Std Error | t Ratio | Prob>|t| |
|--------|----------|-----------|---------|-------|
| Methanol | 9.7133  | 0.3674    | 26.438  | <.0001* |
| Ethanol | 2.3166  | 0.3674    | 6.3055  | 0.0015* |
| Time    | 4.0796  | 0.3674    | 11.104  | 0.0001* |

RMSE 1.3747
DF 5

- **Term**  Main effects identified as active. These effects have $p$-values less than the threshold when tested as described in “Stage 1 Methodology” on page 287.
- **Estimate**  Parameter estimate for a regression fit of Y on the main effects.
- **Std Error**  The standard error of the estimate, computed using the Stage 1 RMSE.
- **t Ratio**  The Estimate divided by its Std Error.
- **Prob>|t|**  The $p$-value computed using the t Ratio and the degrees of freedom for error (DF).
- **RMSE**  The square root of the mean square error that results from the Stage 1 analysis.
  - If fake factors or centerpoint replicates are available, the mean square error is the estimate of variance from fake factors and centerpoints pooled with the variance estimate constructed from the main effects that are not identified as active.
  - If no fake factors or centerpoint replicates are available, the mean square error is the estimate of variance constructed from the main effects that are not identified as active.
- **DF**  The degrees of freedom associated with the error estimate used to construct RMSE.
  - If fake factors or centerpoint replicates are available, DF is the sum of the number of fake factors, centerpoint replicates, and main effects not identified as active.
– If no fake factors or centerpoint replicates are available, DF is the number of main effects that are not identified as active.

**Quadratic Terms Obey Strong Heredity**  Check or uncheck to control heredity rules applied to quadratic terms in Stage 2.

**Interactions Obey Strong Heredity**  Check or uncheck to control heredity rules applied to interactions in Stage 2.

**Note:** Strong effect heredity means that the A*B interaction can only be considered for inclusion in the model if both A and B have been included. Strong effect heredity requires that all lower-order components of a model effect be included in the model.

### Stage 2 - Even Order Effect Estimates

The Even Order Effect Estimates report lists second-order effects that are identified as active. Active second-order effects are identified using the guided variable selection procedure or forward selection as described in “Stage 2 Methodology” on page 288. The block effect (if one is included) is also listed, whether it is significant or not.

**Figure 8.9 Stage 2 Report**

| Term         | Estimate | Std Error | t Ratio | Prob>|t| |
|--------------|----------|-----------|---------|----------|
| Intercept    | 34.568   | 1.3459    | 25.683  | 0.0015*  |
| Log[1]       | 17.197   | 0.7757    | 22.171  | 0.0002*  |
| Methanol*Ethanol | -0.367 | 0.7127    | -0.515  | 0.6581   |
| Methanol*Time | 0.5266   | 0.7127    | 0.7393  | 0.5369   |
| Ethanol*Time  | 9.8258   | 0.8534    | 11.514  | 0.0075*  |
| Methanol*Methanol | 7.837 | 1.4914    | 5.1208  | 0.0361*  |
| Ethanol*Ethanol | -1.449 | 1.417    | -1.0081 | 0.4499   |
| Time*Time    | -3.297   | 1.477    | -2.239  | 0.1392   |

**Term**  The block factor and second-order effects identified as active.

**Estimate**  Parameter estimates for a regression fit of Y on the Stage 2 second-order effects defined by $Y_{2nd}$. See “Decomposition of Response” on page 286.

**Std Error**  The standard error of the estimate, computed using the Stage 2 RMSE.

**t Ratio**  The Estimate divided by its Std Error.

**Prob>|t|**  The $p$-value computed using the t Ratio and the degrees of freedom for error (DF).

**RMSE**  The square root of the mean square error that results from the Stage 2 analysis. RMSE is estimated as the residual variance from $Y_{2nd}$ after fitting the second order effects identified as active. See “Decomposition of Response” on page 286.
**DF**  The degrees of freedom associated with the error estimate used to construct RMSE.

### Combined Model Parameter Estimates

The Combined Model Parameter Estimates report lists the terms in the final model and their usual standard least squares estimates, standard errors, t ratios, \( p \)-values, RMSE, and model degrees of freedom.

Below the report are buttons that construct or run the combined model.

**Figure 8.10  Combined Model Parameter Estimates Report**

| Term            | Estimate | Std Error | t Ratio | Prob>|t| |
|-----------------|----------|-----------|---------|------|---|
| Intercept       | 34.568   | 1.0452    | 33.074  | < .0001* |
| Lot[1]          | 17.197   | 0.6023    | 28.552  | < .0001* |
| Methanol        | 9.7133   | 0.4281    | 22.691  | < .0001* |
| Ethanol         | 2.3166   | 0.4281    | 5.4118  | 0.0001* |
| Time            | 4.0798   | 0.4281    | 9.5307  | < .0001* |

**Make Model**  Creates a model for the Fit Model window containing the model terms in the Combined Model Parameter Estimates report and the response specified for the Fit Definitive Screening analysis. The Standard Least Squares personality is specified.

**Run Model**  Runs a standard least squares fit for the model terms in the Combined Model Parameter Estimates report and the response specified for the Fit Definitive Screening analysis.

### Main Effects Residual Plots

Shows a plot of the residuals from a main effects model fit to all other factors versus the levels of the plotted factor. A factor with residuals that differ across levels indicates an important main effect.

**Note:** There is not a plot for a block factor.
Prediction Profiler

Shows a prediction profiler for the combined model. For more information about the prediction profiler, see Profilers.

Fit Definitive Screening Platform Options

**Set Stage 1 p value**  
Set the $p$-value threshold used for Stage 1. See “Stage 1 Methodology” on page 287.

**Set Stage 2 ratio**  
Specify the ratio of the Stage 2 MSE to the Stage 1 MSE. See “Stage 2 Methodology” on page 288.

See Using JMP for more information about the following options:

**Local Data Filter**  
Shows or hides the local data filter that enables you to filter the data used in a specific report.

**Redo**  
Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

**Save Script**  
Contains options that enable you to save a script that reproduces the report to several destinations.

Technical Details for the Fit Definitive Screening Platform

The Effective Model Selection for DSDs Algorithm

This section provides a summary of the algorithm used in the Fit Definitive Screening platform. See Jones and Nachtsheim (2016).

Decomposition of Response

The Effective Model Selection algorithm expresses the response, $Y$, in terms of two responses $Y_{ME}$ and $Y_{2nd}$, so that $Y = Y_{ME} + Y_{2nd}$.

- $Y_{ME}$ is the predicted value obtained from a regression of $Y$ on the main effects and fake factors.
There is no need to include the block factor in $Y_{ME}$ because of the fold-over structure of the design. The block factor is included in $Y_{2nd}$.

- $Y_{2nd}$ is given by $Y_{2nd} = Y - Y_{ME}$.

**Note:** In a DSD, the columns $Y_{ME}$ and $Y_{2nd}$ are orthogonal.

The analysis proceeds in two stages:

- **Stage 1:** The response $Y_{ME}$ is used to identify main effects. Stage 1 identifies the main effects that are considered active.

- **Stage 2:** The response $Y_{2nd}$ is used to identify second-order effects. Stage 2 considers all second-order terms in the active main effects from Stage 1 and determines a subset of these containing effects considered to be active.

  **Note:** If there is a blocking factor, it is included in the Stage 2 list of effects even if it is not significant.

**Stage 1 Methodology**

The Stage 1 methodology depends on whether the design contains fake factors or centerpoint replicates.

**Case 1: Fake Factors or Centerpoint Replicates Available**

1. Using the fake factors or center point replicates, an estimator of error variance that is independent of the model is constructed. Assuming that there are no active third or higher odd order effects, this estimate is unbiased.

2. Using $Y_{ME}$, main effects are tested against this estimate. Main effects with $p$-values less than a threshold $p$-value are considered active. The threshold values are the following:
   - For one error degree of freedom, the threshold value is 0.20.
   - For two error degrees of freedom, the threshold value is 0.10.
   - For more than two error degrees of freedom, the threshold value is 0.05.
   - User specified $p$-value is the threshold.

   **Note:** To specify a different $p$-value threshold select **Set Stage 1 p value** from the Fit Definitive Screening red triangle menu.

3. If no main effect has a $p$-value less than the threshold value, conclude that there are no active main effects and no active two-factor effects. The procedure terminates.

4. If active main effects are found, then variability from the inactive main effects is pooled into the error variance constructed in (1).
**Note:** If Categorical factors are in the design, the estimated coefficients are recalculated each time a main effect is chosen as active.

### Case 2: No Fake Factors or Centerpoint Replicates Available

In this case, there is no model-independent estimator of error variance available. Subsets of main effects are tested sequentially against an estimate of error variance constructed from the inactive main effects. Suppose that there are \( m \) main effects.

1. The absolute values of the estimated effects, using \( Y_{ME} \) as the response, are ordered from largest to smallest.
2. For each \( 1 \leq i < m \), the effect with the \( i \)th largest absolute value is tested against the adjusted residual sum of squares for the model containing that effect and all effects with larger absolute values.
3. The effects in the model with the smallest \( p \)-value are considered to be the active effects.
4. If active main effects are found, then variability from the inactive main effects is used to construct an estimate of error variance, using \( Y_{ME} \) as the response.

**Note:** For the Fit Definitive Screening procedure to work properly in Case 2, at least one of the main effects must be active and at least one must be inactive. If no main effects are active, or if all main effects are active, the procedure will identify a set of main effects, but the procedure for arriving at that subset is compromised.

### Stage 2 Methodology

In Stage 2, the factors considered depend on the Strong Heredity options. When strong heredity is selected, only second-order effects involving the factors whose main effects are identified as active in Stage 1 are considered. The Stage 2 methodology depends on the number of active main effects identified in Stage 1.

#### Case 1: Seven or Fewer Active Main Effects

Stage 2 uses a guided subset selection procedure. The goal is to continue to add second-order effects to the model as long as the ratio of the RMSE from Stage 2 to the RMSE from Stage 1 is greater than the specified threshold. When the ratio is less than or equal to the threshold, this indicates that there are no additional second-order effects to add to the model. The default threshold is 1. Smaller thresholds increases the number of terms likely to identified as active as compared to larger thresholds.

**Note:** To specify a RMSE ratio threshold other than one, select Set Stage 2 ratio from the Fit Definitive Screening red triangle menu.
For Stage 2:

- For one error degree of freedom, the threshold value is 0.20.
- For two error degrees of freedom, the threshold value is 0.10.
- For more than two error degrees of freedom, the threshold value is 0.05.
- User specified p-value is the threshold.

1. The variability for $Y_{2nd}$ is tested against the error estimate from Stage 1 to determine if there is additional variability due to second-order effects.
   - If the p-value for this test exceeds the threshold value the procedure terminates and no active second-order effects are identified.

2. If the p-value for this test is less than or equal to the threshold value, then subsets of size $k$, $k = 1,2,3,...$ are successively tested, starting with $k = 1$.

3. For each $k$, the residual sum of squares for each subset of that size is tested against the error estimate from Stage 1. The subset with the smallest RMSE is identified.

4. The procedure continues until a $k$ is found with a ratio of RMSE to the Stage 1 RMSE smaller than the Stage 2 ratio.

5. The effects in the subset preceding the one that corresponds to the terminal value of $k$ are considered to be the active two-factor effects.

**Case 2: Eight or More Active Main Effects**

Stage 2 uses forward selection for second order terms when eight or more active main effects are identified in Stage 1.
Screening designs are among the most popular designs for industrial experimentation. Typically used in the initial stages of experimentation, they examine many factors in order to identify those factors that have the greatest effect on the response. The factors that are identified are then studied using more sensitive designs. Because screening designs generally require fewer experimental runs than other designs, they are a relatively inexpensive and efficient way to begin improving a process.

If a standard screening design exists for your experimental situation, you can choose from several standard screening designs. The list includes blocked designs when applicable. Your factors can be two-level continuous factors, three-level categorical factors, or continuous factors that can assume only discrete values (discrete numeric factors).

However, there are situations where standard screening designs are not available. In these cases, the Screening Design platform constructs a main effects screening design. A main effects screening design is either orthogonal or near orthogonal. It focuses on estimating main effects in the presence of negligible interactions.

Note that JMP also provides two compelling alternatives to screening designs:

- Definitive screening designs are particularly useful if you suspect active two-factor interactions or if you suspect that a plot of a continuous factor’s effect on the response might exhibit strong curvature. See Chapter 7, “Definitive Screening Designs”.
- Custom designs are highly flexible and often more cost-effective than a design obtained using alternative methods. See Chapter 4, “Custom Designs”.

Overview of Screening Designs

Screening experiments tend to be small and are aimed at identifying the factors that affect a response. Because identification is the goal (rather than sophisticated modeling), continuous factors in a screening design are typically set at only two levels. However, a screening situation might also involve discrete numeric or categorical factors, in which case classical screening designs might not fit your situation. The Screening Design platform can handle all three types of factors: two-level continuous factors, categorical factors, and discrete numeric factors.

There are two types of designs:

- Classical designs: For situations where standard screening designs exist, you can choose from a list that includes fractional factorial designs, Plackett-Burman, Cotter, and mixed-level designs.
- Main effects screening designs: Whether a standard design is available, you can ask JMP to construct a main effects screening design. These designs are orthogonal or near orthogonal and focus on estimating main effects in the presence of negligible interactions. See “Main Effects Screening Designs” on page 318.

Underlying Principles

The emphasis on studying main effects early on in the experimentation process is supported by the empirical principle of effect hierarchy. This principle maintains that lower order effects are more likely to be important than higher order effects. For this reason, screening designs focus on identifying active main effects. In cases where higher order interactions are of interest, screening designs assume that two-factor interactions are more important than three-factor interactions, and so on. See “Effect Hierarchy” on page 64 in the “Starting Out with DOE” chapter and Wu and Hamada (2009).

The efficiency of screening designs also depends on the principle of effect sparsity. Effect sparsity asserts that most of the variation in the response is explained by a relatively small number of effects. See “Effect Sparsity” on page 65 in the “Starting Out with DOE” chapter.

To appreciate the importance of effect sparsity, consider an example where you have seven two-level factors. Contrast a full factorial design to a screening design:

- A full factorial design consists of all combinations of the levels of the factors. The number of runs is the product of the numbers of levels for each factor. In this example, a full factorial design has $2^7 = 128$ runs.
- In contrast, a screening design requires only a fraction of the runs in the full factorial design. The main effects of the seven factors can be studied in an eight-run screening design.
Analysis of Screening Design Results

Screening designs are often used to test a large number of factors or interactions. When there are degrees of freedom for error, allowing construction of an error estimate, the experimental results can be analyzed using the usual regression techniques (Analyze > Fit Model).

However, sometimes there are no degrees of freedom for error. In this case, assuming effect sparsity, the Screening platform (DOE > Classical > Two Level Screening > Fit Two Level Screening) provides a way to analyze the results of a two-level design. The Screening platform accepts multiple responses and multiple factors. It automatically shows significant effects with plots and statistics. See “The Fit Two Level Screening Platform” chapter on page 337. For an examples in the current chapter, see “Modify Generating Rules in a Fractional Factorial Design” on page 326 and “Plackett-Burman Design” on page 331.

Examples of Screening Designs

- “Compare a Fractional Factorial Design and a Main Effects Screening Design”
- “Main Effects Screening Design where No Standard Design Exists”

Compare a Fractional Factorial Design and a Main Effects Screening Design

In this example, suppose an engineer wants to investigate a process that uses an electron beam welding machine to join two parts. The engineer fits the two parts into a welding fixture that holds them snugly together. A voltage applied to a beam generator creates a stream of electrons that heats the two parts, causing them to fuse. The ideal depth of the fused region is 0.17 inches. The engineer wants to study the welding process to determine the best settings for the beam generator to produce the desired depth in the fused region.

For this study, the engineer wants to explore the following seven factors:

- Operator is the technician operating the welding machine. Two technicians typically operate the machine.
- Speed (in rpm) is the speed at which the part rotates under the beam.
- Current (in amps) is a current that affects the intensity of the beam.
- Mode is the welding method used.
- Wall Size (in mm) is the thickness of the part wall.
- Geometry indicates whether the joint is a single-bevel joint or a double-bevel joint.
- Material is the type of material being welded.
Notice that three of these factors are continuous: Speed, Current, and Wall Size. Four are categorical: Operator, Mode, Geometry, and Material. Each of these categorical factors has two levels.

After each processing run, the engineer cuts the part in half. This reveals an area where the two parts have fused. The length of this fused area, measured in inches, is the depth of penetration of the weld. The depth of penetration is the response for the study.

The goals of the study are the following:

- Find which factors affect the depth of the weld.
- Quantify those effects.
- Find specific factor settings that predict a weld depth of 0.17 inches with a tolerance of ±0.05 inches.

Your experimental budget allows you at most 12 runs. Construct and compare two designs for your experimental situation. The first is a classical fractional factorial design using eight runs. The second is a main effects screening design using 12 runs.

**Constructing a Standard Screening Design**

In this section, construct a standard screening design for this experimental situation.

**Specify the Response**

1. Select **DOE > Classical > Two Level Screening > Screening Design**.
2. In the Responses panel, double-click **Y** under Response Name and type **Depth**.
   
   Note that the default Goal is Maximize. Your goal is to find factor settings that enable you to obtain a target depth of 0.17 inches with limits of 0.12 and 0.22.
3. Click the default Goal of Maximize and change it to **Match Target**.
4. Click under **Lower Limit** and type 0.12.
5. Click under **Upper Limit** and type 0.22.
6. Leave the area under **Importance** blank.
   
   Because there is only one response, that response is given Importance 1 by default.

The completed Responses outline appears in Figure 9.2. Now, specify the factors.

**Specify Factors**

You can enter the factors manually or automatically:

- To enter the factors manually, see “Specify Factors Manually” on page 296.
- To enter the factors automatically, use the Weld Factors.jmp data table:
1. Select **Help > Sample Data Library** and open Design Experiment/Weld Factors.jmp.

2. Click the Screening Design red triangle and select **Load Factors**. Proceed to “Choose a Design” on page 297.

**Specify Factors Manually**

1. Type **3** in the **Add N Factors** box and click **Continuous**.

2. Double-click X1 and type **Speed**.

3. Use the Tab key to move through the rest of the values and factors. Make the following changes:
   a. Change the **Speed** values to 3 and 5.
   b. Change X2 to **Current**, with values of 150 and 165.
   c. Change X3 to **Wall Size**, with values of 20 and 30.

4. Type **4** in the **Add N Factors** box and select **Categorical > 2 Level**.

5. Double-click X4 and type **Operator**.

6. Use the Tab key to move through the rest of the values and factors. Make the following changes:
   a. Change the **Operator** values to John and Mary.
   b. Change X5 to **Mode**, with values of Conductance and Keyhole.
   c. Change X6 to **Geometry**, with values of Double and Single.
   d. Change X7 to **Material**, with values of Aluminum and Magnesium.
Choose a Design

1. Click Continue.

Because the combination of factors and levels that you have specified can be accommodated by a standard fractional factorial design, the Choose Screening Type panel appears. You can either select a standard design from a list or construct a main effects design.

**Note:** Setting the Random Seed in the next step reproduces the results shown in this example. When you are constructing a design on your own, this step is not necessary.

2. (Optional) Click the Screening Design red triangle, select **Set Random Seed**, type 12345, and click OK.

3. Accept the default selection to **Choose from a list of fractional factorial designs** and click Continue.

4. Select the first Fractional Factorial design.
This specifies an eight-run Resolution 3 fractional factorial design. For information about resolution, see “Resolution as a Measure of Confounding” on page 314.

5. Click **Continue**.

In the Output Options outline, note that **Run Order** is set to **Randomize**. This means that the design runs will appear in random order. This is the order you should use to conduct your experimental runs.
6. Open the Aliasing of Effects outline under Display and Modify Design.

Recall that you selected a Resolution 3 design (Figure 9.3). In a Resolution 3 design, some main effects are confounded with two-way interactions. The Aliasing of Effects outline indicates that, for this Resolution 3 design, every main effect is completely confounded with three two-way interactions. If you suspect that two-way interactions are active, this is a poor design. For a description of confounding, see “Two-Level Regular Fractional Factorial” on page 312.

7. Click Make Table.

Notice the following:
- The table uses the names for the responses, factors, and levels that you specified.
- The Pattern column shows the assignment of high and low settings for the design runs.
- This fractional factorial design is a Resolution 3 design. It enables you to study the main effects of seven factors in eight runs.

Constructing a Main Effects Screening Design

Main effects screening designs are orthogonal or near orthogonal designs. In this section, construct a main effects screening design for your seven factors.

1. Open your Screening Design window. If you have closed it, then run the DOE Dialog script in the Design Data table.
2. Click Back.
3. Click Continue.

**Note:** Setting the Random Seed and the Number of Starts in the next two steps reproduces the exact results shown in this example. When constructing a design on your own, these steps are not necessary.

4. (Optional) Click the Screening Design red triangle, select Set Random Seed, type 12345, and click OK.
5. (Optional) Click the Screening Design red triangle, select Number of Starts, type 50, and click OK.
6. In the Choose Screening Type panel, select the Construct a main effects screening design option.
7. Click Continue.

Under Number of Runs, the selected option is Default with the number of runs set to 12. Keep this setting.
8. Click Make Design.

9. Open the Design Evaluation outline and then open the Color Map on Correlations outline.

Figure 9.8 Color Map on Correlations for 12-Run Main Effects Screening Design

The Color Map on Correlations shows that the main effects are uncorrelated with each other. This is indicated by the white off-diagonal cells in the upper left corner of the color map. Each main effect is partially aliased with some two-way interactions, indicated by the gray cells. Hover over one of the gray cells to see that the absolute correlations are 0.333.

In this case, the 12-run main effects screening design is a Plackett-Burman design, which you could have obtained in the Design List. However, in many design situations, the partial aliasing that occurs in a main effects design is preferable to the complete...
confounding that occurs in a fractional factorial design that you adapt to your experimental situation.

The next section shows an example of a situation where no standard design exists. In this case, JMP constructs a main effects screening design.

**Main Effects Screening Design where No Standard Design Exists**

Main effects screening designs are orthogonal or near orthogonal designs for the main effects. You can use them in place of standard designs and in situations where standard designs do not exist. Main effects screening designs are excellent for estimating main effects when interactions are negligible.

In this experimental situation, no standard design exists. You need a design to study 13 factors: 2 are categorical, one with 4 levels and one with 6 levels, and 11 are continuous.

1. Select **DOE > Classical > Two Level Screening > Screening Design.**
   - In the Responses panel, there is a single default response called Y. Keep this as the default response.
2. In the Factors panel, click **Categorical** and select **4 Level**.
   - This adds the variable X1 with levels L1 through L4.
3. Click **Categorical** and select **6 Level**.
   - This adds the variable X2, with levels L1 through L6.
4. Enter 11 next to **Add N Factors**.
5. Click **Continuous**.
   - This adds 11 factors, X3 to X13, each at two levels, -1 and 1.
6. Click **Continue**.
   - The Design Generation panel appears.
   - There is no option to select a design from the Design List since there are no available standard designs in this situation.
   - Keep the default number of runs, which is 24.
Figure 9.9 Screening Design Window for 13-Factor Design with Design Generation Panel

7. Click **Make Design**.

A Design and a Design Evaluation outline appear.

8. Open the Design outline to see the randomized design.

   **Note:** The algorithm that generates the design uses a random starting design. To reproduce this design, save the script with the random seed by selecting **Save Script to Script Window** from the red triangle menu next to the report title.

Next, examine the Color Map on Correlations to see that this specific design is orthogonal.

9. Open the **Design Evaluation > Color Map on Correlations** outline.

The color map (Figure 9.10) shows black entries (using JMP default colors) on the main diagonal, indicating correlations of one. This is because each diagonal cell corresponds to the correlation of a term with itself, which is one. Off-diagonal correlations are all white, indicating that correlations between distinct terms are zero. Hover over any cell to see the relevant terms and their absolute correlation.
10. Click **Make Table** to construct the design table.

   The table contains the runs for your experiment in random order. Conduct the experiment in this randomized order and insert the results in column Y. Run the **Model** script in the data table to analyze your results.

---

**Screening Design Window**

The Screening Design window updates as you work through the design steps. See “The DOE Workflow: Describe, Specify, Design” on page 59. The outlines that appear are separated by buttons that update the window. These follow the flow in the figures below.
**Figure 9.11** Screening Design Flow when a Standard Design Exists

**Figure 9.12** Screening Design Flow when No Standard Design Exists

**Responses**

Use the Responses outline to specify one or more responses.
Tip: When you have completed the Responses outline, consider selecting **Save Responses** from the red triangle menu. This option saves the response names, goals, limits, and importance values in a data table that you can later reload in DOE platforms.

Figure 9.13 Responses Outline

<table>

</tbody>
</table>

Add Response  Enters a single response with a goal type of Maximize, Match Target, Minimize, None, or Functional. If you select Match Target, enter limits for your target value. If you select Maximize or Minimize, entering limits is not required but can be useful if you intend to use desirability functions.

**Functional**  (Available only in JMP Pro.) Adds multiple Y columns with FDE column properties to the design data table. These columns can be used in the Functional Data Explorer platform with the DOE factors as supplementary factors.

Remove  Removes the selected responses.

Number of Responses  Enters additional responses so that the number that you enter is the total number of responses. If you have entered a response other than the default Y, the Goal for each of the additional responses is the Goal associated with the last response entered. Otherwise, the Goal defaults to Match Target. Click the Goal type in the table to change it.

The Responses outline contains the following columns:

**Response Name**  The name of the response. When added, a response is given a default name of Y, Y2, and so on. To change this name, double-click it and enter the desired name.

**Goal, Lower Limit, Upper Limit**  The Goal tells JMP whether you want to maximize your response, minimize your response, match a target, or that you have no response goal. JMP assigns a Response Limits column property, based on these specifications, to each response column in the design table. It uses this information to define a desirability function for each response. The Profiler and Contour Profiler use these desirability functions to find optimal factor settings. For further details, see the Profiler chapter in Profilers and “Response Limits” on page 784 in the “Column Properties” appendix.

-  A Goal of Maximize indicates that the best value is the largest possible. If there are natural lower or upper bounds, you can specify these as the Lower Limit or Upper Limit.
– A Goal of Minimize indicates that the best value is the smallest possible. If there are natural lower or upper bounds, you can specify these as the Lower Limit or Upper Limit.

– A Goal of Match Target indicates that the best value is a specific target value. The default target value is assumed to be midway between the Lower Limit and Upper Limit.

– A Goal of None indicates that there is no goal in terms of optimization. No desirability function is constructed.

**Note:** If your target response is not midway between the Lower Limit and the Upper Limit, you can change the target after you generate your design table. In the data table, open the Column Info window for the response column (**Cols > Column Info**) and enter the desired target value.

**Importance**  
When you have several responses, the Importance values that you specify are used to compute an overall desirability function. These values are treated as weights for the responses. If there is only one response, then specifying the Importance is unnecessary because it is set to 1 by default.

**Detection Limits**  
The lower and upper detection limits are bounds beyond which the response cannot be measured. The detection limits are saved as a column property. You can use these limits to specify a censored response in the Generalized Regression platform. See the Generalized Regression chapter in *Fitting Linear Models*.

**Editing the Responses Outline**

In the Responses outline, note the following:

- Double-click a response to edit the response name.
- Click the goal to change it.
- Click on a limit or importance weight to change it.
- For multiple responses, you might want to enter values for the importance weights.

**Response Limits Column Property**

The Goal, Lower Limit, Upper Limit, and Importance that you specify when you enter a response are used in finding optimal factor settings. For each response, the information is saved in the generated design data table as a Response Limits column property. JMP uses this information to define the desirability function. The desirability function is used in the Prediction Profiler to find optimal factor settings. For further details about the Response Limits column property and examples of its use, see “Response Limits” on page 784 in the “Column Properties” appendix.
If you do not specify a Lower Limit and Upper Limit, JMP uses the range of the observed data for the response to define the limits for the desirability function. Specifying the Lower Limit and Upper Limit gives you control over the specification of the desirability function. For more details about the construction of the desirability function, see the Profiler chapter in Profilers.

Factors

Add factors in the Factors outline.

Tip: When you have completed the Factors outline, consider selecting Save Factors from the red triangle menu. This option saves the factor names, roles, changes, and values in a data table that you can later reload in DOE platforms.

Figure 9.14 Factors Outline

Continuous  Adds a Continuous factor. The data type in the resulting data table is Numeric. A continuous factor is a factor that you can conceptually set to any value between the lower and upper limits you supply, given the limitations of your process and measurement system.

Discrete Numeric  Adds a Discrete Numeric factor. A discrete numeric factor can assume only a discrete number of numeric values. These values have an implied order. The data type in the resulting data table is Numeric.

A screening design includes all levels of a discrete numeric factor and attempts to balance the levels. Fit Model treats a discrete numeric factor as a continuous predictor.

The default values for a discrete numeric factor with \( k \) levels, where \( k > 2 \), are the integers 1, 2, ..., \( k \). The default values for a discrete numeric factor with \( k = 2 \) levels are -1 and 1. Replace the default values with the settings that you plan to use in your experiment.

Categorical  Adds a Categorical factor. Click to select or specify the number of levels. The data type in the resulting data table is Character. The value ordering of the levels is the
order of the values, as entered from left to right. This ordering is saved in the Value Order column property after the design data table is created.

The default values for a categorical factor are L1, L2,..., Lk, where k is the number of levels that you specify. Replace the default values with level names that are relevant for your experiment.

**Remove**  Removes the selected factors.

**Add N Factors**  Adds multiple factors. Enter the number of factors to add, click **Add Factor**, and then select the factor type. Repeat **Add N Factors** to add multiple factors of different types.

### Factors Outline

The Factors outline contains the following columns:

- **Name**  The name of the factor. When added, a factor is given a default name of X1, X2, and so on. To change this name, double-click it and enter the desired name.

- **Role**  The Design Role of the factor. The Design Role column property for the factor is saved to the data table. This property ensures that the factor type is modeled appropriately. The Role of the factor determines other factor properties that are saved to the data table. See “Factor Column Properties” on page 309.

- **Values**  The experimental settings for the factors.

### Editing the Factors Outline

In the Factors outline, note the following:

- To edit a factor name, double-click the factor name.

- To edit a value, click the value in the Values column.

### Factor Column Properties

For each factor, various column properties are saved to the design table after you create the design by selecting Make Table in the Screening Design window. These properties are also saved automatically to the data table that is created when you select the Save Factors option. You can find more information about these column properties and related examples in Appendix A, “Column Properties”.

**Coding**  If the Role is Continuous or Discrete Numeric, the Coding column property for the factor is saved. This property transforms the factor values so that the low and high values correspond to –1 and +1, respectively. See “Coding” on page 795 in the “Column Properties” appendix.
Value Order  If the Role is Categorical or if a Block variable is constructed, the Value Order column property for the factor is saved. This property determines the order in which levels of the factor appear. See “Value Order” on page 811 in the “Column Properties” appendix.

Design Role  Each factor is given the Design Role column property. The Role that you specify in defining the factor determines the value of its Design Role column property. When you select a design with a block, that Block factor is assigned the Blocking value. The Design Role property reflects how the factor is intended to be used in modeling the experimental data. Design Role values are used in the Augment Design platform. See “Design Role” on page 792 in the “Column Properties” appendix.

Factor Changes  Each factor is assigned the Factor Changes column property with the value of Easy. The Factor Changes property reflects how the factor is used in modeling the experimental data. Factor Changes values are used in the Augment Design and Evaluate Design platforms. See “Factor Changes” on page 808 in the “Column Properties” appendix.

RunsPerBlock  For a blocking factor, indicates the maximum allowable number of runs in each block. When a Blocking factor is specified in the Factors outline, the RunsPerBlock column property is saved for that factor. See “RunsPerBlock” on page 817 in the “Column Properties” appendix.

Choose Screening Type

After you enter your responses and factors and click Continue, one of the following results occurs:

- If a standard design can accommodate your factors and levels, two options appear in the Choose Screening Type panel. See “Choose Screening Type Options” on page 310.
- If no listed standard design exists for your factors and levels, then the Choose Screening Type panel does not appear. The Design Generation outline for constructing a main effects screening design opens. See “Design Generation” on page 319.

Choose Screening Type Options

Choose from a list of fractional factorial designs  Enables you to select from a list of designs. This option is the default. See “Choose from a List of Fractional Factorial Designs” on page 311.

Construct a main effects screening design  Opens the Design Generation outline where you can specify the number of runs in the main effects screening design. For more information about main effects screening designs, see “Main Effects Screening Designs” on page 318.
Choose from a List of Fractional Factorial Designs

The list of screening designs that you can choose from includes designs that group the experimental runs into blocks of equal sizes where the size is a power of two. Select the type of screening design that you want to use and click *Continue*.

**Figure 9.15** Choosing a Type of Fractional Factorial Design

The Design List contains the following columns:

- **Number of Runs**: Total number of runs in the design.
- **Block Size**: Number of runs in a block. The number of blocks is the Number of Runs divided by Block Size.
- **Design Type**: Description of the type of design. See “Design Type” on page 311.
- **Resolution**: Gives the resolution of the design and a brief description of the type of aliasing. See “Resolution as a Measure of Confounding” on page 314.

**Design Type**

The Design List provides the following types of designs:

- “Two-Level Full Factorial” on page 311
- “Two-Level Regular Fractional Factorial” on page 312
- “Plackett-Burman Designs” on page 312
- “Mixed-Level Designs” on page 313
- “Cotter Designs” on page 313

**Two-Level Full Factorial**

A full factorial design has runs for all combinations of the levels of the factors. The sample size is the product of the levels of the factors. For two-level designs, this is $2^k$ where $k$ is the number of factors.
Full factorial designs are orthogonal for all effects. It follows that estimates of the effects are uncorrelated. Also, if you remove an effect from the analysis, the values of the other estimates do not change. Their $p$-values change slightly, because the estimate of the error variance and the degrees of freedom are different.

Full factorial designs allow the estimation of interactions of all orders up to the number of factors. However, most empirical modeling involves only first- or second-order approximations to the true functional relationship between the factors and the responses. From this perspective, full factorial designs are an inefficient use of experimental runs.

**Two-Level Regular Fractional Factorial**

A regular fractional factorial design also has a sample size that is a power of two. For two-level designs, if $k$ is the number of factors, the number of runs in a regular fractional factorial design is $2^k - p$ where $p < k$. A $2^k - p$ fractional factorial design is a $2^p$ fraction of the $k$-factor full factorial design. Like full factorial designs, regular fractional factorial designs are orthogonal.

A full factorial design for $k$ factors provides estimates of all interaction effects up to degree $k$. But because experimental runs are typically expensive, smaller designs are preferred. In a smaller design, some of the higher-order effects are confounded with other effects, meaning that the effects cannot be distinguished from each other. Although a linear combination of the confounded effects is estimable, it is not possible to attribute the variation to a specific effect or effects.

In fact, fractional factorials are designed by deciding in advance which interaction effects are confounded with other interaction effects. Experimenters are usually not concerned with interactions involving more than two factors. Three-way and higher-order interaction effects are often assumed to be negligible.

**Plackett-Burman Designs**

Plackett-Burman designs are an alternative to regular fractional factorials for screening. The number of runs in a Plackett-Burman design is a multiple of four rather than a power of two. There are no two-level fractional factorial designs with run sizes between 16 and 32. However, there are 20-run, 24-run, and 28-run Plackett-Burman designs.

In a Plackett-Burman design, main effects are orthogonal and two-factor interactions are only partially confounded with main effects. By contrast, in a regular Resolution 3 fractional factorial design, some two-factor interactions are indistinguishable from main effects. Plackett-Burman designs are useful when you are interested in detecting large main effects among many factors and where interactions are considered negligible.
Mixed-Level Designs

For most designs that involve categorical or discrete numeric factors at three or more levels, standard designs do not exist. In such cases, the screening platform generates main effects screening designs. These designs are orthogonal or near orthogonal for main effects.

For cases where standard mixed-level designs exist, the possible designs are given in the Design List. The Design List provides fractional factorial designs for pure three-level factorials with up to 13 factors. For mixed two-level and three-level designs, the Design list includes the complete factorials and the orthogonal-array designs listed in Table 9.1.

If your number of factors does not exceed the number for a design listed in the table, you can adapt that design by using an appropriate subset of its columns.

Table 9.1 Table of Mixed-Level Designs

Cotter Designs

Note: By default, Cotter designs are not included in the Design List. To include Cotter designs, deselect Suppress Cotter Designs in the Screening Design red triangle menu. To always show Cotter designs, select File > Preferences > Platforms > DOE and deselect Suppress Cotter Designs.

Cotter designs are useful when you must test many factors, some of which might interact, in a very small number of runs. Cotter designs rely on the principle of effect sparsity. They assume that the sum of effects shows an effect if one of the components of the sum has an active effect. The drawback is that several active effects with mixed signs might sum to near zero, thereby failing to signal an effect. Because of this false-negative risk, many statisticians discourage their use.

For $k$ factors, a Cotter design has $2k + 2$ runs. The design structure is similar to the “vary one factor at a time” approach.
The Cotter design is constructed as follows:

- A run is defined with all factors set to their high level.
- For each of the next \( k \) runs, one factor in turn is set at its low level and the others high.
- The next run sets all factors at their low level.
- For each of the next \( k \) runs, one factor in turn is set at its high level and the others low.
- The runs are randomized.

When you construct a Cotter design, the design data table includes a set of columns to use as regressors. The column names are of the form \(<factor name> \text{ Odd}\) and \(<factor name> \text{ Even}\). They are constructed by summing the odd-order and even-order interaction terms, respectively, that contain the given factor.

For example, suppose that there are three factors, A, B, and C. Table 9.2 shows how the values in the regressor columns are calculated.

<table>
<thead>
<tr>
<th>Effects Summed for Odd and Even Regressor Columns</th>
</tr>
</thead>
<tbody>
<tr>
<td>A\text{Odd} = A + ABC</td>
</tr>
<tr>
<td>A\text{Even} = AB + AC</td>
</tr>
<tr>
<td>B\text{Odd} = B + ABC</td>
</tr>
<tr>
<td>B\text{Even} = AB + BC</td>
</tr>
<tr>
<td>C\text{Odd} = C + ABC</td>
</tr>
<tr>
<td>C\text{Even} = BC + AC</td>
</tr>
</tbody>
</table>

The Odd and Even columns define an orthogonal transformation. For this reason, tests for the parameters of the odd and even columns are equivalent to testing the combinations on the original effects.

**Resolution as a Measure of Confounding**

The *resolution* of a design is a measure of the degree of confounding in the design. The trade-off in screening designs is between the number of runs and the resolution of the design.

Experiments are classified by *resolution number* into these groups:

- Resolution 3 means that some main effects are confounded with one or more two-factor interactions. In order for the main effects to be meaningful, these interactions must be assumed to be negligible.
- Resolution 4 means that main effects are not confounded with other main effects or two-factor interactions. However, some two-factor interactions are confounded with other two-factor interactions.
• Resolution 5 means that there is no confounding between main effects, between main effects and two-factor interactions, and between pairs of two-factor interactions. Some two-factor interactions are confounded with three-factor interactions.

• Resolution 5+ means that the design has resolution greater than 5 but is not a full factorial design.

• Resolution 6 means that there is no confounding between effects of any order. The design is a full factorial design.

A minimum aberration design is one that minimizes the number of confoundings for a given resolution. A minimum aberration design of a given resolution minimizes the number of words in the defining relation that are of minimum length. For a description of words, see “Change Generating Rules” on page 316. For a discussion of minimum aberration designs, see Fries and Hunter (1984).

Display and Modify Design

In the Design List, if you select a fractional factorial design with all continuous or two-level categorical factors, and possibly a blocking factor, the Display and Modify Design outline opens after you click Continue. Modify your design using the reports in this outline. See “Modify Generating Rules in a Fractional Factorial Design” on page 326 for an example of changing the generating rules to construct a design.

Note: The Change Generating Rules and Aliasing of Effects outlines do not appear for Plackett-Burman designs or Cotter designs, because interactions are not identically equal to main effects.

Change Generating Rules Specify the defining relation for the design. The defining relation determines which fraction of the full factorial design that JMP provides. See “Change Generating Rules” on page 316.

Aliasing of Effects Shows the confounding pattern for the fractional factorial design. Click the red arrow at the bottom of the panel to see interactions to a specified order. The interactions and their aliases are presented in a data table.

Coded Design Shows the pattern of high and low values for the factors in each run.

Note: For Cotter designs, the Change Generating Rules and Aliasing of Effects outlines do not apply and are not shown.
Change Generating Rules

The generating rules define the relation used to construct a specific fractional factorial design. The default generator in the screening platform results in a minimum aberration design. A minimum aberration design minimizes the aliasing of lower-order effects. Your experimental situation might require that you define a fraction of the design that provides a coding or aliasing structure that is different from the standard fraction. You can do this by changing the generating rules in the Display and Modify Design outline. For more information about defining relations and generating rules, see Montgomery (2009).

**Tip:** If you want to create a design to estimate particular effects, consider using the Custom Designer. For more information about custom designs see the “Custom Designs” chapter on page 67.

The defining relation for a design is determined by the words in the generating rules. A word is represented by a product of factors, but it is interpreted as the element wise product of the entries in the design matrix for those columns. A defining relation consists of words whose product is a column of ones, called the identity.

Figure 9.16 shows the default-generating rules for a $2^{5-2}$ fractional factorial design (five factors and eight runs).

**Figure 9.16 Generating Rules for the Standard $2^{5-2}$ Design**

In each column of the Change Generating Rules panel, the factor listed at the top and the factors in the column whose boxes are selected form a word in the defining relation. For example, the first column indicates that $\text{Temperature} = \text{Feed Rate} \times \text{Catalyst} \times \text{Stir Rate}$ is a word in the defining relation.

- If the +/- box is selected, the sign associated with the generating rule is positive and the corresponding word equals the identity.
• If the +/- box is not selected, the sign associated with the generating rule is negative and the corresponding word equals minus the identity.

See “Obtain the Defining Relations in the 2^{5-2} Design” on page 317.

The principal fraction of a full factorial design is the fractional factorial design obtained by setting all the defining relations equal to the identity. By default, the factorial design that JMP provides is the principal fraction. Notice that the +/- box is selected by default for all generating rules, so that each word in the defining relation equals the identity.

Generating rules determine the coding and aliasing of effects for the design. In some cases, you might want to use a fraction that results in a coding or an aliasing structure that differs from that of the standard fraction.

• To change the generating rules, select the appropriate boxes.

• To see the effect of your selections on the Aliasing of Effects results and on the Coded Design, click Apply.

For an example, see “Change the Generating Rules to Obtain a Different Fraction” on page 328.

**Obtain the Defining Relations in the 2^{5-2} Design**

Figure 9.16 shows two columns of check boxes:

• The first column represents the word $\text{Temperature} = \text{Feed Rate} \times \text{Catalyst} \times \text{Stir Rate}$.

• The second column represents the word $\text{Concentration} = \text{Catalyst} \times \text{Stir Rate}$.

Define $I$ to represent a column consisting of the values +1. Because all factor levels are -1 or +1, the word in the first column is equivalent to $\text{Temperature} \times \text{Feed Rate} \times \text{Catalyst} \times \text{Stir Rate} = I$. The word in the second column is equivalent to $\text{Concentration} \times \text{Catalyst} \times \text{Stir Rate} = I$. Together, these give the defining relations for the $2^{5-2}$ design:

$$I = \text{Temperature} \times \text{Feed Rate} \times \text{Catalyst} \times \text{Stir Rate} = \text{Concentration} \times \text{Catalyst} \times \text{Stir Rate}$$

**Obtain the Aliasing of Effects Relations in the 2^{5-2} Design**

The aliasing structure in the Aliasing of Effects outline is determined by the defining relations and the fact that factor levels are +1 and -1. Recall that the first generating rule is $\text{Temperature} = \text{Feed Rate} \times \text{Catalyst} \times \text{Stir Rate}$ and the second is $\text{Concentration} = \text{Catalyst} \times \text{Stir Rate}$.

To obtain the first relation in the Aliasing of Effects outline, notice that applying these two generating rules gives the expression:

$$\text{Temperature} = \text{Feed Rate} \times \text{Catalyst} \times \text{Stir Rate} = \text{Feed Rate} \times \text{Concentration}$$

The second equality follows from replacing $\text{Catalyst} \times \text{Stir Rate}$ by $\text{Concentration}$ using the second generating rule.
Now, post-multiply the first and third expressions by Concentration to obtain the following expression:

\[ \text{Temperature} \times \text{Concentration} = \text{Feed Rate} \times \text{Concentration} \times \text{Concentration} \]

Because the column for Concentration in the design matrix contains values of -1 and +1, the term Concentration \times \text{Concentration} represents a column of +1 values. The expression becomes the first alias relation shown in the Aliasing of Effects outline:

\[ \text{Temperature} \times \text{Concentration} = \text{Feed Rate} \times \text{I} = \text{Feed Rate} \]

The other alias relations can be obtained using similar calculations.

**Main Effects Screening Designs**

If an experiment involves categorical or discrete numeric factors, or if the number of runs is constrained, it might not be possible to construct an orthogonal design for screening main effects. However, a main effects screening design can be constructed. See Lekivetz et al. (2015).

A main effects screening design is a design with good balance properties as described by a Chi-square criterion. See “Chi-Square Efficiency” on page 318. Such designs have desirable statistical properties for main effect models.

The algorithm used to generate the design attempts to construct an orthogonal array of strength two. Strength-two orthogonal arrays permit orthogonal estimation of main effects when interactions are negligible. These arrays are ideal for screening designs. Regular fractional factorial designs of Resolution 3 and Plackett-Burman designs are examples of strength-two orthogonal arrays.

Consider all possible pairs of levels for factors in the design. The algorithm attempts to balance the number of pairs of levels as far as possible. Given that a fixed number of columns has been generated, a new balanced column is randomly constructed. A measure is defined that reflects the degree of balance achieved for pairs that involve the new column. The algorithm attempts to minimize this measure by interchanging levels within the new column.

**Chi-Square Efficiency**

Suppose that a design has \( n \) runs and \( p \) factors corresponding to the columns of the design matrix.

- Denote the levels of factors \( k \) and \( l \) by \( a = 0, 1, \ldots, s_k - 1 \) and \( b = 0, 1, \ldots, s_l - 1 \), respectively.
- Denote the number of times that the combination of levels \( (a,b) \) appears in columns \( k \) and \( l \) by \( n_{kl}(a,b) \).
A measure of the lack of orthogonality evidenced by columns $k$ and $l$ is given by the following expression:

$$
\chi_{kl}^2 = \sum_{a=0}^{s_k-1} \sum_{b=0}^{s_l-1} \frac{[n_{kl}(a, b) - n/(s_k s_l)]^2}{n/(s_k s_l)}
$$

A measure of the average non-orthogonality of the design is given by this expression:

$$
\chi^2 = \sum_{1 \leq k < l \leq p} \chi_{kl}^2 / [p(p - 1)/2]
$$

The maximum possible value of $\chi^2$, denoted $\chi_{max}^2$, is obtained. The chi-square efficiency of a design is defined as follows:

$$
\text{Chi-Square Efficiency} = 100(1 - \chi^2 / \chi_{max}^2)
$$

Chi-square efficiency indicates how close $\chi^2$ is to zero, relative to a design in which pairs of levels show extreme lack of balance.

**Design Generation**

When you construct a main effects screening design, the Design Generation outline enables you to specify the number of runs. To generate the design, click **Make Design**.

**Minimum**  A lower bound on the number of runs necessary to avoid failures in design generation. When you select Minimum, the resulting design is saturated. There are no degrees of freedom for error.

**Note:** If you select the Minimum number of runs, there is no error term for testing. You cannot test parameter estimates. This choice is appropriate only when the cost of additional runs is prohibitive.

**Default**  Suggests the number of runs. This value is based on heuristics for creating a balanced design with at least four runs more than the Minimum number of runs.

**User Specified**  Specify the number of runs that you want. Enter that value into the Number of Runs text box. This option enables you to balance the cost of additional runs against the potential gain in information.
Design

The Design outline shows the runs for the main effects screening design. To change the run order for your design table, you can select Run Order options in the Output Options panel before generating the table.

Design Evaluation

**Note:** The Design Evaluation outline is not shown for Cotter designs.

The Design Evaluation outline provides a number of ways to evaluate the properties of the generated design. Open the Design Evaluation outline to see the following options:

**Power Analysis**  Enables you to explore your ability to detect effects of given sizes.

**Prediction Variance Profile**  Shows the prediction variance over the range of factor settings.

**Fraction of Design Space Plot**  Shows how much of the model prediction variance lies below (or above) a given value.

**Prediction Variance Surface**  Shows a surface plot of the prediction variance for any two continuous factors.

**Estimation Efficiency**  For each parameter, gives the fractional increase in the length of a confidence interval compared to that of an ideal (orthogonal) design, which might not exist. Also gives the relative standard error of the parameters.

**Alias Matrix**  Gives coefficients that indicate the degree by which the model parameters are biased by effects that are potentially active, but not in the model.

**Color Map on Correlations**  Shows the absolute correlation between effects on a plot using an intensity scale.

**Design Diagnostics**  Indicates the optimality criterion used to construct the design. Also gives efficiency measures for your design.

**Note:** The model used for the design diagnostics contains all main effects and two-factor interactions when all two-factor interactions are estimable. Otherwise, the model contains all main effects.

For more details about the Design Evaluation panel, see “Design Evaluation” on page 451 in the “Evaluate Designs” chapter.
Output Options

Specify details for the output data table in the Output Options panel. When you have finished, click Make Table to construct the data table for the design. Figure 9.17 shows the Output Options panel for a standard design selected from the Design List. For a main effects screening design, only Run Order is available.

**Run Order**

The Run Order options determine the order of the runs in the design table.

- **Keep the Same**  
  Rows in the design table are in the same order as in the Coded Design or Design outlines.

- **Sort Left to Right**  
  Columns in the design table are sorted from left to right.

- **Randomize**  
  Rows in the design table are in random order.

- **Sort Right to Left**  
  Columns in the design table are sorted from right to left.

- **Randomize within Blocks**  
  Rows in the design table are in random order within the blocks.  
  (Not available if you select Construct a main effects screening design.)

**Center Points and Replicates**

- **Number of Center Points**  
  Specifies how many additional runs to add as center points to the design. A center point is a run where every continuous factor is set at the center of the factor’s range. This option is not available if you select Construct a main effects screening design.

Suppose that your design includes both continuous and categorical factors. If you request center points in the Output Options panel, the center points are distributed as follows:

1. The settings for the categorical factors are ordered using the value ordering specified in the Factors outline.

2. One center point is assigned to each combination of the settings of the categorical factors in order, and this is repeated, until all center points are assigned.
**Number of Replicates**  For designs in the Design List, specify the number of times to replicate the entire design, including center points. One replicate doubles the number of runs. This option is not available if you select *Construct a main effects screening design*.

**Note:** If you request center points or replicates and click Make Table repeatedly, these actions are applied to the most recently constructed design table.

## Make Table

Click **Make Table** to create a data table that contains the runs for your experiment. In the table, the high and low values that you specified appear for each run.

**Figure 9.18** The Design Data Table

</tbody>
</table>

The name of the table is the design type that generated it.

The design table includes the following scripts:

- **Screening**  Runs the DOE > Classical > Two Level Screening > Fit Two Level Screening platform. Only provided when all factors are at two levels.

- **Model**  Runs the Analyze > Fit Model platform.

- **Evaluate Design**  Runs the DOE > Design Diagnostics > Evaluate Design platform.

- **DOE Dialog**  Re-creates the Screening Design window that you used to generate the design table. The script also contains the random seed used to generate your design.

Run the **Screening** or **Model** scripts to analyze the data.
If the design was selected from the Design List, the design table contains a **Pattern** column. The **Pattern** column contains entries that summarize the run in the given row. Low settings are denoted by “-”, high settings by “+”, and center points by “0”. **Pattern** can be useful as a label variable in plots.

### Screening Design Options

The Screening Design red triangle menu contains the following options:

- **Save Responses**  Saves the information in the Responses panel to a new data table. You can then quickly load the responses and their associated information into most DOE windows. This option is helpful if you anticipate reusing the responses.

- **Load Responses**  Loads responses that you saved using the Save Responses option.

- **Save Factors**  Saves the information in the Factors panel to a new data table. Each factor’s column contains its levels. Other information is stored as column properties. You can then quickly load the factors and their associated information into most DOE windows.

  **Note:** It is possible to create a factors table by entering data into an empty table, but remember to assign each column an appropriate Design Role. Do this by right-clicking on the column name in the data grid and selecting **Column Properties > Design Role**. In the Design Role area, select the appropriate role.

- **Load Factors**  Loads factors that you saved using the Save Factors option.

- **Save Constraints**  (Unavailable for some platforms) Saves factor constraints that you defined in the Define Factor Constraints or Linear Constraints outline into a data table, with a column for each constraint. You can then quickly load the constraints into most DOE windows.

  In the constraint table, the first rows contain the coefficients for each factor. The last row contains the inequality bound. Each constraint’s column contains a column property called **ConstraintState** that identifies the constraint as a “less than” or a “greater than” constraint. See “**ConstraintState**” on page 818 in the “Column Properties” appendix.

- **Load Constraints**  (Unavailable for some platforms) Loads factor constraints that you saved using the Save Constraints option.

- **Set Random Seed**  Sets the random seed that JMP uses to control actions that have a random component. These actions include one or more of the following:

  - initializing search algorithms for design generation
– randomizing Run Order for design construction
– selecting a starting design for designs based on random starts

To reproduce a design, enter the random seed that generated the design before clicking **Make Design**.

**Note:** The random seed associated with a design is included in the DOE Dialog script that is saved to the design data table.

**Simulate Responses** Adds response values and a column containing a simulation formula to the design table. Select this option before you click Make Table.

When you click Make Table, the following occur:

– A set of simulated response values is added to each response column.
– For each response, a new column that contains a simulation model formula is added to the design table. The formula and values are based on the model that is specified in the design window.
– A Model window appears where you can set the values of coefficients for model effects and specify one of three distributions: Normal, Binomial, or Poisson.

**Note:** Not all distributions are available for all design types.

– A script called **DOE Simulate** is saved to the design table. This script reopens the Model window, enabling you to re-simulate values or to make changes to the simulated response distribution.

Make selections in the Model window to control the distribution of simulated response values. When you click Apply, a formula for the simulated response values is saved in a new column called <Y> Simulated, where Y is the name of the response. Clicking Apply again updates the formula and values in <Y> Simulated.

For additional details, see “Simulate Responses” on page 112 in the “Custom Designs” chapter.

**Note:** You can use Simulate Responses to conduct simulation analyses using the JMP Pro Simulate feature. For more information and DOE examples, see the Simulate chapter in *Basic Analysis*.

**Save X Matrix** Saves the Moments Matrix and Model Matrix to table scripts in the design data table. These scripts contain the moments and design matrices. See “Save X Matrix” on page 114 in the “Custom Designs” chapter.
Caution: For a design with nominal factors, the Model Matrix saved by the Save X Matrix option is not the coding matrix used in fitting the linear model. You can obtain the coding matrix used for fitting the model by selecting the option Save Columns > Save Coding Table in the Fit Model report that you obtain when you run the Model script.

Suppress Cotter Designs Excludes Cotter designs from the Design List. This option is selected by default. Deselect it to show Cotter designs in the Design List.

Note: You can set a preference to always show Cotter designs. Select File > Preferences > Platforms > DOE and deselect Suppress Cotter Designs.

Number of Starts (Available only for Main Effects Screening Designs.) Specify the maximum number of times that the algorithm regenerates entire designs from scratch, attempting to optimize the final design.

Design Search Time (Available only for Main Effects Screening Designs.) Specify the maximum number of seconds spent searching for a design. The default search time is 15 seconds.

If the iterations of the algorithm require more than a few seconds, a Computing Design progress window appears. The progress bar displays Chi2 Efficiency. See “Chi-Square Efficiency” on page 318. If you click Cancel in the progress window, the calculation stops and gives the best design found at that point.

Note: You can set a preference for Design Search Time. Select File > Preferences > Platforms > DOE. Select Design Search Time and enter the maximum number of seconds. If an orthogonal array is found, the search terminates. In certain situations where more time is required, JMP automatically extends the search time.

Number of Column Starts (Available only for Main Effects Screening Designs.) Specify the maximum number of times that the algorithm attempts to optimize a given column before moving on to constructing the next column. The default number of column starts is 50. See “Main Effects Screening Designs” on page 318.

Save Script to Script Window Creates the script for the design that you specified in the Screening Design window and places it in an open script window.

Additional Examples of Screening Designs

• “Modify Generating Rules in a Fractional Factorial Design”
• “Plackett-Burman Design”
Modify Generating Rules in a Fractional Factorial Design

This example, adapted from Meyer, et al. (1996), shows how to use the Screening Design platform when you have many factors. In this example, a chemical engineer investigates the effects of five factors on the percent reaction of a chemical process. The factors are:

- Feed Rate - the amount of raw material added to the reaction chamber in liters per minute
- Catalyst (as a percent)
- Stir Rate - the RPMs of a propeller in the chamber
- Temperature (in degrees Celsius)
- Concentration of reactant

Production constraints limit the size of the experiment to no more than twelve runs. You decide to consider the 8-run fractional factorial design and the 12-run Plackett-Burman design. Also, you suspect the following statements to be true:

- The Temperature*Concentration interaction is active, so you want a design that does not alias this interaction with a main effect.
- The Catalyst*Temperature* interaction is not likely to be active.
- The Stir Rate*Concentration interaction is not likely to be active.

Use this information in constructing your design.

Create the Standard Fractional Factorial Design

To create the standard fractional factorial design, do the following:

- “Specify the Response” on page 326
- “Specify the Factors” on page 327 or “Specify Factors Manually” on page 327
- “Choose a Design” on page 328

Specify the Response

1. Select DOE > Classical > Two Level Screening > Screening Design.
2. Double-click Y under Response Name and type Percent Reacted.
   Note that the default Goal is Maximize. The Goal is to maximize the response, but the minimum acceptable reaction percentage is 90 (Lower Limit) and the upper limit is 100 (Upper Limit).
3. Click under Lower Limit and type 90.
4. Click under Upper Limit and type 100.
5. Leave the area under Importance blank.
   Because there is only one response, that response is given Importance 1 by default.
See Figure 9.19 for the completed Responses outline. Now, specify the factors.

**Specify the Factors**

You can enter the factors manually or automatically:

- To enter the factors automatically, use the Reactor Factors.jmp data table:
  1. Select Help > Sample Data Library and open Design Experiment/Reactor Factors.jmp.
  2. Click the Screening Design red triangle and select Load Factors. Proceed to “Choose a Design” on page 328.

- To enter the factors manually, follow the steps below.

**Specify Factors Manually**

1. Add five continuous factors by entering 5 in the Add N Factors box and clicking Continuous.
2. Change the default factor names (X1-X5) to Feed Rate, Catalyst, Stir Rate, Temperature, and Concentration.
3. Enter the low and high values for each factor:
   - Feed Rate: 10, 15
   - Catalyst: 1, 2
   - Stir Rate: 100, 120
   - Temperature: 140, 180
   - Concentration: 3, 6

*Figure 9.19  Responses and Factors Outlines*
Choose a Design

1. Click **Continue**.

2. From the Choose Screening Type pane, accept the default selection to **Choose from a list of fractional factorial designs** and click **Continue**.

   Designs for the factors and levels that you specified are listed in the Design List (Figure 9.20).

**Figure 9.20** Fractional Factorial Designs for Five Continuous Factors

3. The design that you want is the first in the list and happens to be selected by default (Figure 9.20). Accept that selection and click **Continue**.

   Because you are limited to eight runs and have no blocking factor, your best design option is the 8-run fractional factorial design with no blocks. This design is a $2^{5-2}$ fractional factorial design. It is one quarter of the full factorial design for five factors.

**Change the Generating Rules to Obtain a Different Fraction**

In this example, you want to know whether the Temperature*Concentration interaction is confounded with a main effect. Use the Display and Modify Design outline to view the aliasing structure for the design that you selected and to change it, if appropriate.

1. Open the Aliasing of Effects outline.
The Temperature*Concentration interaction, which you suspect is active, is confounded with Feed Rate, a main effect. You want to change the generating rules to construct a design where Feed Rate is aliased with effects that you suspect are inactive, and where the Temperature*Concentration interaction is not aliased with a main effect.

2. Open the Change Generating Rules outline.

The default-generating rules give you the standard (or principal) one-quarter fraction of the full factorial design. Recall that you suspect that the Catalyst*Temperature and Stir Rate*Concentration interactions are not likely to be active. Redefine the generating rules so that these two interactions are confounded with Feed Rate. The redefined generating rules give you a different one-quarter fraction of the full factorial design.

3. Do the following:
   - Deselect Stir Rate in the Temperature column.
   - Deselect Catalyst in the Concentration column.
   - Select Feed Rate in the Concentration column.

4. Click Apply.
In the design that you have defined, Feed Rate is confounded with Catalyst*Temperature and Stir Rate*Concentration. Also, the Temperature*Concentration interaction is now confounded with the two-way interaction Catalyst*Stir Rate.

5. In the Output Options outline, accept the default Run Order setting of Randomize and click Make Table.

Figure 9.24 Eight-Run Fractional Factorial Design Table

The design table shows the design that you constructed. Notice that the table contains a column for the response that you defined in the Screening window, Percent Reacted, where you can record your experimental results.

The Screening, Model, and DOE Dialog scripts are also included. For more information about these scripts, see “Make Table” on page 322.

Analyze the Results

Next you conduct the experiment, record your data, and proceed to analyze the results.

1. Select Help > Sample Data Library and open Design Experiment/Reactor 8 Runs.jmp.

   You can estimate seven effects with your eight runs. Of these, you expect only a few to be active. Because you want to estimate seven effects, there are no degrees of freedom for error. For these reasons, you use the Screening platform to analyze the results.

2. Run the Screening script in the data table.

   The Screening script launches the Screening platform (DOE > Classical > Two Level Screening > Fit Two Level Screening) for your response and factors.
Figure 9.25  Report for Screening Example

Note: Since the \( p \)-values are obtained using a simulation-based technique, your \( p \)-values might not precisely match those shown here.

The report shows both Individual and Simultaneous \( p \)-values based on Lenth t-ratios. None of the effects are significant, even with respect to the Individual \( p \)-values. The Half Normal Plot suggests that the effects reflect only random noise.

For more information about the Screening report, see “The Screening Report” on page 343 in the “The Fit Two Level Screening Platform” chapter.

Plackett-Burman Design

The Fractional Factorial example shows an 8-run fractional factorial design for five continuous factors. But suppose you can afford 4 additional runs. In this example, construct a 12-run Plackett-Burman design. To facilitate completing the Screening window, use the Load Responses and Load Factors commands.

Create the Plackett-Burman Design

1. Select DOE > Classical > Two Level Screening > Screening Design.
2. Select Help > Sample Data Library and open Design Experiment/Reactor Response.jmp.
3. Click the Screening Design red triangle and select Load Responses.
4. Select **Help > Sample Data Library** and open Design Experiment/Reactor Factors.jmp.

5. Click the Screening Design red triangle and select **Load Factors**.

   The **Load Responses** and **Load Factors** commands fill in the Responses and Factors outlines with the response and factor names, goal and limits for the response, and values for the factors. See Figure 9.19 for the completed Responses and Factors outlines.

6. Click **Continue**.

   **Note:** Setting the random seed in the next step reproduces the run order shown in this example. In constructing a design on your own, this step is not necessary.

7. (Optional) Click the Screening Design red triangle, select **Set Random Seed**, type 34567, and click **OK**.

8. From the Choose Screening Type pane, accept the default selection to **Choose from a list of fractional factorial designs** and click **Continue**.

9. Select the Plackett-Burman design.

   Plackett-Burman designs with run sizes that are not a power of two tend to have complex aliasing structures. In particular, main effects can be partially aliased with several two-way interactions. See “Evaluate the Design” on page 333. Notice that the 12-run Plackett-Burman design is designated as having Resolution 3.

**Figure 9.26**  Design List Showing Plackett-Burman Screening Design

10. Click **Continue**.

11. Click **Make Table**.
Figure 9.27  Design Table for Placket-Burman Design

A column called Percent Reacted is included in the design table. You should conduct your experimental runs in the order shown in the table, recording your results in the Percent Reacted column.

Evaluate the Design

1. Return to your Screening Design window. If you have closed this window, run the DOE Dialog script in your design table.
2. Open the Design Evaluation > Color Map on Correlations outline.
Figure 9.28 Color Map for Absolute Correlations

The diagonal cells have correlations of one, as expected. White cells correspond to effects that have correlations equal to 0. The gray and black cells correspond to effects that have correlations greater than zero. Hover over cells to see the effects involved and their absolute correlations. For example, notice that Feed Rate is correlated with several two-way and three-way interactions.

Note: The color map from the screening design contains 3-way interactions for designs with 8 or fewer factors. The color map from the design evaluation script only contains up to 2-way interactions.

3. Open the Alias Matrix outline.

Figure 9.29 Alias Matrix - Partial View Showing Up to Two-Way Interactions
Because the design is orthogonal for the main effects, the Alias Matrix gives the numerical values of the correlations between effects. See “Alias Matrix” on page 464 in the “Evaluate Designs” chapter. For example, notice that Feed Rate is partially aliased with six two-way interactions and with four three-way interactions. These are the interactions corresponding to the entries of 0.333 and -0.33 in the row for Feed Rate.

**Analyze the Results**

The data table Plackett-Burman.jmp contains the results of the designed experiment. Recall that you suspect that the Temperature*Concentration interaction is active. You proceed under the assumption that this is the only potentially active interaction.

1. Select Help > Sample Data Library and open Design Experiment/Plackett-Burman.jmp.
2. Run the Model script by clicking the icon to its left.
3. Select Temperature in the Select Columns list and Concentration in the Construct Model Effects list.
4. Click Cross.
5. Click Run.

**Figure 9.30** Parameter Estimates for Full Model

<td>-0.50</td>
<td>0.100</td>
<td>-0.50</td>
<td>0.8572</td>
<td></td>
</tr>
</tbody>
</table>

The Actual by Predicted Plot indicates no lack of model fit. The Parameter Estimates report shows that Catalyst is significant at the 0.05 level and that the Concentration*Temperature interaction is almost significant at the 0.10 level.

**Reduce the Model**

You want to identify those effects that have the most impact on the response. To see these active effects more clearly, remove insignificant effects using the Effect Summary outline.

**Figure 9.31** Effect Summary Outline for Full Model
Although Concentration is the least significant effect, it is involved in a higher-order interaction (Concentration*Temperature), as indicated by the caret to the right of its PValue. Based on the principle of effect heredity, Concentration should not be removed from the model while the Concentration*Temperature interaction remains in the model. See “Effect Heredity” on page 64 in the “Starting Out with DOE” chapter. The next least significant effect is Stir Rate.

1. In the Effect Summary outline, select Stir Rate and click **Remove**.

   Feed Rate is the next least significant effect that can be removed.

2. In the Effect Summary outline, select Feed Rate and click **Remove**.

**Figure 9.32** Effect Summary Outline for Reduced Model

The PValue column indicates that the Catalyst main effect and the Concentration*Temperature interaction are both significant at the 0.05 level. The model should not be reduced any further. If all other interactions are inactive or negligible, then you can conclude that Catalyst and the Concentration*Temperature interaction are active effects.
The Fit Two Level Screening platform is a modeling platform that you can use to analyze experimental data results from a screening design. The Fit Two Level Screening platform helps you identify effects that have a large impact on the response.

The Fit Two Level Screening platform is based on the principle of effect sparsity (Box and Meyer 1986). This principle asserts that relatively few of the effects that you study in a screening design are active. Most are inactive, meaning that their true effects are negligible and that their estimates can be treated as random error.

A screening design often provides no degrees of freedom for error when the model of interest includes interaction terms. Consequently, classical tests for effects are not available. In such cases, the Fit Two Level Screening platform is particularly useful.

Overview of the Fit Two Level Screening Platform

The analysis of screening designs depends on the principle of effect sparsity, where most of the variation in the response is explained by a small number of effects. Under this principle, effects with small estimates are used to estimate the error in the model. This then allows one to test whether the larger effects are active.

You can analyze data from a screening experiment using Fit Model (Analyze > Fit Model) or Fit Two Level Screening (DOE > Classical > Two Level Screening > Fit Two Level Screening). Use the following guidelines to select the appropriate modeling platform:

- If your factors are all two-level and orthogonal, all of the statistics in the Fit Two Level Screening platform are appropriate.
- If you have data from a highly supersaturated main effect design, the Fit Two Level Screening platform is effective in selecting active factors, but it is not effective at estimating the error or the significance. The Monte Carlo simulation to produce \( p \)-values uses assumptions that are not valid for this case.
- If you have a categorical or a discrete numeric factor with more than two levels, the Fit Two Level Screening platform is not appropriate. JMP treats the associated model terms as continuous. For such factor, the variation is scattered across main effects and polynomial effects. In this situation, it is recommended that you use the Fit Model platform.
- If your data are not orthogonal, the constructed estimates in the Fit Two Level Screening Platform are different from standard regression estimates. JMP can identify large effects, but it does not effectively test each effect. This is because effects are artificially orthogonalized as they are entered into the model, making effects that enter early in the model appear less significant than in standard regression. See “Order of Effect Entry” on page 350.
- For mixture designs, the Fit Two Level Screening platform is not appropriate. See instead “Fitting Mixture Designs” on page 414 in the “Mixture Designs” chapter.

Example of Fit Two Level Screening Platform

The Reactor Half Fraction.jmp sample data table contains the results of an experiment derived from a design discussed in Box et al. (1978). You are interested in identifying significant effects in a model that contains main effects and two-way interactions. This example uses a model with fifteen parameters for a design with sixteen runs. The example illustrates the analysis both with the Fit Two Level Screening Platform and the Fit Model Platform.
Fit Two Level Screening

1. Select Help > Sample Data Library and open Reactor Half Fraction.jmp.
2. Select DOE > Classical > Two Level Screening > Fit Two Level Screening.
3. Select Percent Reacted and click Y.
4. Select Feed Rate through Concentration, click X, and then click OK.

**Note:** The Fit Two Level Screening Platform automatically constructs a model with interaction terms. This is in contrast to the Fit Model Platform, where you manually specify the interactions that you want to include in your model.

**Figure 10.2** Reactor Half Fraction.jmp Fit Two Level Screening Design Report

Note the following features of the Screening report:
- The effects that have an individual p-value less than 0.10 are selected.
- A t-ratio is calculated using Lenth’s PSE (pseudo-standard error). The Lenth PSE value is shown below the Half Normal Plot.
– Both individual and simultaneous \( p \)-values are shown. Those that are less than 0.05 are shown with an asterisk.

– The Half Normal Plot enables you to quickly examine the effects. The effects that are initially selected in the effects list are also labeled in this plot.

In this example, Catalyst, Temperature, and Concentration, along with two of their two-factor interactions, are selected. Alternatively, you can fit the same model in the Fit Model Platform.

**Fit Model**

1. From the Reactor Half Fraction.jmp table, select **Analyze > Fit Model**.
2. Select Percent Reacted, **click Y**.
3. Select Feed Rate through Concentration, and then select **Macros > Factorial to Degree**.
4. **Click Run**.
5. Open the Parameter Estimates outline.

**Figure 10.3** Saturated Reactor Half Fraction.jmp Design Parameter Estimates

</table>

Since there are 16 observations and 16 model terms, there are not enough observations to estimate an error term. Without an estimate of error, it is not possible to conduct standard tests. Parameter estimates are provided, but because there are no degrees of freedom for error, standard errors, \( t \)-ratios, and \( p \)-values are all missing. This illustrates the strength of the Fit Two Level Screening platform for getting the most information out of a screening design.
Launch the Fit Two Level Screening Platform

Launch the Fit Two Level Screening platform by selecting **DOE > Classical > Two Level Screening > Fit Two Level Screening.**

**Figure 10.4** Launch Window for the Fit Two Level Screening Platform

Y  The columns to be analyzed. These must have a Numeric data type.

X  Continuous or discrete two-level orthogonal factors.

By  A column whose level define separate analyses. For each level of the specified column, the corresponding rows are analyzed. The results appear in separate reports. If more than one By variable is assigned, a separate analysis is produced for each possible combination of the levels of the By variables.

**Note:** If you created your design in the Screening Design Platform from a list of fractional factorial designs, the design table contains a script called **Screening**. Run this script to run the analysis directly.
The Screening Report

The Fit Two Level Screening report shows a summary table of the design contrasts (candidate model terms) and a half normal plot. You can launch or run the selected model from the report.

Figure 10.5  Screening Report

- “Contrasts” on page 344
- “Half Normal Plot” on page 344
- “Make or Run Model” on page 345
Contrasts

The Contrasts report lists model effects, a contrast value, Lenth $t$-ratios, individual and simultaneous $p$-values, and aliases (if there are any). Effects are entered into the analysis following a hierarchical ordering. See “Order of Effect Entry” on page 350. Effects that have an Individual $p$-Value less than 0.10 are selected.

**Term**  The name of the factor.

**Contrast**  Estimate for the factor. For orthogonal designs, this number is the same as the regression parameter estimate. This is not the case for non-orthogonal designs. An asterisk might appear next to the contrast, indicating a lack of orthogonality.

**Bar Chart**  Shows the Lenth $t$-ratios with blue vertical lines that indicate a value that is significant at the 0.10 level.

**Lenth $t$-Ratio**  Lenth’s $t$-ratio, calculated as $\text{Contrast/PSE}$, where PSE is Lenth’s Pseudo-Standard Error. See “Lenth’s Pseudo-Standard Error” on page 351.

**Individual $p$-Value**  Analogous to the standard $p$-values for a linear model. Small individual $p$-values indicate a significant effect. See “Lenth’s Pseudo-Standard Error” on page 351.

**Note:** Do not expect the $p$-values to be exactly the same if the analysis is re-run. The Monte Carlo method should give similar, but not identical, values if the same analysis is repeated.

**Simultaneous $p$-Value**  A multiple-comparison adjusted $p$-value.

**Aliases**  Appears only if there are exact aliases of later effects to earlier effects.

Half Normal Plot

The Half Normal Plot shows the absolute value of the contrasts plotted against the absolute value of quantiles for the half-normal distribution. The blue line passes through the origin with a slope of the Lenth’s estimate of $\sigma$. Effects that are small are considered error terms and assumed to have a normal distribution with mean zero and standard deviation $\sigma$. These terms fall on the blue line. Significant effects are those that have nonzero means and do not fall on the blue line.

The Half Normal Plot is interactive. You can select model effects by dragging a rectangle around the effects of interest. You can also press Ctrl and click an effect name(s) in the report.
Make or Run Model

The **Make Model** button launches a Fit Model window that is populated with the selected effects.

The **Run Model** button runs an effect screening model for the selected effects.

**Note:** A JMP alert appears if your selected model does not follow effect heredity. You can **Cancel**, use the **Make Model** button to launch the Fit Model window, and add the missing terms. Or, you can **Continue** and build a model that does not follow effect heredity rules. See “Effect Heredity” on page 64 in the “Starting Out with DOE” chapter.

Additional Fit Two Level Screening Analysis Examples

- “Analyze a Plackett-Burman Design”
- “Effect Heredity Example”
- “Analyze a Supersaturated Design”

Analyze a Plackett-Burman Design

Plackett-Burman designs are an alternative to fractional-factorial screening designs. Two-level fractional factorial designs must, by their nature, have a number of runs that are a power of two. However, Plackett-Burman designs exist for 12-, 24-, and 28-run designs.

The Weld-Repaired Castings.jmp sample data table uses a Plackett-Burman design, and is found in Box et al. (1978). Seven factors are thought to be influential on weld quality. The seven factors include Initial Structure, Bead Size, Pressure Treatment, Heat Treatment, Cooling Rate, Polish, and Final Treatment. A Plackett-Burman design with 12 runs is used to investigate the importance of the seven factors. The response is $100 \times \log(\text{lifetime})$. (The sample data table also contains four terms that were used to model error, but those terms are not used in this analysis.)

1. Select **Help > Sample Data Library** and open Weld-Repaired Castings.jmp.
2. Select **DOE > Classical > Two Level Screening > Fit Two Level Screening**.

   The launch window is populated based on the column properties. Log Life (x100) is the response $Y$.

   The seven factors Initial Structure, Bead Size, Pressure Treatment, Heat Treatment, Cooling Rate, Polish, and Final Treatment are specified for $X$. 

3. Scroll to the bottom of the X window. Select $\varepsilon_1$, $\varepsilon_2$, $\varepsilon_3$, and $\varepsilon_4$, and click **Remove**.

4. **Click OK**.

**Figure 10.6** Screening Report for Weld-Repaired Castings.jmp

The only significant effect identified is **Polish**. Note that asterisks mark four terms, indicating that they are not orthogonal to the effects preceding them. The contrast values obtained for these effects are after orthogonalization. As a result, these estimates do not match estimates obtained from a corresponding regression analysis. You can use the **Run Model** button to fit the single-factor model.

**Effect Heredity Example**

This example illustrates building a model when the Fit Two Level Screening platform identifies a model that does not follow effect heredity.

1. Select **Help > Sample Data Library** and open Design Experiment/Plackett-Burman.jmp.
2. Select **DOE > Classical > Two Level Screening** > **Fit Two Level Screening**.
3. Select Percent Reacted and click **Y**.
4. Select Feed Rate through Concentration and click **X**.
5. Click **OK**.

**Figure 10.7** Model Contrasts

</tbody>
</table>

The Catalyst*Stir Rate interaction is highlighted, but the Stir Rate main effect is not. In accordance with the principle of Effect Heredity, you should add the Stir Rate main effect to the model. See “Effect Heredity” on page 64 in the “Starting Out with DOE” chapter.

6. Click **Make Model**.
7. Select Stir Rate and click **Add** in the Construct Model Effects section.
8. Click **Run**.
The ^ symbol to the right of the PValue for Stir Rate and Temperature show that while not significant, these effects are contained in significant higher-order effect.

**Analyze a Supersaturated Design**

Supersaturated designs have more factors than runs. They rely heavily on effect sparsity for their analysis, so the Fit Two Level Screening platform is ideal for their analysis. The objective is to determine which effects are active.

In this example, a simulated design with 18 factors but only 12 runs is considered. Y is generated by:

\[ Y = 2(X7) + 5(X10) - 3(X15) + \varepsilon \]

where \( \varepsilon \sim N(0,1) \). So, Y has been constructed with three active factors.

1. Select **Help > Sample Data Library** and open Supersaturated.jmp.
2. Select **DOE > Classical > Two Level Screening > Fit Two Level Screening**.
3. Select Y and click Y.
4. Select X1 through X18 and click X.
5. Click **OK**.
Note that four factors have been highlighted. Factors X10, X15, and X7 are active based on a 0.05 critical value criteria. In the Half Normal Plot, X18 is close to the blue line, which indicates that it is close to the 0.1 cutoff value for significance. The 0.1 critical value is generous in its selection of factors so that you do not miss those that are possibly active.

The contrast estimates for X10, X15, and X7 of 5.1, –3, and 1.8 are close to their simulated values (5, –3, 2).

The p-values are not entirely valid statistically, since they are based on a simulation that assumes orthogonal designs, which is not the case for supersaturated designs. However, as shown, they can be useful in identifying effects for further investigation.
Technical Details for the Fit Two Level Screening Platform

- “Order of Effect Entry”
- “Fit Two Level Screening as an Orthogonal Rotation”
- “Lenth’s Pseudo-Standard Error”
- “Lenth t-Ratios”

Order of Effect Entry

The Fit Two Level Screening platform has a carefully defined order of operations:

1. First, the main effect terms enter the model according to the absolute size of their contrast. All effects are orthogonalized to the effects preceding them in the model. This method assures that their order is the same as it would be in a forward stepwise regression. Ordering by main effects also helps in selecting preferred aliased terms later in the process.

2. After main effects, all second-order interactions enter the model, followed by third-order interactions, and so on. The second-order interactions cross with all earlier terms before bringing in a new term because B and C are both larger than D. The complete order of entry is AB, AC, BC, AD, BD, and then CD.

3. An effect that is an exact alias for an effect already in the model appears in the Alias column. Effects that are a linear combination of several previous effects do not appear. If there is partial aliasing (due to a lack of orthogonality), the effects involved are marked with an asterisk.

4. The process continues until \( n \) effects are obtained, where \( n \) is the number of rows in the data table, thus fully saturating the model. If complete saturation is not possible with the factors, JMP generates random orthogonalized effects to absorb the rest of the variation. They are labeled Null \( n \) where \( n \) is a number. For example, this situation occurs if there are exact replicate rows in the design.

Fit Two Level Screening as an Orthogonal Rotation

Mathematically, the Fit Two Level Screening platform takes the \( n \) values in the response vector and rotates them into \( n \) new values. The rotated values are then mapped by the space of the factors and their interactions.

\[
\text{Contrasts} = T' \times \text{Responses}
\]
In the above equation, \( T \) is an \( n \) by \( n \) orthonormalized set of values starting with the intercept, main effects of factors, two-way interactions, three-way interactions, and so on, until \( n \) values have been obtained. Since the first column of \( T \) is an intercept, and all the other columns are orthogonal to it, these other columns are all contrasts, that is, they sum to zero. Since \( T \) is orthogonal, it can serve as \( X \) in a linear model. It does not need inversion, since \( T' \) is equivalent to \( T^{-1} \) and \( (T'T)T' \). The contrasts are the parameters estimated in a linear model.

If no effect in the model is active other than the intercept, the contrasts are just an orthogonal rotation of random independent variates into different random independent variates. These orthogonally-rotated random variates have the same variance as the original random independent variates. To the extent that some effects are active, the inactive effects still represent the same variation as the error in the model. The hope is that the effects and the design are strong enough to separate the active effects from the random error effects.

### Lenth’s Pseudo-Standard Error

Lenth’s method (Lenth 1989), known as the Lenth Pseudo Standard Error (PSE), constructs an estimate of the residual standard error using effects that appear to be inactive. Lenth’s PSE can be used to estimate the standard error for experiments where contrasts are independent and have a common variance.

If there are \( n \) rows, the platform constructs \( n - 1 \) contrasts. Denote these contrasts by \( \hat{C}_i \), where \( i = 1, \ldots, n - 1 \).

To obtain Lenth’s PSE, first calculate the following:

\[
v = 1.5[\text{median}_{i = 1, \ldots, n - 1} |\hat{C}_i|]
\]

Lenth’s PSE is based on the effects that are likely to be inactive and is defined as follows:

\[
PSE = 1.5\left[\text{median}_{\hat{C}_i < 2.5v}|\hat{C}_i|\right]
\]

The value for Lenth’s PSE is shown at the bottom of the Screening report.

### Lenth t-Ratios

For each contrast, a \( t \)-ratio is computed by dividing the contrast by the PSE. The reference distribution of these \( t \)-ratios under the null hypothesis is not computationally tractable. Therefore, it is obtained by simulation. The method, described below, is based on a discussion in Ye and Hamada (2000).

Denote the \( t \)-ratio for the \( i \)th contrast by \( t_i \):

\[
t_i = \frac{\hat{C}_i}{(PSE)}
\]
Of primary importance in screening experiments is the individual error rate, namely the probability of declaring a given effect as active when it is not. For the $i^{th}$ effect, this occurs when $|t_i|$ is large and falls into the upper tail of its reference distribution.

Because the platform constructs a relatively large number of effects, the experimentwise error rate is also of importance. The experimentwise error rate is the probability of declaring any effect as active when no effects are active. An experimentwise error occurs when no effects are active and the maximum of the absolute $t$-ratios, $\max|t_i|$, is large and falls into the upper tail of its reference distribution.

The Fit Two Level Screening platform obtains reference distributions for both types of error rates using Monte Carlo simulation. Consider a set of $n - 1$ values that is simulated from a normal distribution with mean 0 and standard deviation equal to PSE. This set of values represents potential contrast values for the experiment under the null hypothesis of no active effects. In all, 10,000 sets of $n - 1$ random contrast values are generated.

**Individual p-Values**

Consider the $i^{th}$ contrast. Lenth $t$-ratios are constructed using each of the $10,000^*(n - 1)$ simulated values. The reference distribution for the individual error rate is approximated by the absolute values of these $t$-ratios. The Individual $p$-value is the interpolated fractional position of the observed absolute Lenth t-Ratio among the $10,000^*(n - 1)$ simulated absolute $t$-ratios arranged in descending order. This approximates the area to the right of the absolute value of the observed absolute Lenth t-Ratio with respect to the reference distribution.

**Simultaneous p-Values**

An experimentwise error occurs if any $t$-ratio leads to rejecting the null hypothesis when all effects are inactive. Equivalently, an experimentwise error occurs if the maximum of the absolute $t$-ratios, $\max|t_i|$, leads to rejecting the null hypothesis.

To obtain a reference distribution in this case, consider the maximum of the computed absolute $t$-ratios in each of the 10,000 simulations. These 10,000 maximum values form the reference distribution. The Simultaneous $p$-value is the interpolated fractional position of the observed absolute Lenth t-Ratio among the 10,000 simulated maximum absolute $t$-ratios arranged in descending order. This approximates the area to the right of the absolute value of the observed absolute Lenth t-Ratio with respect to the reference distribution based on the simulated maximum absolute $t$-ratios.

**Monte Carlo Simulation Options**

To change the number of default sets of simulations from 10,000, you must assign a value to a global JSL variable named LenthSimN. The number of simulations used to derive the $p$-values is reported in the report window.
The following example sets the number of simulations to 50,000.

1. Select **Help > Sample Data Library** and open Reactor Half Fraction.jmp.
2. Select **DOE > Classical > Two Level Screening > Fit Two Level Screening.**
3. Select Percent Reacted and click **Y.**
4. Select Feed Rate through Concentration, click **X,** and then click **OK.**
5. Click the red triangle next to Screening for Percent Reacted and select **Save Script > To Script Window.**
6. Insert **LenthSimN=50000;** as the first line of the script.

```
LenthSimN=50000;
Fit Two Level Screening(
    Y( :Percent Reacted),
    X( :Feed Rate, :Catalyst, :Stir Rate, :Temperature, :Concentration )
);
```
7. Right-click in the script window and select **Run Script.**

**Figure 10.10** Fit Two Level with N = 50,000 Simulations for p-Value Derivations

The number of simulations is stated in the report window.

**Note:** If LenthSimN=0, the standard *t*-distribution is used and simultaneous *p*-values are not provided. This approach is not recommended.
Response surface designs are useful for modeling quadratic surfaces. A response surface model can identify a point where a minimum or maximum value of the response occurs, if one exists inside the design region. Three distinct values for each factor are necessary to fit a quadratic function, so standard two-level designs are not appropriate for fitting curved surfaces.

Response surface designs are capable of fitting a second-order prediction equation for the response. The quadratic terms in these equations model the curvature in the true response function. If a maximum or minimum exists inside the design region, the point where that value occurs can be estimated.

Overview of Response Surface Designs

The Response Surface Design platform provides the classical central composite and Box-Behnken designs, including blocked versions of these designs. For central composite designs, you can control the placement of axial points and other aspects of the design. Response surface designs are available for continuous factors only and are provided for up to eight factors.

**Tip:** You can use DOE > Custom Design to construct optimal response surface designs that accommodate your specific experimental situation. Custom Design constructs response surface designs that are much more flexible than classical response surface designs. In particular, you can use the Custom Design platform to create response surface designs that involve categorical factors or more than eight continuous factors. You can also specify the number of runs and restrictions on the design space. For examples, see “Response Surface Experiments” on page 159 in the “Examples of Custom Designs” chapter.

A central composite design (Figure 11.2) combines a two-level fractional factorial design and two other types of points:

- **Center points,** where all the factor values are set to the midrange value.
- **Axial points,** where one factor is set to a high or low value (an axial value) and all other factors are set to the midrange value.

Depending on your selections relative to axial points, a central composite design can have as many as five distinct settings for each factor and the axial points can extend beyond the specified range of the factors.
Figure 11.2 Central Composite Design for Three Factors

A Box-Behnken design (Figure 11.3) has only three levels per factor and has no design points at the vertices of the cube defined by the ranges of the factors. This type of design can be useful when you must avoid these points due to engineering considerations. But, the lack of design points at the vertices of the cube means that a Box-Behnken design has higher prediction variance, and so less precision, near the vertices compared to a central composite design.
In JMP, you can construct a response surface design in two ways:

- Using the Response Surface Design platform (for up to eight continuous factors)
- Using the Custom Design platform (and clicking the RSM button in the Model outline)

In both cases, the design table contains a Model script that you can run to fit a model. The Model script applies the Response Surface Effect attribute to each main effect, so that the main effects appear with a `&RS` suffix in the Fit Model window. This attribute ensures that the Fit Least Squares report contains a Response Surface report. For more information about this report, see *Fitting Linear Models*.

**Note:** The Response Surface outline in the Standard Least Squares report is not shown for response surface designs that contain more than 20 continuous factors.

---

**Example of a Response Surface Design**

In this example, you construct a Box-Behnken design for a tire tread experiment. Your objective is to match a target value of 450 for a measure of elongation (Stretch). The stretch varies as a function of the amounts of Silica, Silane, and Sulfur used to manufacture the tire tread compound. You want to experiment over a wide range of factor settings to find the settings that achieve the target.

- “Construct a Box-Behnken Design”
- “Analyze the Experimental Data”
- “Explore Optimal Settings”
Construct a Box-Behnken Design

In this example, for convenience, you load the responses and factors from existing tables. When designing a new experiment on your own, enter the responses and factors manually. See “Responses” on page 367 and “Factors” on page 369.

1. Select DOE > Classical > Response Surface Design.
2. Select Help > Sample Data Library and open Design Experiment/Bounce Response.jmp.
3. Click the Response Surface Design red triangle and select Load Responses.
4. Select Help > Sample Data Library and open Design Experiment/Bounce Factors.jmp.
5. Click the Response Surface Design red triangle and select Load Factors.

Figure 11.4 Responses and Factors Outlines for Tire Tread Design

In the Responses outline, notice that the Goal for Stretch is set to Match Target.

In the Choose a Design panel, possible designs appear.

**Note:** Setting the Random Seed in step 6 reproduces the exact results shown in this example. In constructing a design on your own, this step is not necessary.
6. (Optional) Click the Response Surface Design red triangle and select **Set Random Seed**. Type 12345 and click **OK**.

7. Click **Continue** to retain the Box-Behnken design selection.

8. Click **Make Table**.

**Figure 11.5** Box-Behnken Design Table

</tbody>
</table>

At this point, conduct the experiment and enter the responses into the data table.

**Analyze the Experimental Data**

1. Select **Help > Sample Data Library** and open **Design Experiment/Bounce Data.jmp**. The file Bounce Data.jmp contains your experiment results.

2. Run the **Model** script.

   Notice that the main effects in the Construct Model Effects list are followed by the **& RS** suffix. This suffix indicates that these are response surface effects, which produce a Response Surface report in the Standard Least Squares report.

3. Click **Run**.
Figure 11.6 Lack of Fit and Effect Tests Reports

There is no indication of lack of fit and the Effect Tests report indicates that all but two higher-order terms (Silica\*Silane and Silane\*Silane) have \( p \)-values below 0.0001. See *Fitting Linear Models* for more information about interpretation of the tables in Figure 11.6.

4. Click the disclosure icon next to Response Surface to open the report.

5. Click the disclosure icon next to Canonical Curvature.

Figure 11.7 Response Surface Report

The Coef table shown as the first part of the report gives a concise summary of the estimated model parameters. The first three columns give the coefficients of the second-order terms. The last column gives the coefficients of the linear terms. To see the prediction expression in its entirely, select Estimates > Show Prediction Expression from the Response Stretch red triangle.
The Solution report gives the coordinates of the point where the single critical value occurs. In this instance, that point is a saddle point (a point where neither a maximum nor a minimum occurs) and falls outside the range of the design space.

The Canonical Curvature report shows eigenvalues and eigenvectors of the effects. These give information about the nature and direction of the surface’s curvature. The large positive eigenvalue of 62.9095 indicates positive curvature and the eigenvector values indicate that the curvature is primarily in the Silica direction. The large negative eigenvalue of -74.9584 indicates negative curvature and the eigenvector values indicate that the curvature is primarily in the Sulfur direction.

See *Fitting Linear Models* for more information about the response surface analysis tables in Figure 11.7.

Next, use the prediction profiler and the contour profiler to find optimal settings.

**Explore Optimal Settings**

1. Click the Prediction Profiler red triangle and select *Optimization and Desirability > Maximize Desirability*.

![Figure 11.8 Prediction Profiler for Bounce Data.jmp with Desirability Maximized](image)

**Note:** Your optimal settings might differ. This is because there are many points for which the predicted Stretch is 450.

When you specified the response, the goal was set to match a target of 450, with lower and upper limits of 350 and 550. This goal was carried over to the design table and these limits were put in a Response Limits column property for Stretch. A desirability function is constructed from these response limits (top right cell in Figure 11.8). See “Response Limits” on page 784 in the “Column Properties” appendix.
When you maximize the desirability function, JMP identifies one combination of factor level settings (usually out of many possible combinations) that results in a predicted Stretch of 450. Figure 11.8 shows these settings as Silica = 1.069, Sulfur = 1.972, and Silane = 40.000. Next, you use the Contour Profiler to identify other points that maximize the desirability function.

For more information about the Prediction Profiler, see Profile.

2. Click the Response Stretch red triangle and select Factor Profiling > Contour Profiler. Suppose that you want to achieve your target while setting Sulfur to the value 2.0. Also, you want to make sure that the settings that you choose for Silane and Silica maintain predicted Stretch within 5 units of 450.

3. On the vertical axis, click the red triangle next to Sulfur and select Silane.

Figure 11.9 Contour Profiler for Bounce Data.jmp

The plot shows the contour of values of Silane and Silica for Stretch at 425 and Sulfur at 2.3.

4. Set the Current X for Sulfur to 2.
5. Set the Contour for Stretch to 450.
6. Set the Lo Limit and Hi Limit for Stretch to 445 and 455, respectively. Press Enter.
The unshaded band of Silica and Silane values gives predicted Stretch between 445 and 455 when Sulfur is set at 2.0. The values on the solid red curve give predicted Stretch of 450.

7. Drag the crosshairs that appear in the plot to the unshaded band to find settings for Silica and Silane that are best for your process from a practical perspective.

Suppose that your process is known to be more robust at low levels of Silane than at high levels. Then you might consider the settings in Figure 11.11.
**Figure 11.11** Contour Profiler Showing Specific Settings for Silica and Silane

For Sulfur = 2.0, the factor settings identified by the crosshairs are Silica = 1.045 and Silane = 41.71. These settings are shown under Current X. At these settings, the predicted Stretch is 449.62071, shown next to Current Y.

For further information about the Contour Profiler, see *Profiler*.

---

**Response Surface Design Window**

The Response Surface Design window walks you through the steps to construct a design for modeling a quadratic surface. You can select a central composite design, a Box-Behnken design, or a blocked version of one of these design types. If you select a central composite design, you can adjust the axial points.

The Response Surface Design window updates as you work through the design steps. The outlines, separated by buttons that update the outlines, follow the flow in Figure 11.12.

**Figure 11.12** Response Surface Design Flow
## Responses

Use the Responses outline to specify one or more responses.

**Tip:** When you have completed the Responses outline, consider selecting **Save Responses** from the red triangle menu. This option saves the response names, goals, limits, and importance values in a data table that you can later reload in DOE platforms.

### Figure 11.13 Responses Outline

<table>
<thead>

<th>Upper Detection Limit</th>
</tr>
</thead>
<tbody>
<tr>
<td>Y</td>
<td>Maximize</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

**Add Response**  
Enters a single response with a goal type of Maximize, Match Target, Minimize, None, or Functional. If you select Match Target, enter limits for your target value. If you select Maximize or Minimize, entering limits is not required but can be useful if you intend to use desirability functions.

**Functional**  
(Available only in JMP Pro.) Adds multiple Y columns with FDE column properties to the design data table. These columns can be used in the Functional Data Explorer platform with the DOE factors as supplementary factors.

**Remove**  
Removes the selected responses.

**Number of Responses**  
Enter additional responses so that the number that you enter is the total number of responses. If you have entered a response other than the default Y, the Goal for each of the additional responses is the Goal associated with the last response entered. Otherwise, the Goal defaults to Match Target. Click the Goal type in the table to change it.

The Responses outline contains the following columns:

**Response Name**  
The name of the response. When added, a response is given a default name of Y, Y2, and so on. To change this name, double-click it and enter the desired name.

**Goal, Lower Limit, Upper Limit**  
The Goal tells JMP whether you want to maximize your response, minimize your response, match a target, or that you have no response goal. JMP assigns a Response Limits column property, based on these specifications, to each response column in the design table. It uses this information to define a desirability function for each response. The Profiler and Contour Profiler use these desirability functions to find optimal factor settings. For further details, see the Profiler chapter in *Profilers* and “Response Limits” on page 784 in the “Column Properties” appendix.
- A Goal of Maximize indicates that the best value is the largest possible. If there are natural lower or upper bounds, you can specify these as the Lower Limit or Upper Limit.

- A Goal of Minimize indicates that the best value is the smallest possible. If there are natural lower or upper bounds, you can specify these as the Lower Limit or Upper Limit.

- A Goal of Match Target indicates that the best value is a specific target value. The default target value is assumed to be midway between the Lower Limit and Upper Limit.

- A Goal of None indicates that there is no goal in terms of optimization. No desirability function is constructed.

**Note:** If your target response is not midway between the Lower Limit and the Upper Limit, you can change the target after you generate your design table. In the data table, open the Column Info window for the response column (Cols > Column Info) and enter the desired target value.

**Importance** When you have several responses, the Importance values that you specify are used to compute an overall desirability function. These values are treated as weights for the responses. If there is only one response, then specifying the Importance is unnecessary because it is set to 1 by default.

**Detection Limits** The lower and upper detection limits are bounds beyond which the response cannot be measured. The detection limits are saved as a column property. You can use these limits to specify a censored response in the Generalized Regression platform. See the Generalized Regression chapter in *Fitting Linear Models*.

**Editing the Responses Outline**

In the Responses outline, note the following:

- Double-click a response to edit the response name.
- Click the goal to change it.
- Click on a limit or importance weight to change it.
- For multiple responses, you might want to enter values for the importance weights.
Response Limits Column Property

The Goal, Lower Limit, Upper Limit, and Importance that you specify when you enter a response are used in finding optimal factor settings. For each response, the information is saved in the generated design data table as a Response Limits column property. JMP uses this information to define the desirability function. The desirability function is used in the Prediction Profiler to find optimal factor settings. For further details about the Response Limits column property and examples of its use, see “Response Limits” on page 784 in the “Column Properties” appendix.

If you do not specify a Lower Limit and Upper Limit, JMP uses the range of the observed data for the response to define the limits for the desirability function. Specifying the Lower Limit and Upper Limit gives you control over the specification of the desirability function. For more details about the construction of the desirability function, see the Profiler chapter in Profiles.

Factors

Factors in a response surface design can only be continuous.

Tip: Use DOE > Custom Design to create response surface designs that involve categorical factors.

The initial Factors panel for a response surface design appears with two continuous factors.

Figure 11.14 Factors Outline

The factors outline contains the following buttons.

Add Enters the number of continuous factors specified.

Remove Selected Removes the selected factors.
Tip: When you have completed your Factors panel, select Save Factors from the red triangle menu. This saves the factor names and values in a data table that you can later reload. See “Response Surface Design Options” on page 374.

The Factors outline contains the following columns:

**Name**  The name of the factor. When added, a factor is given a default name of X1, X2, and so on. To change this name, double-click it and enter the desired name.

**Role**  Specifies the Design Role of the factor as Continuous. The Design Role column property for the factor is saved to the data table. This property ensures that the factor type is modeled appropriately.

**Values**  The experimental settings for the factors. To insert Values, click the default values and enter the desired values.

**Factor Column Properties**

For each factor, various column properties are saved to the data table for the completed design.

**Design Role**  Each factor is assigned the Design Role column property. The Role that you specify in defining the factor determines the value of its Design Role column property. When you select a design with a block, that factor is assigned the Blocking value. The Design Role property reflects how the factor is intended to be used in modeling the experimental data. Design Role values are used in the Augment Design platform.

**Factor Changes**  Each factor is assigned the Factor Changes column property with a setting of Easy. In the Response Surface Design platform, it is assumed that factor levels can be changed for each experimental run. Factor Changes values are used in the Evaluate Design and Augment Design platforms.

**Coding**  If the Design Role is Continuous, the Coding column property for the factor is saved. This property transforms the factor values so that the low and high values correspond to –1 and +1, respectively. The estimates and tests in the Fit Least Squares report are based on the transformed values.

**RunsPerBlock**  Indicates the number of runs in each block. When you select a design with a block and then click Make Table, a factor with the default name Block is added to the Factors list. The RunsPerBlock column property is saved for that factor.
Choose a Design

After you enter your responses and factors and click **Continue**, you select from a list of designs. The designs include two types:

- “Box-Behnken Designs” on page 371
- “Central Composite Designs” on page 371

Select the design that you want to use and click **Continue**.

**Figure 11.15** Choose a Design Panel for Four Factors

### Box-Behnken Designs

Box-Behnken designs have only three levels for each factor and have no design points at the vertices of the cube defined by the ranges of the factors. These designs can be useful when it is desirable to avoid extreme settings for engineering considerations. However, these designs result in higher prediction variance near the vertices than do central composite designs.

### Central Composite Designs

Central composite designs have center points and axial points. An *axial point* is a point where one factor is set to a high or low value (an *axial* value) and all other factors are set to the midrange, or center, value.

A central composite design can have axial points that fall beyond the faces of the hypercube defined by the specified factor ranges. This means that each factor might require five distinct settings, including two that fall beyond the range of values specified in the Factors outline. However, JMP enables you to place design points on the face.

The following types of central composite designs are available:

**Central Composite Design**  The usual central composite design for the specified number of factors.
**CCD-Uniform Precision**  The number of center points is chosen so that the prediction variance near the center of the design space is very flat.

**CCD-Orthogonal**  The number of center points and the axial values are chosen so that the second-order parameter estimates are minimally correlated with the other parameter estimates.

**CCD-Orthogonal Blocks**  The second-order parameter estimates and block effects are minimally correlated with the other parameter estimates.

**Axial Value**

When you select a central composite design and then click **Continue**, you have the option to provide axial scaling information. In placing axial values, the values shown are used to multiply half of the specified range of a factor. If you specify a value of 1.0 next to Axial Value, then axial points in the resulting design are placed on the faces of the cube defined by the factors. You can set the axial value according to the following options:

**Figure 11.16** Axial Value Panel

**Rotatable**  The prediction variance depends only on the scaled distance from the center of the design. The axial points are more extreme than the factor ranges. If this factor range cannot be practically achieved, select **On Face** or specify your own value.

**Orthogonal**  The effects are orthogonal. The axial points are more extreme than the factor ranges. If this factor range cannot be practically achieved, select **On Face** or specify your own value.

**On Face**  Places the axial points at the extremes of the specified factor ranges.

**User Specified**  Places the axial points at a distance specified by the value that you enter in the Axial Value text box.

**Inscribe**  Rescales the design so that the axial points are at the low and high ends of the factor range. The factorial design points are shrunken based on that scaling.

**Specify Output Options**

You can specify details for the output data table in the Output Options panel. When you finish, click **Make Table** to construct the data table for the design.
Run Order

The Run Order options determine the order of the runs in the design table. Choices include the following:

**Keep the Same**  
Rows in the design table are in the same order as in the Design and Anticipated Coefficients outline.

**Sort Left to Right**  
Columns in the design table are sorted from left to right.

**Randomize**  
Rows in the design table are in random order.

**Sort Right to Left**  
Columns in the design table are sorted from right to left.

**Randomize within Blocks**  
Rows in the design table are in random order within the blocks.

Center Points and Replicates

**Number of Center Points**  
The number of center points that appear in the design. A center point is a run where every continuous factor is set at the center of the factor’s range. The initial value shown is the number of center points in the design that you selected.

**Number of Replicates**  
The number of times to replicate the entire design, including center points. One replicate doubles the number of runs.

Make Table

Click Make Table to create a design table that contains the runs for your experiment.

**Figure 11.17** Orthogonal Central Composite Design for Bounce Factors and Response
The **Design** note in the Table panel at the upper left gives the design type that generated the table (Central Composite Design). This information can be helpful if you are comparing multiple designs.

**Pattern Column**

A Pattern column gives a symbolic description of the run in each row in terms of the factor values.

**Tip:** Pattern can be a useful label variable in plots.

### Table 11.1 Pattern Column Description

<table>
<thead>
<tr>
<th>Symbol</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>-</td>
<td>Low value</td>
</tr>
<tr>
<td>+</td>

<td>Midrange (center) value</td>
</tr>
<tr>
<td>a</td>
<td>Low axial value</td>
</tr>
<tr>
<td>A</td>
<td>High axial value</td>
</tr>
</tbody>
</table>

**Design Table Scripts**

The design table includes the following scripts:

- **Model**: Runs the **Analyze > Fit Model** platform.
- **Evaluate Design**: Runs the **DOE > Design Diagnostics > Evaluate Design** platform.
- **DOE Dialog**: Re-creates the Response Surface Design window that you used to generate the design table. The script also contains the random seed used to generate your design.

---

**Response Surface Design Options**

The red triangle menu in the Response Surface Design platform contains these options:

- **Save Responses**: Saves the information in the Responses panel to a new data table. You can then quickly load the responses and their associated information into most DOE windows. This option is helpful if you anticipate reusing the responses.
- **Load Responses**: Loads responses that you saved using the Save Responses option.
**Save Factors**  Saves the information in the Factors panel to a new data table. Each factor’s column contains its levels. Other information is stored as column properties. You can then quickly load the factors and their associated information into most DOE windows.

*Note:* It is possible to create a factors table by entering data into an empty table, but remember to assign each column an appropriate Design Role. Do this by right-clicking on the column name in the data grid and selecting **Column Properties > Design Role**. In the Design Role area, select the appropriate role.

**Load Factors**  Loads factors that you saved using the Save Factors option.

**Save Constraints**  (Unavailable for some platforms) Saves factor constraints that you defined in the Define Factor Constraints or Linear Constraints outline into a data table, with a column for each constraint. You can then quickly load the constraints into most DOE windows.

In the constraint table, the first rows contain the coefficients for each factor. The last row contains the inequality bound. Each constraint’s column contains a column property called **ConstraintState** that identifies the constraint as a “less than” or a “greater than” constraint. See “**ConstraintState**” on page 818 in the “Column Properties” appendix.

**Load Constraints**  (Unavailable for some platforms) Loads factor constraints that you saved using the Save Constraints option.

**Set Random Seed**  Sets the random seed that JMP uses to control actions that have a random component. These actions include one or more of the following:

- initializing search algorithms for design generation
- randomizing Run Order for design construction
- selecting a starting design for designs based on random starts

To reproduce a design, enter the random seed that generated the design before clicking **Make Design**.

*Note:* The random seed associated with a design is included in the DOE Dialog script that is saved to the design data table.

**Simulate Responses**  Adds response values and a column containing a simulation formula to the design table. Select this option before you click Make Table.

When you click Make Table, the following occur:

- A set of simulated response values is added to each response column.
- For each response, a new column that contains a simulation model formula is added to the design table. The formula and values are based on the model that is specified in the design window.
– A Model window appears where you can set the values of coefficients for model effects and specify one of three distributions: Normal, Binomial, or Poisson.

**Note:** Not all distributions are available for all design types.

– A script called **DOE Simulate** is saved to the design table. This script reopens the Model window, enabling you to re-simulate values or to make changes to the simulated response distribution.

Make selections in the Model window to control the distribution of simulated response values. When you click Apply, a formula for the simulated response values is saved in a new column called <Y> Simulated, where Y is the name of the response. Clicking Apply again updates the formula and values in <Y> Simulated.

For additional details, see “Simulate Responses” on page 112 in the “Custom Designs” chapter.

**Note:** You can use Simulate Responses to conduct simulation analyses using the JMP Pro Simulate feature. For more information and DOE examples, see the Simulate chapter in Basic Analysis.

**Save X Matrix** Saves the Moments Matrix and Model Matrix to table scripts in the design data table. These scripts contain the moments and design matrices. See “Save X Matrix” on page 114 in the “Custom Designs” chapter.

**Caution:** For a design with nominal factors, the Model Matrix saved by the Save X Matrix option is not the coding matrix used in fitting the linear model. You can obtain the coding matrix used for fitting the model by selecting the option Save Columns > Save Coding Table in the Fit Model report that you obtain when you run the Model script.

**Save Script to Script Window** Creates the script for the design that you specified in the Response Surface Design window and saves it in an open script window.
A full factorial design defines an experiment where trials are run at all possible combinations of factor settings. A full factorial design allows the estimation of all possible interactions. Full factorial designs are large compared to screening designs, and since high-level interactions are often not active, they can be inefficient. They are typically used when you have a small number of factors and levels and want information about all possible interactions. For example, full factorial designs often form the basis for a measurement systems analysis (MSA).

Full Factorial Design Options ........................................................................ 392
Overview of Full Factorial Design

In a full factorial design, you perform an experimental run at every combination of the factor levels. The sample size is the product of the numbers of levels of the factors. For example, a factorial experiment with a two-level factor, a three-level factor, and a four-level factor has $2 \times 3 \times 4 = 24$ runs.

The Full Factorial Design platform supports both continuous factors and categorical factors with arbitrary numbers of levels. It is assumed that you can run the trials in a completely random fashion.

Full factorial designs are the most conservative of all design types. Unfortunately, because the sample size grows exponentially with the number of factors, full factorial designs are often too expensive to run. Custom designs, definitive screening designs, and screening designs are less conservative but more efficient and cost-effective.

Example of a Full Factorial Design

In this example, you construct a full factorial design to study the effects of five two-level factors (Feed Rate, Catalyst, Stir Rate, Temperature, and Concentration) on the yield of a reactor. Because there are five factors, each at two levels, the full factorial design includes at least $2^5 = 32$ runs. For smaller screening designs involving this experimental situation, see “Additional Examples of Screening Designs” on page 325 in the “Screening Designs” chapter.

In this example, you load the responses and factors from existing tables. When designing a new experiment on your own, enter the responses and factors manually. See “Responses” on page 385 and “Factors” on page 388.

Construct the Design

1. Select \texttt{DOE > Classical > Full Factorial Design}.  
2. Select \texttt{Help > Sample Data Library} and open Design Experiment/Reactor Response.jmp.  
3. Click the Full Factorial Design red triangle and select \texttt{Load Responses}.  
4. Select \texttt{Help > Sample Data Library} and open Design Experiment/Reactor Factors.jmp.  
5. Click the Full Factorial Design red triangle and select \texttt{Load Factors}.  
6. Click \texttt{Continue}. 
Figure 12.2  Full Factorial Example Response and Factors Panels

Note: Setting the Random Seed in step 7 ensures that the runs in your design table appear in the same order as in this example. In constructing a design on your own, this step is not necessary.

7. (Optional) Click the Full Factorial Design red triangle and select Set Random Seed. Type 12345 and click OK.

The Run Order in the Output Options panel is set to Randomize. The order of runs in the design table will be random, as determined by the random seed.

The Number of Runs is set to 32. This is the number of all possible factor level combinations.

8. Click Make Table.

The first column in the design data table shows the factor level combination for each run in terms of + and - signs, indicating high and low factor settings. The table also has an empty Y column named Percent Reacted for entering response values as you conduct the experiment.
Analyze the Experimental Data

Next, proceed to analyze the data from the completed experiment. You will use two methods to analyze the results: Screening and Stepwise Regression. Then you will find optimal settings using the Prediction Profiler.

Analysis Using Screening Platform

1. Select Help > Sample Data Library and open Design Experiment/Reactor 32 Runs.jmp.
2. Run the Screening script.

The Screening report shows a Contrasts report and a Half Normal Plot. The Contrasts report shows estimates for all 31 potential effects, up to the five-way interaction.
Figure 12.4 Contrasts Report for Reactor 32 Runs.jmp

Note: Because the $p$-values in the Contrasts report are obtained using a Monte Carlo simulation, you might not obtain the same values as shown in Figure 12.4. See “Lenth’s Pseudo-Standard Error” on page 351 in the “The Fit Two Level Screening Platform” chapter.

The six highlighted effects in the Contrasts outline are labeled in the Half Normal Plot.
The Half Normal Plot provides strong evidence that at least five of the labeled effects are larger than would be expected if they were the result of random variation. This suggests that these effects are active. The plot does not provide a clear indication that the three-way Concentration*Feed Rate*Stir Rate interaction is active.

In the Contrasts outline in Figure 12.4, the Individual p-Value for the three-way Concentration*Feed Rate*Stir Rate interaction is 0.0705 and its Simultaneous p-Value is 0.7592. Because the effect does not stand out on the Half Normal Plot and because its p-values are large, you decide not to include this effect in your model.

3. In the Half Normal Plot, drag a rectangle to select all labeled effects except for Concentration*Feed Rate*Stir Rate.

4. Click Make Model to open a Fit Model window containing the five effects.

5. Click Run.

The Actual by Predicted plot shows no evidence of lack of fit and the Effect Summary outline shows that all five effects are significant.

**Analysis Using Stepwise Regression**

1. Return to the Reactor 32 Runs.jmp data table, or reopen it by selecting Help > Sample Data Library and opening Design Experiment/Reactor 32 Runs.jmp.

2. Run the Model script.

   The Construct Model Effects list contains only up to two-way interactions. You want to consider all interactions.
3. From the Select Columns list, select Feed Rate through Concentration.

4. Click **Macros > Full Factorial**.
   All possible effects are added in the Construct Model Effects list.

5. Change the **Personality** to **Stepwise**.

6. Click **Run**.

7. Change the **Stopping Rule** to **Minimum AICc**.
   For designed experiments, AICc is preferred to BIC. This is because BIC is typically a more lenient stopping rule than AICc as it tends to allow inactive effects into the model.

8. Click **Go**.
   The Stepwise procedure selects six effects as potentially active.

9. Click **Run Model**.
   This fits a model using the six effects. The Effect Summary outline indicates that Catalyst*Concentration is not significant at the 0.05 significance level as the \( p \)-value is 0.0896.

10. Select Catalyst*Concentration in the Effect Summary outline and click **Remove**.
   The five remaining effects are all highly significant. These are the same five effects that you identified using the Screening platform ("Analysis Using Screening Platform" on page 381).

### Optimal Settings Using the Prediction Profiler

Now, find optimal settings for the three active factors involved in the five significant effects that you retained in your model.

1. In the Reactor 32 Runs.jmp data table, run the **Reduced Model** script.
   The Reduced Model script opens a Fit Model window for the five-effect model that you identified in "Analysis Using Screening Platform" on page 381 and "Analysis Using Stepwise Regression" on page 383.

2. Click **Run**.
   The Prediction Profiler report displays Desirability because in the Full Factorial window, you specified a Goal of Maximize when you defined your response. The desirability function shown in the rightmost cell in the top row of the profiler shows that a value of 100 is most desirable and a value of 90 or below is least desirable.

3. Click the Prediction Profiler red triangle and select **Optimization and Desirability > Maximize Desirability**.
Figure 12.6 Prediction Profiler Showing Settings That Optimize Desirability

![Prediction Profiler](image)

The predicted mean Percent Reacted at the settings that are shown is 95.875, with a confidence interval of 92.91 to 98.84. Note that, for all three factors, the settings that are identified are at the extremes of the ranges used in the experiment. In a future experiment, you should explore the process behavior beyond these settings.

Build a Full Factorial Design

Build a Full Factorial design by selecting **DOE > Classical > Full Factorial Design**. First define your responses and factors. Next, continue to the output options. The design process follows the flow in Figure 12.7. For more information on workflow see “The DOE Workflow: Describe, Specify, Design” on page 59.

Figure 12.7 Full Factorial Design Flow

![Flow Chart](image)

Responses

Use the Responses outline to specify one or more responses.

**Tip:** When you have completed the Responses outline, consider selecting **Save Responses** from the red triangle menu. This option saves the response names, goals, limits, and importance values in a data table that you can later reload in DOE platforms.
Figure 12.8 Responses Outline

<table>
<thead>
<tr>
<th>Responses</th>
<th>Add Response</th>
<th>Remove</th>
<th>Number of Responses</th>
</tr>
</thead>
<tbody>
<tr>
<td>Response Name</td>
<td>Goal</td>
<td>Lower Limit</td>
<td>Upper Limit</td>
</tr>
<tr>
<td>Y</td>
<td>Maximize</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Add Response  Enters a single response with a goal type of Maximize, Match Target, Minimize, None, or Functional. If you select Match Target, enter limits for your target value. If you select Maximize or Minimize, entering limits is not required but can be useful if you intend to use desirability functions.

Functional  (Available only in JMP Pro.) Adds multiple Y columns with FDE column properties to the design data table. These columns can be used in the Functional Data Explorer platform with the DOE factors as supplementary factors.

Remove  Removes the selected responses.

Number of Responses  Enters additional responses so that the number that you enter is the total number of responses. If you have entered a response other than the default Y, the Goal for each of the additional responses is the Goal associated with the last response entered. Otherwise, the Goal defaults to Match Target. Click the Goal type in the table to change it.

The Responses outline contains the following columns:

Response Name  The name of the response. When added, a response is given a default name of Y, Y2, and so on. To change this name, double-click it and enter the desired name.

Goal, Lower Limit, Upper Limit  The Goal tells JMP whether you want to maximize your response, minimize your response, match a target, or that you have no response goal. JMP assigns a Response Limits column property, based on these specifications, to each response column in the design table. It uses this information to define a desirability function for each response. The Profiler and Contour Profiler use these desirability functions to find optimal factor settings. For further details, see the Profiler chapter in Profilers and “Response Limits” on page 784 in the “Column Properties” appendix.

- A Goal of Maximize indicates that the best value is the largest possible. If there are natural lower or upper bounds, you can specify these as the Lower Limit or Upper Limit.
- A Goal of Minimize indicates that the best value is the smallest possible. If there are natural lower or upper bounds, you can specify these as the Lower Limit or Upper Limit.
- A Goal of Match Target indicates that the best value is a specific target value. The default target value is assumed to be midway between the Lower Limit and Upper Limit.
– A Goal of None indicates that there is no goal in terms of optimization. No desirability function is constructed.

**Note:** If your target response is not midway between the Lower Limit and the Upper Limit, you can change the target after you generate your design table. In the data table, open the Column Info window for the response column (Cols > Column Info) and enter the desired target value.

**Importance** When you have several responses, the Importance values that you specify are used to compute an overall desirability function. These values are treated as weights for the responses. If there is only one response, then specifying the Importance is unnecessary because it is set to 1 by default.

**Detection Limits** The lower and upper detection limits are bounds beyond which the response cannot be measured. The detection limits are saved as a column property. You can use these limits to specify a censored response in the Generalized Regression platform. See the Generalized Regression chapter in *Fitting Linear Models*.

**Editing the Responses Outline**

In the Responses outline, note the following:

- Double-click a response to edit the response name.
- Click the goal to change it.
- Click on a limit or importance weight to change it.
- For multiple responses, you might want to enter values for the importance weights.

**Response Limits Column Property**

The Goal, Lower Limit, Upper Limit, and Importance that you specify when you enter a response are used in finding optimal factor settings. For each response, the information is saved in the generated design data table as a Response Limits column property. JMP uses this information to define the desirability function. The desirability function is used in the Prediction Profiler to find optimal factor settings. For further details about the Response Limits column property and examples of its use, see “Response Limits” on page 784 in the “Column Properties” appendix.

If you do not specify a Lower Limit and Upper Limit, JMP uses the range of the observed data for the response to define the limits for the desirability function. Specifying the Lower Limit and Upper Limit gives you control over the specification of the desirability function. For more details about the construction of the desirability function, see the Profiler chapter in *Profilers*.
Factors

Factors in a full factorial design can be continuous or categorical.

Tip: When you have completed the Factors outline, consider selecting Save Factors from the red triangle menu. This option saves the factor names, roles, changes, and values in a data table that you can later reload in DOE platforms.

Figure 12.9 Factors Outline

Continuous  Adds a Continuous factor. The data type in the resulting data table is Numeric. A continuous factor is a factor that you can conceptually set to any value between the lower and upper limits you supply, given the limitations of your process and measurement system.

Categorical  Adds a Categorical factor. Click to select or specify the number of levels. The data type in the resulting data table is Character. The value ordering of the levels is the order of the values, as entered from left to right. This ordering is saved in the Value Order column property after the design data table is created.

The default values for a categorical factor are L1, L2,..., Lk, where k is the number of levels that you specify. Replace the default values with level names that are relevant for your experiment.

Remove  Removes the selected factors.

Add N Factors  Adds multiple factors. Enter the number of factors to add, click Add Factor, and then select the factor type. Repeat Add N Factors to add multiple factors of different types.

Factors Outline

The Factors outline contains the following columns:

Name  The name of the factor. When added, a factor is given a default name of X1, X2, and so on. To change this name, double-click it and enter the desired name.
Role  The Design Role of the factor. The Design Role column property for the factor is saved to the data table. This property ensures that the factor type is modeled appropriately. The Role of the factor determines other factor properties that are saved to the data table. See “Factor Column Properties” on page 389.

Values  The experimental settings for the factors.

Editing the Factors Outline
In the Factors outline, note the following:
• To edit a factor name, double-click the factor name.
• To edit a value, click the value in the Values column.

Factor Column Properties
For each factor, various column properties are saved to the design table after you create the design by selecting Make Table in the Screening Design window. These properties are also saved automatically to the data table that is created when you select the Save Factors option. You can find more information about these column properties and related examples in Appendix A, “Column Properties”.

Coding  If the Role is Continuous, the Coding column property for the factor is saved. This property transforms the factor values so that the low and high values correspond to –1 and +1, respectively. See “Coding” on page 795 in the “Column Properties” appendix.

Value Order  If the Role is Categorical or if a Block variable is constructed, the Value Order column property for the factor is saved. This property determines the order in which levels of the factor appear. See “Value Order” on page 811 in the “Column Properties” appendix.

Design Role  Each factor is given the Design Role column property. The Role that you specify in defining the factor determines the value of its Design Role column property. The Design Role property reflects how the factor is intended to be used in modeling the experimental data. Design Role values are used in the Augment Design platform. See “Design Role” on page 792 in the “Column Properties” appendix.

Factor Changes  Each factor is assigned the Factor Changes column property with the value of Easy. The Factor Changes property reflects how the factor is used in modeling the experimental data. Factor Changes values are used in the Augment Design and Evaluate Design platforms. See “Factor Changes” on page 808 in the “Column Properties” appendix.
Select Output Options

After you enter your responses and factors and click Continue, you can make selections for your design table in the Output Options outline. The structure of the full factorial design appears at the top of the outline.

Figure 12.10 Output Options Panel

Run Order

The Run Order options determine the order of the runs in the design table.

Keep the Same  Rows in the design table are sorted from left to right.

Sort Left to Right  Columns in the design table are sorted from left to right.

Randomize  Rows in the design table are in random order.

Sort Right to Left  Columns in the design table are sorted from right to left.

Center Points and Replicates

Number of Runs  Shows the number of runs in the design before you add center points or replicates.

Number of Center Points  Specifies how many additional runs to add as center points to the design. A center point is a run where every continuous factor is set at the center of the factor’s range.

Suppose that your design includes both continuous and categorical factors. If you request center points in the Output Options panel, the center points are distributed as follows:

1. The settings for the categorical factors are ordered using the value ordering specified in the Factors outline.
2. One center point is assigned to each combination of the settings of the categorical factors in order, and this is repeated until all center points are assigned.

Number of Replicates  The number of times to replicate the entire design, including center points. One replicate doubles the number of runs.
Make Table

Clicking Make Table creates a data table that contains the runs for your experiment. The example in Figure 12.11 shows a full factorial design with five center points for three factors: X1 (a two-level continuous factor), X2 (a three-level continuous factor), and X3 (a two-level categorical factor). The design uses the default values for the factor levels. The center points are in rows 7, 8, 12, 14, and 17. See “Pattern Column” on page 391.

Figure 12.11 Design Data Table

The name of the table, shown in the upper left corner, is the design type that generated it.

Design Table Scripts

The design table includes the following scripts:

- **Model**  Runs the Analyze > Fit Model platform.
- **Evaluate Design**  Runs the DOE > Design Diagnostics > Evaluate Design platform.
- **DOE Dialog**  Re-creates the Full Factorial Design window that you used to generate the design table. The script also contains the random seed used to generate your design.

Run the **Screening** or **Model** scripts to analyze the data.

Pattern Column

The Pattern column contains entries that summarize the run in the given row. You can use Pattern as a label variable in plots.

- For a two-level continuous factor, the low setting is denoted by “–”, the high setting by “+”, and a center point by “0”.
• For a continuous factor with more than two levels:
  – For a non-center point, the factor setting is denoted by an integer that corresponds to the value level for the run.
  – For a center point, the factor setting is denoted by a “0”.
• For a categorical factor, the factor setting is denoted by an integer that corresponds to the value level for the run.

**Full Factorial Design Options**

The red triangle menu in the Full Factorial Design platform contains these options:

**Save Responses**  Saves the information in the Responses panel to a new data table. You can then quickly load the responses and their associated information into most DOE windows. This option is helpful if you anticipate reusing the responses.

**Load Responses**  Loads responses that you saved using the Save Responses option.

**Save Factors**  Saves the information in the Factors panel to a new data table. Each factor’s column contains its levels. Other information is stored as column properties. You can then quickly load the factors and their associated information into most DOE windows.

**Note:** It is possible to create a factors table by entering data into an empty table, but remember to assign each column an appropriate Design Role. Do this by right-clicking on the column name in the data grid and selecting **Column Properties > Design Role**. In the Design Role area, select the appropriate role.

**Load Factors**  Loads factors that you saved using the Save Factors option.

**Save Constraints**  (Unavailable for some platforms) Saves factor constraints that you defined in the Define Factor Constraints or Linear Constraints outline into a data table, with a column for each constraint. You can then quickly load the constraints into most DOE windows.

In the constraint table, the first rows contain the coefficients for each factor. The last row contains the inequality bound. Each constraint’s column contains a column property called **ConstraintState** that identifies the constraint as a “less than” or a “greater than” constraint. See “**ConstraintState**” on page 818 in the “Column Properties” appendix.

**Load Constraints**  (Unavailable for some platforms) Loads factor constraints that you saved using the Save Constraints option.

**Set Random Seed**  Sets the random seed that JMP uses to control actions that have a random component. These actions include one or more of the following:
Chapter 12
Full Factorial Designs

Design of Experiments Guide
Full Factorial Design Options

– initializing search algorithms for design generation
– randomizing Run Order for design construction
– selecting a starting design for designs based on random starts

To reproduce a design, enter the random seed that generated the design before clicking Make Design.

**Note:** The random seed associated with a design is included in the DOE Dialog script that is saved to the design data table.

**Simulate Responses**  Adds response values and a column containing a simulation formula to the design table. Select this option before you click Make Table.

When you click Make Table, the following occur:

– A set of simulated response values is added to each response column.
– For each response, a new column that contains a simulation model formula is added to the design table. The formula and values are based on the model that is specified in the design window.
– A Model window appears where you can set the values of coefficients for model effects and specify one of three distributions: Normal, Binomial, or Poisson.

**Note:** Not all distributions are available for all design types.

– A script called **DOE Simulate** is saved to the design table. This script reopens the Model window, enabling you to re-simulate values or to make changes to the simulated response distribution.

Make selections in the Model window to control the distribution of simulated response values. When you click Apply, a formula for the simulated response values is saved in a new column called \(<Y> \text{ Simulated}\), where \(Y\) is the name of the response. Clicking Apply again updates the formula and values in \(<Y> \text{ Simulated}\).

For additional details, see “Simulate Responses” on page 112 in the “Custom Designs” chapter.

**Note:** You can use Simulate Responses to conduct simulation analyses using the JMP Pro Simulate feature. For more information and DOE examples, see the Simulate chapter in Basic Analysis.

**Advanced Options**  None available.

**Save Script to Script Window**  Creates the script for the design that you specified in the Full Factorial Design window and saves it in an open script window.
Use the Mixture Design platform to build experiments with factors that are components in a mixture. Choose from several classical mixture design approaches, such as simplex, extreme vertices, and lattice. For the extreme vertices approach, you can supply a set of linear inequality constraints limiting the geometry of the mixture factor space.

In mixture experiments, a factor's value is its proportion of the mixture, which falls between zero and one. Mixture experiments have three or more factors with the sum of the factor proportions equal to one (100%). Mixture experiments differ from other experimental types in that you cannot vary factors independently of one another. When you change the proportion of one factor, the proportion of one or more other factors must also change. This simple fact has a profound effect on every aspect of experimentation with mixtures: the factor space, the design properties, and the interpretation of the results.

Because the mixture components are proportions that sum to one, the feasible region of a mixture design takes the form of a simplex. For example, three factor designs can be visualized with a triangular 2-D graph and four factor designs can be visualized with a 3-D tetrahedron.

Overview of Mixture Designs

You can choose from the following types of mixture designs:

**Optimal**  Generates an optimal mixture design using the custom designer. See “Optimal Mixture Design” on page 402.

**Simplex Centroid**  (Available for unconstrained factors or factors with lower bound constraints.) Generates a design of pure mixtures and blends of factors up to a specified degree. In a pure mixture, one component is at 100% and all other components are at 0%. See “Simplex Centroid Design” on page 404.

**Simplex Lattice**  (Available for unconstrained factors or factors with lower bound constraints.) Generates a design of pure mixtures and blends in a space filling triangular grid of runs. You can specify the number of grid levels. See “Simplex Lattice Design” on page 406.

**Extreme Vertices**  (Available when you have linear constraints or restricted upper or lower bounds on one or more of your factors.) Generates a design based on the vertices and combinations of the vertices of a constrained factor space. See “Extreme Vertices Design” on page 407.

**Space Filling**  Generates a space filling design that accommodates linear constraints. See “Space Filling Design” on page 412.

**Note:** The optimal, extreme vertices, and space filling designs can incorporate linear constraints and restrictions on components.

Mixture Design Window

The mixture design window updates as you work through the design steps. See “The DOE Workflow: Describe, Specify, Design” on page 59. The workflow and outlines vary depending on design type.

**Figure 13.2** Mixture Design Workflow
Responses

Use the Responses outline to specify one or more responses.

**Tip:** When you have completed the Responses outline, consider selecting **Save Responses** from the red triangle menu. This option saves the response names, goals, limits, and importance values in a data table that you can later reload in DOE platforms.

**Figure 13.3** Responses Outline

<table>
<thead>
<tr>
<th>Response Name</th>
<th>Goal</th>
<th>Lower Limit</th>
<th>Upper Limit</th>
<th>Importance</th>
<th>Lower Detection Limit</th>
<th>Upper Detection Limit</th>
</tr>
</thead>
<tbody>
<tr>
<td>Y</td>
<td>Maximize</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

**Add Response**  Enters a single response with a goal type of Maximize, Match Target, Minimize, None, or Functional. If you select Match Target, enter limits for your target value. If you select Maximize or Minimize, entering limits is not required but can be useful if you intend to use desirability functions.

**Functional**  (Available only in JMP Pro.) Adds multiple Y columns with FDE column properties to the design data table. These columns can be used in the Functional Data Explorer platform with the DOE factors as supplementary factors.

**Remove**  Removes the selected responses.

**Number of Responses**  Enters additional responses so that the number that you enter is the total number of responses. If you have entered a response other than the default Y, the Goal for each of the additional responses is the Goal associated with the last response entered. Otherwise, the Goal defaults to Match Target. Click the Goal type in the table to change it.

The Responses outline contains the following columns:

**Response Name**  The name of the response. When added, a response is given a default name of Y, Y2, and so on. To change this name, double-click it and enter the desired name.

**Goal, Lower Limit, Upper Limit**  The Goal tells JMP whether you want to maximize your response, minimize your response, match a target, or that you have no response goal. JMP assigns a Response Limits column property, based on these specifications, to each response column in the design table. It uses this information to define a desirability function for each response. The Profiler and Contour Profiler use these desirability functions to find optimal factor settings. For further details, see the Profiler chapter in *Profilers* and “Response Limits” on page 784 in the “Column Properties” appendix.
– A Goal of Maximize indicates that the best value is the largest possible. If there are natural lower or upper bounds, you can specify these as the Lower Limit or Upper Limit.

– A Goal of Minimize indicates that the best value is the smallest possible. If there are natural lower or upper bounds, you can specify these as the Lower Limit or Upper Limit.

– A Goal of Match Target indicates that the best value is a specific target value. The default target value is assumed to be midway between the Lower Limit and Upper Limit.

– A Goal of None indicates that there is no goal in terms of optimization. No desirability function is constructed.

**Note:** If your target response is not midway between the Lower Limit and the Upper Limit, you can change the target after you generate your design table. In the data table, open the Column Info window for the response column (**Cols** > **Column Info**) and enter the desired target value.

**Importance** When you have several responses, the Importance values that you specify are used to compute an overall desirability function. These values are treated as weights for the responses. If there is only one response, then specifying the Importance is unnecessary because it is set to 1 by default.

**JMP PRO Detection Limits** The lower and upper detection limits are bounds beyond which the response cannot be measured. The detection limits are saved as a column property. You can use these limits to specify a censored response in the Generalized Regression platform. See the Generalized Regression chapter in *Fitting Linear Models*.

**Editing the Responses Outline**

In the Responses outline, note the following:

- Double-click a response to edit the response name.
- Click the goal to change it.
- Click on a limit or importance weight to change it.
- For multiple responses, you might want to enter values for the importance weights.
Response Limits Column Property

The Goal, Lower Limit, Upper Limit, and Importance that you specify when you enter a response are used in finding optimal factor settings. For each response, the information is saved in the generated design data table as a Response Limits column property. JMP uses this information to define the desirability function. The desirability function is used in the Prediction Profiler to find optimal factor settings. For further details about the Response Limits column property and examples of its use, see “Response Limits” on page 784 in the “Column Properties” appendix.

If you do not specify a Lower Limit and Upper Limit, JMP uses the range of the observed data for the response to define the limits for the desirability function. Specifying the Lower Limit and Upper Limit gives you control over the specification of the desirability function. For more details about the construction of the desirability function, see the Profiler chapter in Profilers.

Factors

Add factors in the Factors outline.

**Tip:** When you have completed the Factors outline, consider selecting **Save Factors** from the red triangle menu. This saves the factor names, roles, changes, and values in a data table that you can later reload.

Figure 13.4  Factors Outline

<table>
<thead>
<tr>
<th>Factors</th>
</tr>
</thead>
<tbody>
<tr>
<td>Add 1 Mixture</td>
</tr>
<tr>
<td>Remove Selected</td>
</tr>
</tbody>
</table>

**Add**  Enter the number of factors to add and click Add.

**Remove Selected**  Removes the selected factors.
Factors List

The Factors list contains the following columns:

**Name**   The name of the factor. When added, a factor is given a default name of X1, X2, and so on. To change this name, double-click it and enter the desired name.

**Role**   Specifies the Design Role of the factor. The Design Role column property for the factor is saved to the data table. This property ensures that the factor type is modeled appropriately.

**Values**   The experimental settings for the factors. To insert Values, click the default values and enter the desired values.

Editing the Factors List

In the Factors list, do the following:

- To edit a factor name, double-click the factor name.
- To edit a value, click the value in the Values column.

Linear Constraints

Click the **Linear Constraint** button to enter one or more linear inequality constraints. A template appears for a linear expression involving all the continuous factors in your design. Enter coefficient values for the factors and select the direction of the inequality to reflect your linear constraint. Specify the constraining value in the box to the right of the inequality. To add more constraints, click **Linear Constraint** again.

**Note:** When you save a script for a design that involves a linear constraint, the script expresses the linear constraint as a *less than or equal to* inequality (≤).

Ternary Plot Overview

A ternary plot is a two-dimensional representation of three mixture components that sum to a constant. The plot is an equilateral triangle with an edge for each component. When unconstrained, each vertex of the triangle corresponds to a pure blend where one component is 1 (100%) and all other components are 0. When components are constrained, the feasible mixtures are represented by a portion of the ternary plot. Shading is used to exclude infeasible portions of the plot.

Figure 13.5 displays three components P1, P2, and P3. The three components are unconstrained with the range of each proportion ranging from 0 to 1 (100%). Three points are labeled with their coordinates (P1, P2, P3). One point (0.2, 0.2, 0.6) includes blue lines along the axis grid lines for each mixture component to guide you in reading the axes.
Examples of Mixture Design Types

- “Optimal Mixture Design”
- “Simplex Centroid Design”
- “Simplex Lattice Design”
- “Extreme Vertices Design”
- “ABCD Design”
- “Space Filling Design”

Optimal Mixture Design

Optimal mixture designs can be generated using either the Mixture Design Platform or the Custom Design platform.

Here you use the Mixture Platform to create an example optimal mixture design with three factors:

1. Select **DOE > Classical > Mixture Design**.
2. Use three factors for this example. No changes need to be made to the Factors section.
3. Click **Continue**.
4. Click **Optimal** on the Choose Mixture Design Type panel.
5. (Optional) To match the output of this example, click the Mixture Design red triangle and select Set Random Seed, and then enter 1409.
6. (Optional) To match the output of this example, click the Mixture Design red triangle and select Number of Starts, and then enter 2.
7. In the **Define Factor Constraints** panel, click **Specify Linear Constraints**, and then click **Add**.
8. Enter a 1 in the X1 and X2 boxes and enter 0.8 in the constraint box.
   This constrains X1+X2 to less than 80% of the mixture.
9. In the **Model** panel, click **Interactions > 2nd**.
   This adds interaction effects to the model.
10. In the **Design Generation** panel, enter 2 for the **Number of Center Points**.
11. Click **Make Design**.

**Figure 13.6** 12-Run Optimal Design Runs

</tbody>
</table>

12. Click **Make Table**.

**Note:** In practice, you would round the mixtures amounts to the appropriate level of precision.

**Visualize the Design**
1. From the design table, select **Graph > Ternary Plot**.
2. Select X1, X2, and X3 and click **X, Plotting**, and then click **OK**.
Figure 13.7  Ternary Plot for Optimal Design

The ternary plot shows the 7 unique mixtures that make up the design. The shading indicates the constrained region. For more information about ternary plots, see “Ternary Plot Overview” on page 401.

Simplex Centroid Design

A simplex centroid design of degree $k$ with $n$ factors consists of mixtures with the following characteristics:

- all one factor mixtures or pure blends
- all blends of two factors at equal levels
- additional blends, up to $k$ factors at a time blended at $k$ equal levels

A center point run with equal amounts of all the ingredients is included when $k$ is equal to the number of factors.

**Note:** This design can be used with lower bounds on one or more factors.

Creating the Design

To create an example simplex centroid design:

1. Select **DOE > Classical > Mixture Design**.
2. Use three factors for this example. No changes need to be made to the Factors section.
3. Click **Continue**.
4. Click **Simplex Centroid** to generate the design

**Note:** The default setting of $k = 2$ was used. There is a text box that enables you to adjust the value of $k$.

**Figure 13.8** Three Factor Simplex Centroid Design of Degree 2.

<td>0.33333</td>
<td>0.33333</td>
</tr>
</tbody>
</table>

5. Click **Make Table**.

**Visualize the Design**

6. From design table, select **Graph>Ternary Plot**.
7. Select $X_1$, $X_2$, and $X_3$ and click **X, Plotting**, and then click **OK**.

**Figure 13.9** Ternary Plot for Simplex Centroid Design

For more information about ternary plots, see “Ternary Plot Overview” on page 401.
Simplex Lattice Design

The simplex lattice design is a space filling design that creates a triangular grid of runs. The design is the set of blends where the factors’ values are $i/m$, where $i$ varies from 0 to $m$ and the sum of the factors is 1. For a three-level design, a factor can be set at 0, 0.33, 0.66, or 1.

**Note:** This design can be used with lower bounds on one or more factors.

To create an example simplex lattice design:

1. Select **DOE > Classical > Mixture Design**.
2. Use three factors for this example. No changes need to be made to the Factors section.
3. Click **Continue**.
4. Click **Simplex Lattice** to generate the design.

**Note:** The default setting of 5 levels was used. There is a text box that enables you to adjust the number of levels

Figure 13.10 Three Factor Five-Level Simplex Lattice Design

5. Click **Make Table**.

**Visualize the Design**

6. From the design table, select **Graph > Ternary Plot**.
7. Select $X_1$, $X_2$, and $X_3$ and click **X, Plotting**, and then click **OK**.
For more information about ternary plots, see “Ternary Plot Overview” on page 401.

As the number of levels increases, the number of design points increases, decreasing the space between design points. In contrast to the simplex centroid design, the simplex lattice design does not necessarily include the centroid.

**Extreme Vertices Design**

An extreme vertices design requires restricted ranges on one or more of the factors, as defined by limits in the Factors panel or by linear constraints. An extreme vertices design consists of mixtures at the vertices of the factor space and at the averages of vertices up to a specified degree. The centroid point for two neighboring vertices joined by a line is a second-degree centroid. The centroid point for vertices sharing a plane is a third-degree centroid.

**An Extreme Vertices Example with Range Constraints**

To create an example extreme vertices design:

1. Select **DOE > Classical > Mixture Design**.
2. Under Factors, enter 2 for the number of additional factors to add and click **Add**.
3. Set the ranges for the five factors as shown in Figure 13.12 and click **Continue**.
4. Enter 4 in the Degree text box and click Extreme Vertices.

Figure 13.12 Ranges for Five-factors

</tbody>
</table>

5. (Optional) To match the output of this example, click the Mixture Design red triangle and select Set Random Seed, and then enter 1409.

6. Enter 10 in the Choose desired sample size box and click Find Subset to generate the design.

Note: The Find Subset option uses the row exchange method (not coordinate exchange) to find the optimal subset of rows.

Figure 13.14 Ten Run D-optimal Extreme Vertices Design

7. Click Make Table.

Visualize the Design

8. From the design table, select Graph > Ternary Plot.
9. Select \(X_1\), \(X_2\), \(X_3\), \(X_4\), and \(X_5\) and click **X, Plotting**, and then click **OK**.

**Figure 13.15** Partial Output of Ternary Plot for Five-Factor Design

When you have more than three mixture components, the ternary plot shows a series of plots. Each plot has two component axes and the third axis is the sum of all other components. The plots are shaded if you have a constrained region. The unshaded portion represents the feasible region. For more information about ternary plots, see “Ternary Plot Overview” on page 401.

**An Extreme Vertices Example with Linear Constraints**

Consider the classic example presented by Snee (1979) and Piepel (1988). This example has three factors, \(X_1\), \(X_2\), and \(X_3\), with factor bounds and three linear constraints.

To create an extreme vertices design for this example:

1. Select **DOE > Classical > Mixture Design**.
2. Enter the values from Figure 13.16 for \(X_1\), \(X_2\), and \(X_3\) and click **Continue**.

**Figure 13.16** Values and Linear Constraints for the Snee and Piepel Example
3. Click **Linear Constraint** three times. Enter the constraints as shown in Figure 13.16.

4. Click the **Extreme Vertices** button.

5. Click **Make Table**.

**Visualize the Design**

6. From the design table, select **Graph > Ternary Plot**.

7. Select $X_1$, $X_2$, and $X_3$ and click **X, Plotting**, and then click **OK**.

**Figure 13.17** Ternary Plot Showing Piepel Example with Constraints

The ternary plot shows the feasible region as defined by the factor limits and the linear constraints. The design points are at the six vertices of the feasible region, at the six edge mid-points, and the overall centroid. For more information about ternary plots, see “**Ternary Plot Overview**” on page 401.

**Statistical Details for Extreme Vertices Method**

If there are linear constraints, JMP uses the CONSIM algorithm developed by R.E. Wheeler, described in Snee (1979) and presented by Piepel (1988) as CONVRT. The method is also described in Cornell (1990, Appendix 10a). The method combines constraints and checks to see whether vertices violate them. If so, it drops the vertices and calculates new ones. The method named CONAEV for doing centroid points is by Piepel (1988).
If there are no linear constraints (only range constraints), the extreme vertices design is constructed using the XVERT method developed by Snee and Marquardt (1974) and Snee (1975). After the vertices are found, a simplex centroid method generates combinations of vertices up to a specified order.

The XVERT method first creates a full \(2^{n_f - 1}\) design using the given low and high values of the \(n_f - 1\) factors with smallest range. Then, it computes the value of the one factor left out based on the restriction that the factors’ values must sum to one. It keeps points that are not in factor’s range. If not, it increments or decrements the value to bring it within range, and decrements or increments each of the other factors in turn by the same amount. This method keeps the points that still satisfy the initial restrictions.

The above algorithm creates the vertices of the feasible region in the simplex defined by the factor constraints. However, Snee (1975) has shown that it can also be useful to have the centroids of the edges and faces of the feasible region. A generalized \(n\)-dimensional face of the feasible region is defined by \(n_f - n\) of the boundaries and the centroid of a face defined to be the average of the vertices lying on it. The algorithm generates all possible combinations of the boundary conditions and then averages over the vertices generated on the first step.

**ABCD Design**

The ABCD Design is a screening design for mixtures. See Snee (1975).

To create an example ABCD design:

1. Select **DOE > Classical > Mixture Design**.
2. Under Factors, enter 3 for the number of additional factors to add and click **Add**.
3. Click **Continue**.
4. Click **ABCD Design**.

**Figure 13.18** 14 of the 28 Run 6 Factor ABCD Design

5. Click **Make Table**.
Space Filling Design

The Space Filling mixture designs spread design points throughout the design region. It accommodates linear constraints. The design is generated in a fashion similar to the Fast Flexible Filling design method found under DOE > Special Purpose > Space Filling Design (“Fast Flexible Filling Designs” on page 639).

Two Mixture Design red triangle options relate specifically to Space Filling Designs:

**FFF Optimality Criterion** For the Fast Flexible Filling mixture design type, enables you to select between the MaxPro criterion (the default) and the Centroid criterion. See “FFF Optimality Criterion” on page 413.

**Advanced Options > Set Average Cluster Size** For the Fast Flexible Filling mixture design type, enables you to specify the average number of randomly generated points used to define each cluster or, equivalently, each design point. See “Set Average Cluster Size” on page 414.

Space Filling Example

To create an example space filling design:

1. Select **DOE > Classical > Mixture Design**.
2. (Optional) To match the output of this example click the Mixture Design red triangle and select Set Random Seed and enter 1409.
3. Use three factors for this example. No changes need to be made to the Factors section.
4. Click **Continue**.
5. Click **Linear Constraints**
6. Enter 0.7 in the X1 box, 1 in the X3 box, change the direction of the inequality to ≥ and enter 0.4 in the constraint box.
   
   This constrains 0.7X1+X3 to at least 40% of the mixture.
7. Enter 30 in the **Runs** box.
8. Click **Space Filling**.
9. Click **Make Table**.

**Visualize the Design**

10. From the design table, select **Graph > Ternary Plot**.
11. Select X1, X2, and X3 and click **X, Plotting**, and then click **OK**.
**Figure 13.19** Space Filling Design with One Linear Constraint

This design is constructed using the Centroid FFF Optimality Criterion. Note that the points fall in the constrained design region and are fairly well spread throughout this region. For more information about ternary plots, see “Ternary Plot Overview” on page 401.

**Statistical Details for Mixture Space Filling Designs**

**FFF Optimality Criterion**

The algorithms for Fast Flexible Filling designs begin by generating a large number of random points within the specified design region. These points are then clustered using a Fast Ward algorithm into a number of clusters that equals the Number of Runs that you specified.

The final design points can be obtained by using the default MaxPro (maximum projection) optimality criterion or by selecting the Centroid criterion. You can find these options under FFF Optimality Criterion in the report’s red triangle menu.

**MaxPro** For \( p \) factors and \( n \) equal to the specified Number of Runs, the MaxPro criterion strives to find points in the clusters that minimize the following criterion:

\[
C_{MaxPro} = \sum_{i}^{n-1} \sum_{j=i+1}^{n} \left[ \frac{1}{p} \prod_{k=1}^{p} (x_{ik} - x_{jk})^2 \right]
\]

The MaxPro criterion maximizes the product of the distances between potential design points in a way that involves all factors. This supports the goal of providing good space-filling properties on projections of factors. See Joseph et al. (2015). The Max Pro option is the default.
Centroid  This method places a design point at the centroid of each cluster. It has the property that the average distance from an arbitrary point in the design space to its closest neighboring design point is smaller than for other designs.

Note: You can set a preference to always use a given optimality criterion. Select File > Preferences > Platforms > DOE. Select FFF Optimality Criterion and select your preferred criterion.

Set Average Cluster Size

The Set Average Cluster Size option is found under Advanced Options in the Mixture Design red triangle menu. This option enables you to specify the average number of uniformly generated points used to define each cluster or, equivalently, each design point.

By default, if the number of Runs for the Space Filling design type is 200 or smaller, a total of 10,000 random uniformly generated points are used as the basis for the clustering algorithm. When the number of Runs exceeds 200, the default value is 50. Increasing this value can be particularly useful in designs with a large number of factors.

Note: Depending on the number of factors and the specified value for Runs, you might want to increase the average number of initial points per design point by selecting Advanced Options > Set Average Cluster Size.

Linear Constraints

The design region can be restricted by selecting the Linear Constraint option in the Linear Constraints outline.

When you specify linear constraints, the random points that form the basis for the clustering algorithm are randomly distributed within the constrained design region. The clustering algorithm uses these points.

Fitting Mixture Designs

When fitting a model for mixture designs, one must take into account that the factors sum to a constant. A traditional full linear model is not fully estimable.

An appropriate response surface model for mixture responses is the Scheffé polynomial (Scheffé 1958). See the discussion of Cox Mixtures and the Scheffé cubic macro in Fitting Linear Models. The Scheffé polynomial model does the following:

• suppresses the intercept
• includes all the linear main-effect terms
• excludes all the square terms (such as X1*X1)
• includes all the cross terms (such as X1*X2)

In this model, the parameters are easy to interpret (Cornell 1990). The coefficients on the linear terms are the fitted response at the extreme points where the mixture consists of a single factor. The coefficients on the cross terms indicate the curvature across each edge of the factor space.

For a mixture model with third-degree polynomial terms, the Scheffé cubic model can be used. The Scheffé cubic model includes terms of the form X1*X2*(X1-X2).

• To fit a Scheffé polynomial model use the Mixture Response Surface macro in the Fit Model platform.
• To fit the Scheffé cubic model use the Scheffe Cubic macro in the Fit Model platform.
• If you chose to fit a different mixture model the Fit Model platform includes options for a No Intercept model and Mixture Effects as an effect attribute.

**Tip:** The custom design model outline has an option for adding the Scheffé cubic model terms. The generated design table will include a script for the Scheffé cubic model.

### Whole Model Tests and Analysis of Variance Reports

In a whole-model Analysis of Variance table, JMP traditionally tests that all the parameters are zero except for the intercept. In a mixture model without an intercept, JMP looks for a hidden intercept, in the sense that a linear combination of effects is a constant. If it finds a hidden intercept, it does the whole model test with respect to the intercept model rather than a zero-intercept model. This test is equivalent to testing that all the parameters are zero except the linear parameters, and testing that they are equal.

The hidden-intercept property also causes the $R^2$ to be reported with respect to the intercept model rather than reported as missing.

### Understanding Response Surface Reports

When there are effects marked as response surface effects “&RS,” JMP creates additional reports that analyze the fitted response surface. These reports were originally designed for full response surfaces, not mixture models. However, JMP might encounter a no-intercept model and find a hidden intercept with linear response surface terms, but no square terms. Then it *folds* its calculations, collapsing on the last response surface term to calculate critical values for the optimum. This can be done for any combination that yields a constant and involves the last response surface term.
A Chemical Mixture Example

Three plasticizers (p1, p2, and p3) comprise 79.5% of the vinyl used for automobile seat covers (Cornell, 1990). Within this 79.5%, the individual plasticizers are restricted by the following constraints: 0.409 ≤ x1 ≤ 0.849, 0 ≤ x2 ≤ 0.252, and 0.151 ≤ x3 ≤ 0.274. Cornell uses a 14-run design to fit a quadratic mixture model to the collected responses. The design is a 3-degree extreme vertices design with replicate measurements taken at the four vertices and the overall centroid.

- “Create the Design”
- “Analyze the Mixture Model”
- “The Prediction Profiler”
- “The Mixture Profiler”

Create the Design

To create Cornell’s mixture design in JMP

1. Select Help > Sample Data Library and open Plastifactors.jmp.
2. Select DOE > Classical > Mixture Design.
3. Click the Mixture Design red triangle and select Load Factors.

Figure 13.20 Factors and Factor Constraints for the Plasticizer Experiment

4. Click Continue.
5. Enter 3 in the Degree box.
6. Click Extreme Vertices.
7. Click Make Table. JMP uses the 9 factor settings to generate a JMP table.
**Figure 13.21** Extreme Vertices Mixture Design

</tr>
</tbody>
</table>

**Note:** Your table might differ due to the random seed used to generate the design.

Next, you add an extra five design runs by duplicating the vertex points and overall centroid, to generate the 14 run design.

8. To identify the vertex points and the centroid use a ternary plot. From the design table, select **Graph > Ternary Plot**.

9. Select p1, p2, and p3 and click **X, Plotting**, and then click **OK**.

**Figure 13.22** Ternary Plot for Design

10. Highlight the vertices and centroid points.
11. Select **Edit > Copy**, to copy the selected rows to the clipboard.

12. Click in the first cell of row 10 and select **Edit > Paste** to add the duplicate rows to the table.

**Note:** A similar design can be obtained using the custom designer with the quadratic model, 2 center points, 4 replicate designs, and 14 runs.

The Plasticizer design with the results (Y values) that Cornell obtained are available in the sample data file Plasticizer.jmp.

### Analyze the Mixture Model

To analyze the Plasticizer experiment use the sample data table Plasticizer.jmp.

1. Select **Help > Sample Data Library** and open Plasticizer.jmp.

2. Click the green triangle next to the **Model** script in the upper left corner of the data table. A completed Fit Model launch window appears.

**Note:** The model script is saved to the design table when you create a design.

3. Click **Run** to see the response surface analysis.

4. Plasticizer.jmp contains a column called **Pred Formula Y**. This column was added after the analysis by selecting **Save Columns > Prediction Formula** from the Response Y red triangle.

5. To see the prediction formula, click the plus symbol in the column list:

\[
\]

**Note:** These results correct the coefficients reported in Cornell (1990).
The Response Surface Solution report shows that a maximum predicted value of 19.570299 occurs at point (0.63505, 0.15568, 0.20927).

Figure 13.24  Mixture Response Surface Analysis

The report contains a prediction profiler.

1. From the prediction profiler you can see how the crossed effects show as curvature in the prediction traces. As you change values of one component (drag the red lines) the values of the other two components move in the opposite direction to maintain their ratio and the overall mixture constraint (components must sum to 100%).

   Note: The axes of prediction profiler traces range from the defined upper and lower bounds of the factors, p1, p2, and p3. When you explore the effect of a component and the limit of a second component is reached, it cannot move further and only the third variable changes to maintain the mixture constraint.

2. To the visible profile curves to bounds that take into account the levels of all three components, click the Prediction Profiler red triangle and select **Profile at Boundary > Stop at Boundaries**.

3. To optimize the mixture components click the Prediction Profiler red triangle and select **Optimization and Desirability > Desirability Functions**.

4. Click the Prediction Profiler red triangle and select **Optimization and Desirability > Maximize Desirability** to obtain the optimal factor settings for maximum Y.

The profiler displays optimal settings (rounded) of 0.6350 for p1, 0.1557 for p2, and 0.2093 for p3, which give an estimated response of 19.5703.
The Mixture Profiler

The Fit Model report also has a **Mixture Profiler** that is useful for visualizing and optimizing response surfaces from mixture experiments. Many of the features are the same as those of the Contour Profiler. However, some are unique to the Mixture Profiler:

- A ternary plot is used instead of a Cartesian plot, which enables you to view three mixture factors at a time.
- If you have more than three factors, radio buttons let you choose which factors to plot.
- If the factors have constraints, you can enter their low and high limits in the Lo Limit and Hi Limit columns. This setting shades non-feasible regions in the profiler.

Click the Response Y red triangle and select **Factor Profiling > Mixture Profiler** to see the mixture profiler for the plasticizer data.
Figure 13.26 Mixture Profiler for Plasticizer Example
A Taguchi design uses crossed array to explore factors in the presence of noise. A Taguchi design has two parts: the inner array is a design for control factors, and the outer array is a design for the noise factors. The full design is the cross product of the two arrays.

Note that noise factors in production that are not easy or cost effective to control must be controlled during an experiment. Alternatives to Taguchi designs include combined arrays and mixed resolution designs (Borror and Montgomery, 2000). For an example of a design with noise factors using the custom designer see “Experiments for Robust Process and Product Design” on page 209 in the “Examples of Custom Designs” chapter.

Overview of Taguchi Designs

A Taguchi Design uses two types of factors: control factors and noise factors.

- An inner design is constructed for the control factors.
- An outer design is constructed for the noise factors.

The experiment is performed on all combinations of the inner and outer design runs. The noise factors have to be controlled during the experiment. The mean and standard deviation for each setting in the inner array across the noise settings are combined into a signal-to-noise measure for analysis. Table 14.1 lists the signal-to-noise performance statistics.

<table>

Example of a Taguchi Design

Use a Taguchi design to study four control factors evaluated across three noise factors. This example is an experiment described by Byrne and Taguchi (1986). The objective of the experiment is to find settings of control factors to maximize the adhesiveness (pull-off force) of nylon tubing.

The design has four signal factors:

- **Interfer** Tubing and connector interference. Signal factor with 3 levels.
- **Wall** Wall thickness of the connector. Signal factor with 3 levels.
- **Depth** Insertion depth of the tubing into the connector. Signal factor with 3 levels.
- **Adhesive** Percent of adhesive. Signal factor with 3 levels.
The design has three noise factors:

**Time**  Conditioning time. Noise factor with 2 levels.

**Temperature**  Temperature. Noise factor with 2 levels.

**Humidity**  Relative humidity. Noise factor with 2 levels.

**Create the Design**

1. Select **DOE > Classical > Taguchi Arrays**.
2. Select **Help > Sample Data Library** and open **Design Experiment/Byrne Taguchi Factors.jmp**.
3. In the Taguchi Arrays window, click the Taguchi Design red triangle and select **Load Factors**.

   The Factors panel shows the four three-level control (signal) factors and three noise factors.

   **Note:** The Goal selected for the response determines the SN Ratio formula that is added to your design data table.

4. Ensure that **L9-Taguchi** is selected for the inner array.
5. Click **L8** for the outer array design.

**Figure 14.2  Completed Taguchi Design Window**

6. Click **Continue**.
7. Click **Make Table** to create the design table shown in Figure 14.3.
The inner array has nine runs for the four signal factors, each at three levels. The settings for the signal factors are provided in the first four columns of the table.

The outer design is a full factorial design for the three two-level noise factors. The outer array is provided in eight columns of the data table. The column names are the pattern of the outer array runs. For example, the column named “---” is for the results collected when all of the noise levels are at their low levels. Each of the nine trials are conducted at each of the eight combination of noise factors for a total of 72 experimental trials.

The design table allows for entry of the 72 experimental results.

8. Select Help > Sample Data Library and open Design Experiment/Byrne Taguchi Data.jmp.

Figure 14.4 Complete Taguchi Design Table (Byrne Taguchi Data.jmp)

The SN Ratio Y column is the performance statistic (larger is better) to maximize the response. It is computed as \(-10\) times the common logarithm of the average of the squared reciprocals of the responses:

\[
-10\log_{10}\left[ \frac{1}{(Y++-)^2} \frac{1}{(Y+-+)^2} \frac{1}{(Y--+)^2} \frac{1}{(Y+-+)^2} \frac{1}{(Y++-)^2} \right]
\]

This expression is large when all of the individual \(y\) response values are large. That is, you are trying to find the signal settings that result in the largest response across the noise settings.
Analyze the Data

The data are now ready to analyze. The goal of the analysis is to find factor settings that maximize both the mean and the signal-to-noise ratio.

1. In the Byrne Taguchi Data.jmp data table, click the green arrow to run the Model script.

**Figure 14.5** Fit Model Launch Window for Taguchi Data

The script launches the Fit Model window. The model includes the main effects of the four signal factors to model the mean (Mean Y) and signal-to-noise ratio (SN Ratio Y) responses.

2. Click Run.

The Prediction Profiler at the bottom of the report is a quick way to find settings that give the highest signal-to-noise ratio for this experiment and the mean value at that maximum.

**Figure 14.6** The Prediction Profiler
3. Click the Prediction Profiler red triangle and select **Optimization and Desirability > Desirability Functions**.

   This adds a row of traces and a column of function settings to the profiler, as shown in Figure 14.7. The default desirability functions are set to larger-is-better, which is what you want in this experiment. See Profilers for more information about desirability functions in the prediction profiler.

4. Click the Prediction Profiler red triangle and select **Optimization and Desirability > Maximize Desirability**.

**Figure 14.7** Best Factor Settings for Byrne Taguchi Data

In this example, the optimal settings for Interfer and Wall are 2, Depth is 3, and Adhesive is 1. These settings result in a predicted Mean value of 22.8 and an SN Ratio of 26.9.

---

**Build a Taguchi Design**

Build a Taguchi Design by selecting **DOE > Classical > Taguchi Arrays**. First define your responses and factors. Next, continue to the design options, generation, and evaluation. The design process follows the flow in Figure 14.8. See “The DOE Workflow: Describe, Specify, Design” on page 59.

**Figure 14.8** Taguchi Design Flow
Responses

Use the Response outline to specify a response for a Taguchi design.

**Figure 14.9  Response Outline**

<table>
<thead>
<tr>
<th>Response Name</th>
<th>Goal</th>
<th>Lower Limit</th>
<th>Upper Limit</th>
<th>Importance</th>
</tr>
</thead>
<tbody>
<tr>
<td>Y</td>
<td>Larger Is Better</td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

The Response outline contains the following columns:

**Response Name**  The name of the response (the default is Y). To change this name, double-click it and enter a different name.

**Goal, Lower Limit, Upper Limit**  The Goal determines the form of the signal-to-noise function (Table 14.1 on page 425). Select one of the following Goals: Larger Is Better, Nominal is Best, Smaller is Better, or None. When you create your design, JMP saves a formula for the SN Ratio to the data table that reflects your selected goal. To change a goal, click it and enter a different goal. Use the Lower and Upper Limits if you have limits on your response.

**Importance**  When you have several responses, the Importance values that you specify are used to compute an overall desirability function. These values are treated as weights for the responses. In a Taguchi Design there is only one response, the Importance is set to 1 by default. No value is needed for the Importance.

Factors

Use the Factors outline to specify factors for a Taguchi Design.

**Signal**  Specify two or more 2- or 3-level signal factors. Signal factors are system control inputs. These are factors that you can control in production.

**Noise**  Specify one or more noise factors. Noise factors are variables that are difficult or expensive to control in production. However, you must be able to control noise factors during the experiment. Click Noise to add a noise factor.

**Remove**  Removes the selected factors.

**Name**  The name of the factor. When added, a factor is given a default name of X1, X2, and so on. To change this name, double-click it and enter a different name.

**Role**  Specifies the Design Role (Signal or Noise) of the factor. This is set when you add the factor.
Values  The experimental settings for the factors. To insert Values, click the default values and enter the desired values.

Figure 14.10  Factors Outline

<table>

<td>Signal</td>
<td>1, 2</td>
</tr>
</tbody>
</table>

Choose Taguchi Inner and Outer Array Designs

The Choose Inner and Outer Array Design options appear after you clickContinue in the Specify Factors panel. Based on your signal factors, you get one or more choices for orthogonal designs for the inner array. The outer array choices for orthogonal “L” designs depend on the number and type of factors in your design.

Display Coded Design

After you select a design type for the inner and outer arrays, the Coded Design is shown when your inner array has two-level factors.

Figure 14.11  Coding for Eight Factor L12 Design

The Coded Design shows the pattern of high and low values for the factors in each run.
Make the Design Table

When you click **Make Table**, a Taguchi Design table similar to the one in Figure 14.12 appears. In the data table, each row represents an inner array run. In the values for the **Pattern** variable, plus signs designate high levels, and minus signs represent low levels. The table also contains a column for each factor and a column for each pattern that appears in the Pattern column. The columns for the patterns contain the responses to the experiment. If you selected Simulate Responses from the Taguchi Design red triangle menu, the pattern columns are filled with simulated response values.

![Figure 14.12 Taguchi Design Table for an Eight Factor L12 Design](image)

Taguchi Design Options

The Taguchi Design red triangle menu contains options for design setup and generation.

**Save Responses**  Saves the information in the Responses panel to a new data table. You can then quickly load the responses and their associated information into most DOE windows. This option is helpful if you anticipate reusing the responses.

**Load Responses**  Loads responses that you saved using the Save Responses option.

**Save Factors**  Saves the information in the Factors panel to a new data table. Each factor’s column contains its levels. Other information is stored as column properties. You can then quickly load the factors and their associated information into most DOE windows.

**Note:** It is possible to create a factors table by entering data into an empty table, but remember to assign each column an appropriate Design Role. Do this by right-clicking on the column name in the data grid and selecting **Column Properties > Design Role**. In the Design Role area, select the appropriate role.

**Load Factors**  Loads factors that you saved using the Save Factors option.

**Save Constraints**  (Unavailable for some platforms) Saves factor constraints that you defined in the Define Factor Constraints or Linear Constraints outline into a data table, with a
column for each constraint. You can then quickly load the constraints into most DOE windows.

In the constraint table, the first rows contain the coefficients for each factor. The last row contains the inequality bound. Each constraint’s column contains a column property called **ConstraintState** that identifies the constraint as a “less than” or a “greater than” constraint. See “**ConstraintState**” on page 818 in the “Column Properties” appendix.

**Load Constraints**  (Unavailable for some platforms) Loads factor constraints that you saved using the Save Constraints option.

**Set Random Seed**  Sets the random seed that JMP uses to control actions that have a random component. These actions include one or more of the following:

– initializing search algorithms for design generation
– randomizing Run Order for design construction
– selecting a starting design for designs based on random starts

To reproduce a design, enter the random seed that generated the design before clicking **Make Design**.

**Note:** The random seed associated with a design is included in the DOE Dialog script that is saved to the design data table.

**Simulate Responses**  Adds response values and a column containing a simulation formula to the design table. Select this option before you click Make Table.

When you click Make Table, the following occur:

– A set of simulated response values is added to each response column.
– For each response, a new column that contains a simulation model formula is added to the design table. The formula and values are based on the model that is specified in the design window.
– A Model window appears where you can set the values of coefficients for model effects and specify one of three distributions: Normal, Binomial, or Poisson.

**Note:** Not all distributions are available for all design types.

– A script called **DOE Simulate** is saved to the design table. This script reopens the Model window, enabling you to re-simulate values or to make changes to the simulated response distribution.

Make selections in the Model window to control the distribution of simulated response values. When you click Apply, a formula for the simulated response values is saved in a
new column called \(<Y>\) Simulated, where \(Y\) is the name of the response. Clicking Apply again updates the formula and values in \(<Y>\) Simulated.

For additional details, see “Simulate Responses” on page 112 in the “Custom Designs” chapter.

**Note:** You can use Simulate Responses to conduct simulation analyses using the JMP Pro Simulate feature. For more information and DOE examples, see the Simulate chapter in *Basic Analysis.*
Using the Evaluate Design platform, you can:

- See the strengths and limitations of your existing experimental design.
- Determine your design’s ability to detect effects associated with meaningful changes in the response.
- Address prediction variance and the precision of your estimates.
- Gain insight on aliasing.
- Obtain efficiency measures.

The Evaluate Design platform generates the results that appear in the Design Evaluation outlines provided by several DOE platforms. Diagnostics provided by both Evaluate Design and the Design Evaluation outlines include the following:

- power analysis
- a prediction variance profiler and surface plot
- a fraction of design space plot, showing how much of the design space has prediction variance above a given value
- estimation efficiency measures for parameter estimates
- the alias matrix, showing the bias structure for model effects
- a color map showing absolute correlations among effects
- design efficiency values

Overview of the Evaluate Design Platform

The Evaluate Design platform provides powerful tools that enable you to assess the properties of your design, whether it is created by JMP or another tool. You can use the platform before conducting an experiment to choose from several designs. You can also assess the impact of incorrect settings or lost runs in a design that you have conducted. You can modify the terms in your assumed model to see the impact of estimating a modified model. You can also modify the terms that appear in the Alias Terms outline to see the impact on the Alias Matrix.

You start by entering information about the design in the launch window. Then you can modify the assumed model and specify which effects not included in the model are of potential interest. Based on your specifications, the Design Evaluation platform then provides a number of ways to evaluate the properties of the generated design:

**Power Analysis**  Enables you to explore your ability to detect effects of given sizes.

**Prediction Variance Profile**  Shows the prediction variance over the range of factor settings.

**Fraction of Design Space Plot**  Shows how much of the model prediction variance lies below or above a given value.

**Prediction Variance Surface**  Shows a surface plot of the prediction variance for any two continuous factors.

**Estimation Efficiency**  For each parameter, gives the fractional increase in the length of a confidence interval compared to that of an ideal (orthogonal) design, which might not exist. Also gives the relative standard error of the parameters.

**Alias Matrix**  Gives coefficients that indicate the degree to which the model parameters are biased by effects that are potentially active, but not in the model.

**Color Map on Correlations**  Shows the absolute correlations between effects on a plot using an intensity scale.

**Note:** The default intensity scale is a gray scale. To change the color scale, click the Color Map on Correlations red triangle and select Blue to Gray to Red. For a custom color scale, right-click in the plot and select Color Theme.

**Design Diagnostics**  Gives efficiency measures for your design.

**Note:** In several DOE platforms, when you construct a design, a Design Evaluation outline appears. This outline shows results provided by the Evaluate Design platform. The platforms that provide a Design Evaluation outline are: Custom Design, Definitive Screening Design, Screening Design, Response Surface Design, and Mixture Design with Optimal design type.
Example of Evaluate Design

- “Assessing the Impact of Lost Runs”
- “Evaluating Power Relative to a Specified Model”

Assessing the Impact of Lost Runs

An experiment was conducted to explore the effect of three factors (Silica, Sulfur, and Silane) on tennis ball bounciness (Stretch). The goal of the experiment is to develop a predictive model for Stretch. A 15-run Box-Behnken design was selected using the Response Surface Design platform. After the experiment, the researcher learned that the two runs where Silica = 0.7 and Silane = 50 were not processed correctly. These runs could not be included in the analysis of the data.

Use the Evaluate Design platform to assess the impact of not including those two runs. Obtain diagnostics for the intended 15-run design and compare these to the actual 13-run design that is missing the two runs.

Construct the Intended and Actual Designs

Intended Design

1. Select Help > Sample Data Library and open Design Experiment/Bounce Data.jmp.
2. Select DOE > Design Diagnostics > Evaluate Design.
   You can add Stretch as Y, Response if you wish. But specifying the response has no effect on the properties of the design.
4. Click OK.

Leave your Evaluate Design window for the intended design open.

Tip: Place the Evaluate Design window for the intended design in the left area of your screen. After the next steps, you will place the corresponding window for the actual design to its right.
Actual Design with Missing Runs

In this section, you will exclude the two runs where Silica = 0.7 and Silane = 50. These are rows 3 and 7 in the data table.

1. In Bounce Data jmp, select rows 3 and 7, right-click in the highlighted area, and select Hide and Exclude.
2. Select DOE > Design Diagnostics > Evaluate Design.
3. Click Recall.
4. Click OK.

Leave your Evaluate Design window for the actual design open.

Tip: Place the Evaluate Design window for the actual design to the right of the Evaluate Design window for the intended design to facilitate comparing the two designs.

Comparison of Intended and Actual Designs

You can now compare the two designs using these methods:

- “Power Analysis” on page 439
- “Prediction Variance Profile” on page 440
- “Fraction of Design Space Plot” on page 442
- “Estimation Efficiency” on page 443
- “Color Map on Correlations” on page 444
- “Design Diagnostics” on page 445

Power Analysis

In each window, do the following:

1. Open the Power Analysis outline.
   The outline shows default values of 1 for all Anticipated Coefficients. These values correspond to detecting a change in the anticipated response of 2 units across the levels of main effect terms, assuming that the interaction and quadratic terms are not active.
   The power calculations assume an error term (Anticipated RMSE) of 1. From previous studies, you believe that the RMSE is approximately 2.

2. Type 2 next to Anticipated RMSE.
   When you click outside the text box, the power values are updated.
   You are interested in detecting differences in the anticipated response that are on the order of 6 units across the levels of main effects, assuming that interaction and quadratic terms are not active. To set these uniformly, use a red triangle option.
3. Click the Power Analysis red triangle and select **Set Delta for Power**
4. Type 6 as your value for delta.
5. Click **OK**.

Figure 15.2 shows both outlines, with the Design and Anticipated Responses outline closed.

**Figure 15.2** Power Analysis Outlines, Intended Design (Left) and Actual Design (Right)

The power values for the actual design are uniformly smaller than for the intended design. For Silica and Sulfur, the power of the tests in the intended design is almost twice the power in the actual design. For the Silica*Sulfur interaction, the power of the test in the actual design is 0.231, compared to 0.672 in the intended design. The actual design results in substantial loss of power in comparison with the intended design.

**Prediction Variance Profile**

1. In each window, open the Prediction Variance Profile outline.
2. In the window for the actual design, right-click on the vertical axis and from the menu select **Edit > Copy Axis Settings**.
   This action creates a script containing the axis settings. Next, apply these axis settings to the Prediction Variance Profile plot for the intended design.
3. In the Evaluate Design window for the intended design, locate the Prediction Variance Profile outline. Right-click on the vertical axis and from the menu select **Edit > Paste Axis Settings**.
   The plots are shown in Figure 15.5, with the plot for the intended design at the top and for the actual design at the bottom.
Figure 15.3 Prediction Variance Profile, Intended Design (Top) and Actual Design (Bottom)

The Prediction Variance Profile plots are profiler views of the relative prediction variance. You can explore the relative prediction variance in various regions of design space.

Both plots show the same relative prediction variance in the center of the design space. However, the variance for points near the edges of the design space appears greater than for the same points in the intended design. Explore this phenomenon by moving all three vertical lines to points near the edges of the factor settings.

4. In both windows, click the Prediction Variance Profile red triangle and select Maximize Variance.

Figure 15.4 shows the maximum relative prediction variance for the intended and actual designs.
Figure 15.4 Prediction Variance Profile Maximized, Intended Design (Top) and Actual Design (Bottom)

For both designs, the profilers identify the same point as one of the design points where the maximum prediction variance occurs: Silica=0.7, Sulfur=1.8, and Silane=40. The maximum prediction variance is 1.396 for the intended design, and 3.021 for the actual design. Note that there are other points where the prediction variance is maximized. The larger maximum prediction variance for the actual design means that predictions in parts of the design space are less accurate than they would have been had the intended design been conducted.

Fraction of Design Space Plot

1. In each window, open the Fraction of Design Space Plot outline.
2. In the window for the intended design, right-click in the plot and select Edit > Copy Frame Contents.
3. In the window for the actual design, locate the Fraction of Design Space Plot outline.
4. Right-click in the plot and select Edit > Paste Frame Contents.

Figure 15.5 shows the plot with annotations. Each Fraction of Design Space Plot shows the proportion of the design space for which the relative prediction variance falls below a specific value.
The relative prediction variance for the actual design is greater than that of the intended design over the entire design space. The discrepancy increases with larger design space coverage.

**Estimation Efficiency**

In each window, open the Estimation Efficiency outline.

In the actual design (right), the relative standard errors for all parameters either exceed or equal the standard errors for the intended design (left). For all except three of the non-intercept parameters, the relative standard errors in the actual design exceed those in the intended design.
The Fractional Increase in CI Length compares the length of a parameter’s confidence interval as given by the current design to the length of such an interval given by an ideal design of the same run size. The length of the confidence interval, and consequently the Fractional Increase in CI Length, is affected by the number of runs. See “Fractional Increase in CI Length” on page 462. Despite the reduction in run size, for the actual design, the terms Silane, Silica*Silane, and Sulfur*Silane have a smaller increase than for the intended design. This is because the two runs that were removed to define the actual design had Silane set to its center point. By removing these runs, the widths of the confidence intervals for these parameters more closely resemble those of an ideal orthogonal design, which has no center points.

**Color Map on Correlations**

In each report, do the following:

1. Open the **Color Map On Correlations** outline.

   The two color maps show the effects in the Model outline. Each plot shows the absolute correlations between effects colored using the JMP default white to black intensity scale. Ideally, you would like zero or very small correlations between effects.

**Figure 15.7** Color Map on Correlations, Intended Design (Left) and Actual Design (Right)

The absolute values of the correlations range from 0 (white) to 1 (black). Hover over a cell to see the value of the absolute correlation. The color map for the actual design shows more absolute correlations that are large than does the color map for the intended design. For example, the correlation between Sulfur and Silica*Sulfur is < .0001 for the intended design, and 0.5774 for the actual design.
Design Diagnostics

In each report, open the Design Diagnostics outline.

Figure 15.8  Design Diagnostics, Intended Design (Left) and Actual Design (Right)

The intended design (left) has higher efficiency values and a lower average prediction variance than the actual design (right). The results of the Design Evaluation analysis indicate that the two lost runs have had a negative impact on the design.

Note that both the number of runs and the model matrix factor into the calculation of efficiency measures. In particular, the $D$-, $G$-, and $A$- efficiencies are calculated relative to the ideal design for the run size of the given design. It is not necessarily true that larger designs are more efficient than smaller designs. However, for a given number of factors, larger designs tend to have smaller Average Variance of Prediction values than do smaller designs. For more information on how efficiency measures are defined, see “Design Diagnostics” on page 467.

Evaluating Power Relative to a Specified Model

For this example, you have constructed a definitive screening design to determine which of six factors have an effect on the yield of an extraction process. The data are given in the Extraction Data.jmp sample data table, located in the Design Experiment folder. Because the design is a definitive screening design, each factor has three levels. See the “Definitive Screening Designs” chapter on page 239.

You are interested in the power of tests to detect a strong quadratic effect. You consider a strong effect to be one whose magnitude is at least three times as large as the error variation.

Although the experiment studies six factors, effect sparsity suggests that only a small subset of factors is active. Consequently, you feel comfortable investigating power in a model based on a smaller number of factors. Also, past studies on a related process provide strong evidence to suggest that three of the factors, Propanol, Butanol, and pH, have negligible main effects, do not interact with other factors, and do not have quadratic effects. This leads you to believe that the likely model contains main, interaction, and quadratic effects only for Methanol, Ethanol, and Time. You decide to investigate power in the context of a three-factor response surface model.
Use the Evaluate Design platform to determine the power of your design to detect strong quadratic effects for Methanol, Ethanol, or Time.

1. Select Help > Sample Data Library and open Design Experiment/Extraction Data.jmp.
2. Select DOE > Design Diagnostics > Evaluate Design.
   You can add Yield as Y, Response if you wish. But specifying the response has no effect on the properties of the design.
4. Click OK.
5. In the Model outline, click RSM.
   This adds the interaction and quadratic terms for the three factors.
6. Open the Power Analysis outline.
   Note that the Anticipated RMSE is set to 1 by default. Although you have an estimate of the RMSE from past studies, you need not enter it. This is because the magnitude of the effect of interest is three times the error variation.
8. Click Apply Changes to Anticipated Coefficients.

Figure 15.9  Power Analysis Outline after Applying Changes to Coefficients

The power of detecting a quadratic effect whose magnitude is three times the error variation is 0.737. This assumes a final model that is a response surface in three factors. It also assumes a 0.05 significance level for the test.
Evaluate Design Launch Window

To launch the Evaluate Design platform, open the data table of interest and select **DOE > Design Diagnostics > Evaluate Design**. The example in Figure 15.10 uses the Bounce Data.jmp sample data table, located in the Design Experiment folder.

**Figure 15.10** Evaluate Design Launch Window

The launch window contains the following buttons:

**Y, Response** Enter the response column or columns. Entering a response is optional. Response values are not used in evaluating the design. Responses must be numeric.

**X, Factor** Enter the factor columns. Factors can be of any Data Type or Modeling Type.

Evaluate Design Window

The Evaluate Design window consists of two parts. See Figure 15.11, where all outline nodes are closed.

- The Factors, Model, Alias Terms, and Design outlines define the model and design.
- The Design Evaluation outline provides results that describe the properties of your design.
The Factors, Model, Alias Terms, and Design outlines contain information that you enter about the factors, assumed model, potentially aliased effects of interest, and the actual design. JMP populates these outlines using your selections in the launch window and the design table. However, you can modify the effects in the Model and Alias Terms outlines. Once you have made your specifications, the Design Evaluation outlines are updated. You can open these outlines to see reports or control windows that provide information about your design.

- “Factors”
- “Model”
- “Alias Terms”
- “Design”
- “Design Evaluation”
- “Power Analysis”
- “Prediction Variance Profile”
- “Fraction of Design Space Plot”
- “Prediction Variance Surface”
- “Estimation Efficiency”
- “Alias Matrix”
- “Color Map on Correlations”
- “Design Diagnostics”
Factors

The factors outline lists the factors entered in the launch window. You can select factors to construct effects in the Model outline.

Figure 15.12 Factors Outline

Model

What appears in the Model outline depends upon whether the associated data table contains a Model or Fit Model script:

- If there is a script, the Model outline contains the estimable effects specified in the script. Effects are entered into the model in the order specified in the script. If the model script contains more effects than are estimable, those that are not estimable are not included in the model for evaluation.

- If there is no script, the Model outline contains only main effects.

Figure 15.13 shows the Model outline for the Bounce Data.jmp data table, found in the Design Experiment folder. The Model script in the data table contains response surface effects for the three factors Silica, Silane, and Sulfur. Consequently, the Model outline contains the main effects, two-way interactions, and quadratic effects for these three factors.

Figure 15.13 Model Outline for Bounce Data.jmp

You can add effects to the Model outline using the following buttons:

Main Effects  Adds main effects for all factors in the model.
Interactions  Adds interaction effects. If no factors are selected in the Factors outline, select 2nd, 3rd, 4th, or 5th to add all appropriate interactions up to that order. Add interactions up to a given order for specific factors by selecting the factor names in the Factors outline, selecting Interactions, and then specifying the appropriate order. Interactions between non-mixture and mixture factors, and interactions with blocking and constant factors, are not added.

RSM  Adds interaction and quadratic terms up to the second order (response surface model terms) for continuous factors. Categorical factors are not included in RSM terms. Main effects for non-mixture factors that interact with all the mixture factors are removed.

Cross  Adds specific interaction terms. Select factor names in the Factors outline and effect names in the Model outline. Click Cross to add the crossed terms to the Model outline.

Powers  Adds polynomial terms. If no factor names are selected in the Factors outline, adds polynomial terms for all continuous factors. If factor names are selected in the Factors outline, adds polynomial terms for only those factors. Select 2nd, 3rd, 4th, or 5th to add polynomial terms of that order.

Scheffé Cubic  Adds Scheffé cubic terms for all mixture factors. These terms are used to specify a mixture model with third-degree polynomial terms.

Remove Term  Removes selected effects.

Alias Terms

It is possible that effects not included in your assumed model are active. In the Alias Terms outline, list potentially active effects that are not in your assumed model but might bias the estimates of model terms. The Alias Matrix entries represent the degree of bias imparted to model parameters by the effects that you specified in the Alias Terms outline. See “The Alias Matrix” on page 823 in the “Technical Details” appendix.

By default, the Alias Terms outline includes all two-way interaction effects that are not in your Model outline (with the exception of terms involving blocking factors). Add or remove terms using the buttons. For a description of how to use these buttons to add effects to the Alias Terms table, see “Model” on page 449.

In the Evaluate Design platform, the Alias Matrix outline is immediately updated to reflect changes to Alias Matrix effects. In the Custom Design platform, you must click Make Design after modifying the effects in the Alias Terms outline. Within other DOE platforms that construct designs, there is no Alias Terms outline. However, the Alias Matrix outline, containing appropriate effects, appears under Design Evaluation after you construct the design.
Design

The Design outline shows the design runs for the factors that you have specified in the launch window. You can easily view the design as you explore its properties in the Design Evaluation outline.

Design Evaluation

Design Evaluation within the Evaluate Design platform is based on your design and the specifications that you make in the Model and Alias Terms outlines. Several DOE Design platforms provide a Design Evaluation outline: Custom, Definitive Screening, Screening, Response Surface, and Mixture with Optimal design type. Design Evaluation within these platforms is based on the design that you construct.

Power Analysis

The Power Analysis outline calculates the power of tests for the parameters in your model. Power is the probability of detecting an active effect of a given size. The Power Analysis outline helps you evaluate the ability of your design to detect effects of practical importance. The higher your power, the more likely you are to detect significant effects assuming your coefficient and RMSE assumptions are correct. Power depends on the number of runs, the significance level, and the estimated error variation. In particular, you can determine if additional runs are necessary.

This section covers the following topics:

- “Power Analysis Overview” on page 451
- “Power Analysis Details” on page 453
- “Tests for Individual Parameters” on page 454
- “Tests for Categorical Effects with More Than Two Levels” on page 455
- “Design and Anticipated Responses Outline” on page 455
- “Power Analysis for Coffee Experiment” on page 456

Power Analysis Overview

Power is calculated for the effects listed in the Model outline. These include continuous, discrete numeric, categorical, blocking, mixture, and covariate factors. The tests are for individual model parameters and for whole effects. For more information on how power is calculated, see “Power Calculations” on page 824 in the “Technical Details” appendix.
Power is the probability of rejecting the null hypothesis of no effect at specified values of the model parameters. In practice, your interest is not in the values of the model parameters, but in detecting differences in the mean response of practical importance. In the Power Analysis outline, you can compute Anticipated Responses for specified values of the Anticipated Coefficients. This helps you to determine the coefficient values associated with the differences you want to detect in the mean response.

Figure 15.14 shows the Power Analysis outline for the design in the Coffee Data.jmp sample data table, found in the Design Experiment folder. The model specified in the Model script is a main effects only model.

In the Power Analysis outline, you can:

- Specify coefficient values that reflect differences that you want to detect. You enter these as Anticipated Coefficients in the top part of the outline.
- Specify anticipated response values and apply these to determine the corresponding Anticipated Coefficients. You specify Anticipated Responses in the Design and Anticipated Responses panel.

From the Power Analysis red triangle menu, you can:
• Specify a power to determine anticipated coefficients to achieve that power. If coefficients do not exist to satisfy the specified power, then the coefficients are set to zero.

• Specify a value for delta, where anticipated coefficients will be half of the specified delta. The power is then updated based on the anticipated coefficients.

**Power Analysis Details**

Specify values for the Significance Level and Anticipated RMSE. These are used to calculate the power of the tests for the model parameters.

**Significance Level**  The probability of rejecting the hypothesis of no effect, if it is true. The power calculations update immediately when you enter a value.

**Anticipated RMSE**  An estimate of the square root of the error variation. The power calculations update immediately when you enter a value.

The top portion of the Power Analysis report opens with default values for the Anticipated Coefficients (Figure 15.14). The default values are based on Delta. See “Advanced Options > Set Delta for Power” on page 469.

**Note:** If the design is supersaturated, meaning that the number of parameters to be estimated exceeds the number of runs, the anticipated coefficients are set to 0.

Figure 15.15 shows the top portion of the Power Analysis report where values have been specified for the Anticipated Coefficients. These values reflect the differences you want to detect.

**Figure 15.15** Possible Specification of Anticipated Coefficients for Coffee Data.jmp
Tests for Individual Parameters

The Term column contains a list of model terms. For each term, the Anticipated Coefficient column contains a value for that term. The value in the Power column is the power of a test that the coefficient for the term is 0 if the true value of the coefficient is given by the Anticipated Coefficient.

**Term**  The model term associated with the coefficient being tested.

| Note: | The order in which model terms appear in the Power Analysis report may not be identical to their order in the Parameter Estimates report obtained using Standard Least Squares. This difference can only occur when the model contains an interaction with more than one degree of freedom. |

| Anticipated Coefficient | A value for the coefficient associated with the model term. This value is used in the calculations for Power. These values are also used to calculate the Anticipated Response column in the Design and Anticipated Responses outline. When you set a new value in the Anticipated Coefficient column, click **Apply Changes to Anticipated Coefficients** to update the Power and Anticipated Response columns. |

| Note: | The anticipated coefficients have default values of 1 for continuous effects. They have alternating values of 1 and –1 for categorical effects. You can specify a value for Delta be selecting **Advanced Options > Set Delta for Power** from the red triangle menu. If you change the value of Delta, the values of the anticipated coefficients are updated so that their absolute values are one-half of Delta. See “**Advanced Options > Set Delta for Power**” on page 469. |

| Power | Probability of rejecting the null hypothesis of no effect when the true coefficient value is given by the specified Anticipated Coefficient. For a coefficient associated with a numeric factor, the change in the mean response (based on the model) is twice the coefficient value. For a coefficient associated with a categorical factor, the change in the mean response (based on the model) across the levels of the factor equals twice the absolute value of the anticipated coefficient. |

Calculations use the specified Significance Level and Anticipated RMSE. For more information about the power calculation, see “**Power for a Single Parameter**” on page 824 in the “Technical Details” appendix.

| Apply Changes to Anticipated Coefficients | When you set a new value in the Anticipated Coefficient column, click **Apply Changes to Anticipated Coefficients** to update the Power and Anticipated Response columns. |
**Tests for Categorical Effects with More Than Two Levels**

If your model contains a categorical effect with more than two levels, then the following columns appear below the Apply Changes to Anticipated Coefficients button:

- **Effect** The categorical effect.
- **Power** The power calculation for a test of no effect. The null hypothesis for the test is that all model parameters corresponding to the effect are zero. The difference to be detected is defined by the values in the Anticipated Coefficient column that correspond to the model terms for the effect. The power calculation reflects the differences in response means determined by the anticipated coefficients.

Calculations use the specified Significance Level and Anticipated RMSE. For more information about the power calculation, see “Power for a Categorical Effect” on page 826 in the “Technical Details” appendix.

**Design and Anticipated Responses Outline**

The Design and Anticipated Responses outline shows the design preceded by an Anticipated Response column. Each entry in the first column is the Anticipated Response corresponding to the design settings. The Anticipated Response is calculated using the Anticipated Coefficients.

Figure 15.16 shows the Design and Anticipated Responses outline corresponding to the specification of Anticipated Coefficients given in Figure 15.15.

**Figure 15.16** Anticipated Responses for Coffee Data.jmp

In the Anticipated Response column, you can specify a value for each setting of the factors. These values reflect the differences you want to detect.
Click **Apply Changes to Anticipate Responses** to update both the Anticipated Coefficient and Power columns.

**Anticipated Response**  The response value obtained using the Anticipated Coefficient values as coefficients in the model. When the outline first appears, the calculation of Anticipated Response values is based on the default values in the Anticipated Coefficient column. When you set new values in the Anticipated Response column, click **Apply Changes to Anticipated Responses** to update the Anticipated Coefficient and Power columns.

**Design**  The columns to the right of the Anticipated Response column show the factor settings for all runs in your design.

**Apply Changes to Anticipated Responses**  When you set new values in the Anticipated Response column, click **Apply Changes to Anticipated Responses** to update the Anticipated Coefficient and Power columns.

**Power Analysis for Coffee Experiment**

Consider the design in the *Coffee Data.jmp* data table. Suppose that you are interested in the power of your design to detect effects of various magnitudes on Strength. Recall that Grind is a two-level categorical factor, Temperature, Time, and Charge are continuous factors, and Station is a three-level categorical (blocking) factor.

In this example, ignore the role of Station as a blocking factor. You are interested in the effect of Station on Strength. Since Station is a three-level categorical factor, it is represented by two terms in the Parameters list: Station 1 and Station 2.

Specifically, you are interested the probability of detecting the following changes in the mean Strength:

- A change of 0.10 units as you vary Grind from Coarse to Medium.
- A change of 0.10 units or more as you vary Temperature, Time, and Charge from their low to high levels.
- An increase due to each of Stations 1 and 2 of 0.10 units beyond the overall anticipated mean. This corresponds to a decrease due to Station 3 of 0.20 units from the overall anticipated mean.

You set 0.05 as your Significance Level. Your estimate of the standard deviation of Strength for fixed design settings is 0.1 and you enter this as the Anticipated RMSE.

Figure 15.17 shows the Power Analysis node with these values entered. Specifically, you specify the Significance Level, Anticipated RMSE, and the value of each Anticipated Coefficient.

When you click Apply Changes to Anticipated Coefficients, the Anticipated Response values are updated to reflect the model you have specified.
Recall that Temperature is a continuous factor with coded levels of -1 and 1. Consider the test whose null hypothesis is that Temperature has no effect on Strength. Figure 15.17 shows that the power of this test to detect a difference of 0.10 ($=2\times0.05$) units across the levels of Temperature is only 0.291.

Now consider the test for the whole Station effect, where Station is a three-level categorical factor. Consider the test whose null hypothesis is that Station has no effect on Strength. This is the usual $F$ test for a categorical factor provided in the Effect Tests report when you run Analyze > Fit Model. See Fitting Linear Models.

The Power of this test is shown directly beneath the Apply Changes to Anticipated Coefficients button. The entries under Anticipated Coefficients for the model terms Station 1 and Station 2 are both 0.10. These settings imply that the effect of both stations is to increase Strength by 0.10 units above the overall anticipated mean. For these settings of the Station 1 and Station 2 coefficients, the effect of Station 3 on Strength is to decrease it by 0.20 units from the overall anticipated mean. Figure 15.17 shows that the power of the test to detect a difference of at least this magnitude is 0.888.
Prediction Variance Profile

The Prediction Variance Profile helps you to understand where in the design space your predictions have more or less variability. Low prediction variance is desired. Use the **Maximize Variance** option to find the maximum variance. See “Maximize Variance” on page 459.

The Prediction Variance Profile plots the relative variance of prediction as a function of each factor at fixed values of the other factors. Figure 15.18 shows the Prediction Variance Profile for the Bounce Data.jmp data table, located in the Design Experiment folder.

**Figure 15.18** Prediction Variance Profiler

Relative Prediction Variance

For given settings of the factors, the prediction variance is the product of the error variance and a quantity that depends on the design and the factor settings. Before you run your experiment, the error variance is unknown, so the prediction variance is also unknown. However, the ratio of the prediction variance to the error variance is not a function of the error variance. This ratio, called the *relative prediction variance*, depends only on the design and the factor settings. Consequently, the relative variance of prediction can be calculated before acquiring the data. See “Relative Prediction Variance” on page 827 in the “Technical Details” appendix.

After you run your experiment and fit a least squares model, you can estimate the error variance using the mean squared error (MSE) of the model fit. You can estimate the actual variance of prediction at any setting by multiplying the relative variance of prediction at that setting.

It is ideal for the prediction variance to be small throughout the design space. Generally, the error variance drops as the sample size increases. In comparing designs, you may want to place the prediction variance profilers for two designs side-by-side. A design with lower prediction variance on average is preferred.
Maximize Variance

You can evaluate a design or compare designs in terms of the maximum relative prediction variance. Select the Maximize Variance option from the Prediction Variance Profile red triangle menu. JMP uses a desirability function that maximizes the relative prediction variance. The value of the maximum variance in the Prediction Variance Profile is the worst (least desirable from a design point of view) value of the relative prediction variance. The maximum variance can occur at more than one combination of factor settings.

Figure 15.19 shows the Prediction Variance Profile with Maximize Variance selected. The plot is for the Bounce Data.jmp sample data table, located in the Design Experiment folder. The maximum value of the relative prediction variance is 1.3958 when Silica = 0.7, Sulfur = 1.8, and Silane = 40. However, keep in mind that several factor settings can have this same relative variance. The design point with Silica = 1.7, Sulfur = 2.8, and Silane = 60 also has relative prediction variance of 1.3958. To evaluate the prediction variance using a surface, see “Prediction Variance Surface” on page 460.

Figure 15.19 Prediction Variance Profile Showing Maximum Variance

Fraction of Design Space Plot

The Fraction of Design Space Plot shows the proportion of the design space over which the relative prediction variance lies below a given value. It is desirable to have a large proportion of the design space with low prediction variance values. Figure 15.20 shows the Fraction of Design Space plot for the Bounce Data.jmp sample data table, located in the Design Experiment folder.
Figure 15.20  Fraction of Design Space Plot

The X axis in the plot represents the proportion of the design space, ranging from 0 to 100%. The Y axis represents relative prediction variance values. For a point \((x, y)\) that falls on the blue curve, the value \(x\) is the proportion of design space with variance less than or equal to \(y\). Red dotted crosshairs mark the value that bounds the relative prediction variance for 50% of design space.

Figure 15.20 shows that the minimum relative prediction variance is slightly less than 0.3, while the maximum is below 1.4. (The actual maximum is 1.395833, as shown in Figure 15.19.) The red dotted crosshairs indicate that the relative prediction variance is less than 0.34 over about 50% of the design space. You can use the crosshairs tool to find the maximum relative prediction variance that corresponds to any Fraction of Space value. Use the crosshairs tool in Figure 15.20 to see that 90% of the prediction variance values are below approximately 0.55.

**Note:** Monte Carlo sampling of the design space is used in constructing the Fraction of Design Space Plot. Therefore, plots for the same design may vary slightly.

**Prediction Variance Surface**

The Prediction Variance Surface report plots the relative prediction variance surface as a function of any two design factors. Figure 15.21 shows the Prediction Variance Surface outline for the Bounce Data.jmp sample data table, located in the Design Experiment folder. Show or hide the controls by selecting **Control Panel** on the red triangle menu. See “Control Panel” on page 461.
When there are two or more factors, the Prediction Variance Surface outline shows a plot of the relative prediction variance for any two variables. The Prediction Variance Surface outline plots the relative prediction variance formula. Drag on the plot to rotate and change the perspective.

**Control Panel**

The Control Panel contains options for adjusting the plot:

- **Response Grid Slider** The Grid check box superimposes a grid that shows constant values of Variance. The value of the Variance is shown in the text box. The slider enables you to adjust the placement of the grid. Alternatively, you can enter a Variance value in the text box. Click outside the box to update the plot.

- **Independent Variables** This panel enables you to select which two factors are used as axes for the plot and to specify the settings for factors not used as axes. Select a factor for each of the X and Y axes by clicking in the appropriate column. Use the sliders and text boxes to specify values for each factor not selected for an axis. The plot shows the three-dimensional slice of the surface at the specified values of the factors that are not used as axes in the plot. Move the sliders to see different slices.

  Each grid check box activates a grid for the corresponding factor. Use the sliders to adjust the placement of each grid.

  Lock Z Scale locks the z-axis to its current values. This is useful when moving the sliders that are not on an axis.

- **Appearance** The Resolution slider affects how many points are evaluated for a formula. Too coarse a resolution means that a function with a sharp change might not be represented.
very well. But setting the resolution high can make evaluating and displaying the surface slower.

The **Orthographic projection** check box shows a projection of the plot in two dimensions.

The **Contour** menu controls the placement of contour curves. A contour curve is a set of points whose Response values are constant. You can select to turn the contours Off (the default) or place them contours Below, Above, or On Surface.

### Estimation Efficiency

This report gives the Fractional Increase in CI (Confidence Interval) Length and Relative Std (Standard) Error of Estimate for each parameter estimate in the model. Smaller is better for both of these values. Figure 15.22 shows the Estimation Efficiency outline for the Bounce Data.jmp sample data table, located in the Design Experiment folder.

### Fractional Increase in CI Length

The Fractional Increase in CI Length compares the length of a parameter’s confidence interval as given by the current design to the length of such an interval given an ideal design:

- The length of the ideal confidence interval for the parameter is subtracted from the length of its actual confidence interval.
- This difference is then divided by the length of the ideal confidence interval.

For an orthogonal D-optimal design, the fractional increase is zero. In selecting a design, you would like the fractional increase in confidence interval length to be as small as possible.
The Ideal Design

The covariance matrix for the ordinary least squares estimator is $\sigma^2(X'X)^{-1}$. The diagonal elements of $(X'X)^{-1}$ are the relative variances (the variances divided by $\sigma^2$) of the parameter estimates. For two-level designs and using the effects coding convention (see “Coding” on page 795 in the “Column Properties” appendix), the minimum value of the relative variance for any parameter estimate is $1/n$, where $n$ is the number of runs. This occurs when all the effects for the design are orthogonal and the design is D-optimal.

Let $\hat{\beta}$ denote the vector of parameter estimates. The ideal design, which may not exist, is a design whose covariance matrix is given as follows:

$$\text{Var}(\hat{\beta}) = (\sigma^2/n)I_n$$

where $I_n$ is the $n$ by $n$ identity matrix and $\sigma$ is the standard deviation of the response.

If an orthogonal D-optimal design exists, it is the ideal design. However, the definition above extends the idea of an ideal design to situations where a design that is both orthogonal and D-optimal does not exist.

The definition is also appropriate for designs with multi-level categorical factors. The orthogonal coding used for categorical factors allows such designs to have the ideal covariance matrix. For a Custom Design, you can view the coding matrix by selecting Save X Matrix from the options in the Custom Design window, making the design table, and looking at the script Model Matrix that is saved to the design table.

Fractional Increase in Length of Confidence Interval

Note that, in the ideal design, the standard error for the parameter estimates would be given as follows:

$$SE_{\text{Ideal}}(\hat{\beta}) = (\sigma/\sqrt{n})I_n$$

The length of a confidence interval is determined by the standard error. The Fractional Increase in Confidence Interval Length is the difference between the standard error of the given design and the standard error of the ideal design, divided by the standard error of the ideal design.

Specifically, for the $i^{th}$ parameter estimate, the Fractional Increase in Confidence Interval Length is defined as follows:

$$FI = \frac{\frac{1}{\sqrt{n}}(X'X_{ii})^{-1} - (\sigma/\sqrt{n})}{(\sigma/\sqrt{n})} = \frac{\sqrt{n(X'X_{ii})^{-1}} - 1}{n}$$

where

$\sigma^2$ is the unknown response variance,
\[ X \text{ is the model matrix for the given design, defined in “The Alias Matrix” on page 823 in the “Technical Details” appendix,} \]
\[ (X'X)_{ii}^{-1} \text{ is the } i^{th} \text{ diagonal entry of } (XX)^{-1}, \text{ and} \]
\[ n \text{ is the number of runs.} \]

**Relative Std Error of Estimate**

The Relative Std Error of Estimate gives the ratio of the standard deviation of a parameter’s estimate to the error standard deviation. These values indicate how large the standard errors of the model’s parameter estimates are, relative to the error standard deviation. For the \( i^{th} \) parameter estimate, the Relative Std Error of Estimate is defined as follows:

\[
SE = \sqrt{\frac{1}{(X'X)_{ii}^{-1}}} 
\]

where

- \( X \) is the model matrix defined in “The Alias Matrix” on page 823 in the “Technical Details” appendix, and
- \( (X'X)_{ii}^{-1} \) is the \( i^{th} \) diagonal entry of \( (XX)^{-1} \).

**Alias Matrix**

The Alias Matrix addresses the issue of how terms that are not included in the model affect the estimation of the model terms, if they are indeed active. In the Alias Terms outline, you list potentially active effects that are not in your assumed model but that might bias the estimates of model terms. The Alias Matrix entries represent the degree of bias imparted to model parameters by the Alias Terms effects. See “Alias Terms” on page 450.

The rows of the Alias Matrix are the terms corresponding to the model effects listed in the Model outline. The columns are terms corresponding to effects listed in the Alias Terms outline. The entry in a given row and column indicates the degree to which the alias term affects the parameter estimate corresponding to the model term.

In evaluating your design, you ideally want one of two situations to occur relative to any entry in the Alias Matrix. Either the entry is small or, if it is not small, the effect of the alias term is small so that the bias will be small. If you suspect that the alias term may have a substantial effect, then that term should be included in the model or you should consider an alias optimal design.

For more information about the computation of the Alias Matrix, see “The Alias Matrix” on page 823 in the “Technical Details” appendix. See also Lekivetz, R. (2014).
Note the following:

- If the design is orthogonal for the assumed model, then the correlations in the Alias Matrix correspond to the absolute correlations in the Color Map on Correlations.
- Depending on the complexity of the design, it is possible to have alias matrix entries greater than 1 or less than -1.

**Alias Matrix Example**

Consider the Coffee Data.jmp sample data table, located in the Design Experiment folder. The design assumes a main effects model. You can see this by running the Model script in the data table. Consequently, in the Evaluate Design window’s Model outline, only the Intercept and five main effects appear. The Alias Terms outline contains the two-way interactions.

**Figure 15.23** Alias Matrix for Coffee Data.jmp

The Alias Matrix shows the Model terms in the first column defining the rows. The two-way interactions in the Alias Terms are listed across the top, defining the columns. Consider the model effect Temperature for example. If the Grind*Time interaction is the only active two-way interaction, the estimate for the coefficient of Temperature is biased by 0.333 times the true value of the Grind*Time effect. If other interactions are active, then the value in the Alias Matrix indicates the additional amount of bias incurred by the Temperature coefficient estimate.

**Color Map on Correlations**

The Color Map on Correlations shows the absolute value of the correlation between any two effects that appear in either the Model or the Alias Terms outline. The cells of the color map are identified above the map. There is a cell for each effect in the Model outline and a cell for each effect in the Alias Terms outline. Smaller values are desired.

By default, the absolute magnitudes of the correlations are represented by a white to gray to black intensity color theme. In general terms, the color map for a good design shows a lot of white off the diagonal, indicating orthogonality or small correlations between distinct terms. Large absolute correlations among effects inflate the standard errors of estimates.
To see the absolute value of the correlation between two effects, hover over the corresponding cell. To change the color scale, click the Color Map on Correlations red triangle and select **Blue to Gray to Red**. For a custom color scale, right-click in the plot and select **Color Theme**. To save a table of the correlations, right-click to the right of the plot below the legend and select **Table of Correlations**.

**Color Map Example**

Figure 15.24 shows the Color Map on Correlations for the Bounce Data.jmp sample data table, found in the Design Experiment folder. The black coloring indicates absolute correlations of one. Note that there are black cells on the diagonal, showing correlations of model terms with themselves.

All other cells are either white or gray. The gray squares correspond to correlations between quadratic terms. To see this, hover over each of the gray squares. The absolute correlations of quadratic terms with each other are small, 0.0714.

From the perspective of correlation, this is a good design. When effects are highly correlated, it is more difficult to determine which is responsible for an effect on the response.

**Figure 15.24  Color Map on Correlations**

*Tip:* To save a table of the correlations, right-click to the right of the plot below the legend and select **Table of Correlations**.
Design Diagnostics

The Design Diagnostics outline shows \( D-, G-, \) and \( A\)-efficiencies and the average variance of prediction. These diagnostics are not shown for designs that include factors with Changes set to Hard or Very Hard or effects with Estimability designated as If Possible.

When Design Diagnostics is accessed from a DOE platform other than Evaluate Design, the Design Creation Time gives the amount of time required to create the design. When Design Diagnostics is accessed from the Evaluate Design platform, Design Creation Time gives the amount of time required for the Evaluate Design platform to calculate results.

Figure 15.25 shows the Design Diagnostics outline for the *Bounce Data.jmp* sample data table, found in the Design Experiment folder.

**Figure 15.25** Design Diagnostics Outline

---

**Caution:** The efficiency measures should not be interpreted on their own. But they can be used to compare designs. Given two designs, the one with the higher efficiency measure is better. While the maximum efficiency is 100 for any criterion, an efficiency of 100% is impossible for many design problems.

---

**Notation**

The descriptions of the efficiency measures given below use the following notation:

- \( X \) is the model matrix
- \( n \) is the number of runs in the design
- \( p \) is the number of terms, including the intercept, in the model
- \( \text{Var}(\hat{y}|\mathbf{x}) \) is the relative prediction variance at the point \( \mathbf{x} \). See “Relative Prediction Variance” on page 827 in the “Technical Details” appendix.
- \( \text{Var}(\hat{y}|\mathbf{x})_{\text{max}} \) is the maximum relative prediction variance over the design region
D Efficiency

The efficiency of the design to that of an ideal orthogonal design in terms of the D-optimality criterion. A design is D-optimal if it minimizes the volume of the joint confidence region for the vector of regression coefficients:

\[ D\text{-efficiency} = 100 \left( \frac{1}{n} |X'X|^{1/p} \right) \]

G Efficiency

The efficiency of the design to that of an ideal orthogonal design in terms of the G-optimality criterion. A design is G-optimal if it minimizes the maximum prediction variance over the design region:

\[ G\text{-efficiency} = 100 \frac{1}{p n} \text{Var}(\hat{y}|\mathbf{x})_{\text{max}} \]

Letting \( D \) denote the design region,

\[ \text{Var}(\hat{y}|\mathbf{x})_{\text{max}} = \text{maximum}[\mathbf{x}'(X'X)^{-1}\mathbf{x}]_{\mathbf{x} \text{ in } D} \]

Note: G-Efficiency is calculated using Monte Carlo sampling of the design space. Therefore, calculations for the same design may vary slightly.

A Efficiency

The efficiency of the design to that of an ideal orthogonal design in terms of the A-optimality criterion. A design is A-optimal if it minimizes the sum of the variances of the regression coefficients:

\[ A\text{-efficiency} = 100 \frac{1}{n} \text{Trace}(X'X)^{-1} \]

Average Variance of Prediction

At a point \( \mathbf{x} \) in the design space, the relative prediction variance is defined as:

\[ \text{Var}(\hat{y}|\mathbf{x}) = \mathbf{x}'(X'X)^{-1}\mathbf{x} \]

where this is the prediction variance divided by the error variance. For more information about the calculation, see Section 4.3.5 in Goos and Jones (2011).
Note: If the design region is constrained by linear constraints or disallowed combinations, the average variance of prediction is calculated from the prediction variance values found in the Fraction of Design Space plot.

Design Creation Time

Design Creation Time gives the amount of time required for the Evaluate Design platform to calculate results.

Evaluate Design Options

The Evaluate Design red triangle menu contains the following options:

**Advanced Options > Split Plot Variance Ratio**  Specify the ratio of the variance of the random whole plot and the subplot variance (if present) to the error variance. Before setting this value, you must define a hard-to-change factor for your split-plot design, or hard and very-hard-to-change factors for your split-split-plot design. Then you can enter one or two positive numbers for the variance ratios, depending on whether you have specified a split-plot or a split-split-plot design.

**Advanced Options > Set Delta for Power**  Specify a value for the difference you want to detect that is applied to Anticipated Coefficients in the Power Analysis report. The Anticipated Coefficient values are set to Delta/2 for continuous effects. For categorical effects, they are alternating values of Delta/2 and –Delta/2. For more information about power analysis, see “Power Analysis” on page 451.

By default, Delta is set to two. Consequently, the Anticipated Coefficient default values are 1 for continuous effects and alternating values of 1 and –1 for categorical effects. The default values that are entered as Anticipated Coefficients when Delta is 2 ensure these properties:

- The power calculation for a numeric effect assumes a change of Delta in the response mean due to linear main effects as the factor changes from the lowest setting to the highest setting in the design region.
- The power calculation for the parameter associated with a two-level categorical factor assumes a change of Delta in the response mean across the levels of the factor.
- The power calculation for a categorical effect with more than two levels is based on the multiple degree of freedom $F$ test for the null hypothesis that all levels have the same response mean. Power is calculated at the values of the response means that are determined by the Anticipated Coefficients. Various configurations of the Anticipated Coefficients can define a difference in levels as large as Delta. However, the power
values for such configurations will differ based on the Anticipated Coefficients for the other levels.

**Save Script to Script Window**  Creates a script that reproduces the Evaluate Design window and places it in an open script window.
Chapter 16

Compare Designs

Compare and Evaluate Designs Simultaneously

The Compare Designs platform compares up to four designs to a reference design. Use to explore, evaluate, and compare design performance. Diagnostics show how the designs perform relative to each other and how they perform in an absolute sense. To compare designs relative to your specific needs, you can change the terms in the assumed model and in the alias terms list.

Overview of the Compare Designs Platform

The Compare Designs platform, which is an extension of the Evaluate Design platform, enables you to easily compare up to four designs to a reference design. To compare the performance of one or two designs relative to another, you select a reference design that is treated as the base design. You can specify effects in the Model outline, and effects of interest in the Alias Terms outline.

The Design Evaluation report shows diagnostic results and plots covering these areas:

- Power analysis
- Prediction variance
- Fraction of design space
- Relative estimation efficiency
- Alias matrix diagnostics
- Correlations among effects (including confounding)
- Relative efficiency measures for the overall designs

Examples of Comparing Designs

- “Designs of Same Run Size”
- “Designs of Different Run Sizes”
- “Split Plot Designs with Different Numbers of Whole Plots”

Designs of Same Run Size

In this example, you compare two designs for six factors each with 13 runs. One is a 12-run Plackett-Burman (PB) design augmented with a single center point. The other is a Definitive Screening Design (DSD).

Comparison in Terms of Main Effects Only

First, compare the two designs assuming that the model to be estimated contains only the main effects.

1. Select Help > Sample Data, click Open the Sample Scripts Directory, and select Compare Same Run Size.jsl.
2. Right-click in the script window and select Run Script.
Two 13-run design tables are constructed: Definitive Screening Design and Plackett-Burman. You want to compare these two designs. Because the Plackett-Burman table is active, it is the reference design to which you compare the DSD.

3. In the Plackett-Burman data table, select **DOE > Design Diagnostics > Compare Designs**.
4. Select Definitive Screening Design from the **Compare ‘Plackett-Burman’ with** list.
5. Select X1 through X6 in the Plackett-Burman panel and in the Definitive Screening Design panel.
6. Open the Match Columns outline and click **Match**.

**Figure 16.2** Launch Window with Matched Columns

This defines the correspondence between the factors in your two designs.

7. Click **OK**.

The reference design is the Plackett-Burman design. In the Design Evaluation outline, comparison metrics compare the PB to the DSD. The designs are compared relative to power, prediction variance, estimation efficiency, aliasing, and design efficiency measures.
In terms of power, prediction variance, and estimation efficiency, the PB design outperforms the DSD. Figure 16.3 shows the Power Analysis report with the default settings for the significance level, Anticipated RMSE, and coefficients. For tests for the main effects, the PB design has higher power than does the DSD.
The Fraction of Design Space plot indicates that the PB design has smaller prediction variance than the DSD over the entire design space.

You conclude that, if you suspect that only main effects are active, the PB design is preferable.

**Comparison in Terms of Two-Way Interactions**

Now suppose you suspect that some two-way interactions might be active. The analysis below shows that if those two-way interactions are actually active, then the PB design might be less desirable than the DSD.

1. In the Absolute Correlations report, open the Color Map on Correlations report and the color map reports under it.

The Color Map on Correlations plots show that the PB design aliases main effects with two-way interactions. In contrast, the DSD does not alias main effects with two-way interactions.
To gain more insight on how the designs compare if some two-way interactions are active, add two-way interactions in the Model outline.

2. In the Factors outline, select X1 through X3.
3. In the Model outline, select **Interactions > 2nd**.

**Figure 16.6** Power Analysis for PB and DSD Comparison with Interactions

The Term list shows the three two-way interactions. If these two-way interactions are active, then the DSD has better performance in terms of power across all effects than the PB.
The DSD also outperforms the PB design in terms of prediction variance with the three interactions in the model. You can explore the other reports to see that the DSD is preferred when there are potentially active interactions.

**Designs of Different Run Sizes**

In this example, compare three designs with run sizes 16, 20, and 24. The designs are constructed for main effect models. Use the Compare Designs platform to determine whether the potential benefits of using a larger run size are worth the additional cost in resources.

1. Select Help > Sample Data, click Open the Sample Scripts Directory, and select Compare Three Run Sizes.jsl.
2. Right-click in the script window and select Run Script.
   Three design tables are constructed using Custom Design, with only main effects as entries in the Model outline:
   - 16-Run Design
   - 20-Run Design
   - 24-Run Design
   You want to compare these three designs. Notice that the 16-Run Design table is active.
3. In the 16-Run Design table, select DOE > Design Diagnostics > Compare Designs.
4. From the Compare ‘16-Run Design’ with list, select 20-Run Design and 24-Run Design.
   Panels for each of these designs are added to the launch window. JMP automatically matches the columns in the order in which they appear in the three design tables.
5. Click OK.
Figure 16.8  Power Analysis Comparison

All three designs have high power for detecting main effects if the coefficients are on the order of the Anticipated RMSE.
As expected, the 24-run design is superior to the other two designs in terms of prediction variance over the entire design space. The 20-run design is superior to the 16-run design.

6. In the Absolute Correlations report, open the Color Map on Correlations report and the three color map reports under it.

For the 16-run design, the Color Map on Correlations indicates that there is confounding of some main effects with some two-factor interactions, and confounding of two-factor interactions.

For the 20-run design, the Color Map on Correlations indicates that there are some large correlations between some main effects and some two-factor interactions, and between some two-factor interactions.

The 24-run design shows only moderate correlations between main effects and two-factor interactions, and between two-factor interactions.
The Absolute Correlations table summarizes the information shown in the Color Maps on Correlations. Recall that the model for all three designs consists of only main effects and the Alias Matrix contains two-factor interactions.

For the 16-run design, the Model x Alias portion of the table indicates that there are nine confoundings of main effects with two-factor interactions. The Alias x Alias portion indicates that six two-factor interactions are confounded.

The Design Diagnostics report compares the efficiency of the 16-run design to both the 20-run and 24-run designs in terms of several efficiency measures. Relative efficiency values that exceed 1 indicate that the reference design is preferable for the given measure. Values less than 1 indicate that the design being compared to the reference design is preferable. The 16-run design has lower efficiency than the other two designs across all metrics, indicating that the larger designs are preferable.
Split Plot Designs with Different Numbers of Whole Plots

In this example, compare two split-plot designs with different numbers of whole plots. The designs are for three factors:

- A continuous hard-to-change factor
- A continuous easy-to-change factor
- A three-level categorical easy-to-change factor

The designs include all two-factor interactions in the assumed model. You can afford 20 runs and want to compare using 4 or 8 whole plots.

Launch Compare Designs

1. Select Help > Sample Data, click Open the Sample Scripts Directory, and select Compare Split Plots.jsl.
2. Right-click in the script window and select Run Script.

Two design tables are constructed using Custom Design:

- 4 Whole Plots
- 8 Whole Plots

You want to compare these two designs. Notice that the 4 Whole Plots table is active.

3. In the 4 Whole Plots table, select DOE > Design Diagnostics > Compare Designs.
4. From the Compare ‘4 Whole Plots’ with list, select 8 Whole Plots.

A panel for this design is added to the launch window. JMP automatically matches the columns in the order in which they appear in the two design tables.

Figure 16.13 Completed Launch Window
5. Click **OK**.

6. Open the **Matching Specification** outline under Reference Design: 20 run ‘4 Whole Plots’.

**Figure 16.14** Matching Specification for Split-Plot Designs

Notice that the Whole Plots column is entered as part of the design. This is necessary because Compare Designs needs to know the whole plot structure.

**Examine the Report**

The Design Evaluation report provides various diagnostics that compare the two designs.
The Power Analysis report shows that the power for the whole-plot factor, \(X_1\), is much smaller for the four whole-plot design (0.19) than for the eight whole-plot design (0.497). However, the four whole-plot design has higher power to detect split-plot effects, especially the interaction of the two split-plot factors, \(X_2\times X_3\) (0.797 compared to 0.523). Notice that the power for the combined effect \(X_2\times X_3\) is given under the color bar and legend.
The Relative Estimation Efficiency report shows the relative estimation efficiency for $X_1$ to be 0.778. This indicates that the standard error for $X_1$ is notably larger for the four whole-plot design than for the eight whole-plot design.

Open the Relative Std Error of Estimates report. You can see that the relative standard error for $X_1$ in the four whole-plot design is 0.553, compared to the eight whole-plot error of 0.43.

In the Relative Estimation Efficiency report, the relative estimation efficiency for $X_2 \times X_3^2$ is 1.449, indicating that the standard error for the parameter associated with $X_2 \times X_3^2$ is notably larger for the eight whole-plot design than for the four whole-plot design.

The Power Analysis and the Relative Estimation Efficiency reports indicate that the choice of designs revolves around the importance of detecting the whole plot effect $X_1$. The eight whole-plots design gives you a better chance of detecting a whole plot effect. The four whole-plots design is somewhat better for detecting split-plot effects involving the categorical variable.
Launch the Compare Designs Platform

Launch the Compare Designs platform by selecting **DOE > Design Diagnostics > Compare Designs**. All open data tables appear in the list at the left. The active data table and its columns appear in a Source Columns panel. The design in the initial Source Columns panel is the *reference design*, namely, the design to which other designs are compared. When you add designs to compare to the reference design, their columns appear in panels under the reference design panel.

Figure 16.17 shows the launch window for the three designs in “Designs of Different Run Sizes” on page 478.

**Figure 16.17 Compare Designs Launch Window**

![Compare multiple designs from JMP datatables.

Design Table Selection

Select up to four design tables from the list on the left.

- To compare multiple designs to the reference design, you must select their design tables simultaneously from the list on the left.
- To replace a design (or designs) in the Source Columns list, select the desired table (or tables) from the list at the left. The design table (or tables) under the reference design table are replaced.

**Note:** The reference design table can be compared to itself, which can be useful when exploring the assignment of design columns to factors.
Match Columns

Specify which columns in each of the design tables correspond to each other in the Match Columns panel. To match columns, select the columns to match in each of the design table Source Columns lists, and then click Match.

Figure 16.18 Selection of Columns for Matching

- To match single columns in each list, select the single column in each list, and then click Match.
- To match several columns that appear in the correct matching order in each list, select them in each list. Click the Match button. They are matched in their list order (Figure 16.18). In this example, Feed Rate is matched with X1, and Catalyst is matched with X3.
- If the lists contain the same numbers of columns and your desired match order is their order of appearance in the lists, you do not have to click Match. When you click OK to run the launch window, JMP matches the columns automatically in their order of appearance. You can review the matching in the report’s Matching Specification outline.
Compare Designs Window: Specify Model and Alias Terms

The Compare Designs window consists of two sets of outlines:

- Specify which effects are in the model and which effects are potentially active using the Factors, Model, and Alias Terms outlines.
- Compare the designs using the diagnostics in the Design Evaluation outlines. Changes that you make in the Model and Alias Terms outlines are updated in the Design Evaluation report.

The Compare Designs report uses the column names from the reference design.

Reference Design

The name of the window for the reference design appears in the outline title. The Matching Specification outline lists the specifications that you entered in the launch window.

Factors

Use the Factors outline to add effects to the Model and Alias Terms lists.

The Factors outline lists the factors, using the column names from the reference design, and coded values. Because they are not factors, whole plot and subplot columns do not appear in the Factors outline. However, they are required for the analysis.

Model

Add or remove effects to compare your designs for the effects that you believe should be in the model. The Model outline initially lists effects that are in the Model script of the reference design table and that are estimated by all designs being compared. If there is no Model script in the reference design table, the Model outline shows only the main effects that can be estimated by all designs being compared. For more information about how to add and remove effects, see “Model” on page 449 in the “Evaluate Designs” chapter.
Note: If any of the designs are supersaturated, meaning that the number of parameters to be estimated exceeds the number of runs, the Model outline lists only a set of effects that can be estimated.

Alias Terms

Add or remove effects to compare your designs for effects that might be active. The Alias Terms outline initially contains all two-factor interactions that are not in the Model outline. The effects in this outline impact the calculations in the Alias Matrix Summary and Absolute Correlations outline. See “Alias Matrix Summary” on page 498 and “Absolute Correlations” on page 500.

For more information about how to add and remove effects, see “Alias Terms” on page 450 in the “Evaluate Designs” chapter.

Compare Designs Window: Design Evaluation

- “Power Analysis”
- “Prediction Variance Profile”
- “Fraction of Design Space Plot”
- “Relative Estimation Efficiency”
- “Alias Matrix Summary”
- “Absolute Correlations”
- “Design Diagnostics”

Color Dashboard

Several of the Design Evaluation outlines show values colored according to a color bar. The colors are applied to diagnostic measures and they help you see which values (and designs) reflect good or bad behavior. You can edit the legend values to apply colors that reflect your definitions of good and bad behavior.

Figure 16.19 Color Dashboard
You can modify the color bar by selecting these two options in the red triangle menu for the outline or by right-clicking the color bar:

**Show Legend Values**  Shows or hides the values that appear under the color bar.

**Edit Legend Values**  Specify the values that define the colors.

### Power Analysis

Power is the probability of detecting an active effect of a given size. The Power Analysis report helps you evaluate and compare the ability of your designs to detect effects of practical importance. For each of your designs, the Power Analysis report calculates the power of tests for the effects in the Model outline.

The Power Analysis report gives the power of tests for individual model parameters and for whole effects. It also provides a Power Plot and a Power versus Sample Size plot.

Power depends on the number of runs, the significance level, and the estimated error variation. For more information about how power is calculated, see “Power Calculations” on page 824 in the “Technical Details” appendix.

**Figure 16.20**  Power Analysis Outline for Three Designs

Figure 16.20 shows the Power Analysis outline for the three designs constructed in “Designs of Different Run Sizes” on page 478. Two two-way interactions have been added to the Model outline.
Power Analysis Report

When you specify values for the Significance Level and Anticipated RMSE, they are used to calculate the power of the tests for the model parameters. Enter coefficient values that reflect differences that you want to detect as Anticipated Coefficients. To update the results for all designs, click Apply Changes to Anticipated Coefficients.

**Significance Level**  The probability of rejecting the hypothesis of no effect, if it is true. The power calculations update immediately when you enter a value.

**Anticipated RMSE**  An estimate of the square root of the error variation. The power calculations update immediately when you enter a value.

The power values are colored according to a color gradient that appears under the Apply Changes to Anticipated Coefficients button. You can control the color legend using the options in the Power Analysis red triangle menu. See “Color Dashboard” on page 489.

For more information about the Power Plots, see “Power Plot” on page 492.

**Note:** If the design is supersaturated, meaning that the number of parameters to be estimated exceeds the number of runs, the Power Analysis outline lists only a set of effects that can be estimated.

Tests for Individual Parameters

The Term column contains a list of model terms. For each term, the Anticipated Coefficient column contains a value for that term. The Power value is the power of a test that the coefficient for the term is zero if the true value of the coefficient is given by the Anticipated Coefficient, given the design, and the terms in the Model outline.

**Term**  The model term associated with the coefficient being tested.

**Anticipated Coefficient**  A value for the coefficient associated with the model term. This value is used in the calculations for Power. When you set a new value in the Anticipated Coefficient column, click **Apply Changes to Anticipated Coefficients** to update the Power calculations.

**Note:** The anticipated coefficients have default values of 1 for continuous effects. They have alternating values of 1 and –1 for categorical effects.

**Power**  The probability of rejecting the null hypothesis of no effect when the true coefficient value is given by the specified Anticipated Coefficient.

  - For a coefficient associated with a numeric factor, the change in the mean response from the high to low setting (based on the model) is twice the coefficient value.
For a coefficient associated with a categorical factor, the change in the mean response (based on the model) across the levels of the factor equals twice the absolute value of the anticipated coefficient. For more information on power for categorical factors, see “Tests for Categorical Effects with More Than Two Levels” on page 492.

Calculations use the specified Significance Level and Anticipated RMSE. For more information about the power calculation, see “Power for a Single Parameter” on page 824 in the “Technical Details” appendix.

**Apply Changes to Anticipated Coefficients**  When you set a new value in the Anticipated Coefficient column, click **Apply Changes to Anticipated Coefficients** to update the Power values.

**Tests for Categorical Effects with More Than Two Levels**

If your model contains a categorical effect with more than two levels, then the following columns appear below the Apply Changes to Anticipated Coefficients button:

- **Effect**  The categorical effect.
- **Power**  The power calculation for a test of no effect. The null hypothesis for the test is that all model parameters corresponding to the effect are zero. The difference to be detected is defined by the values in the Anticipated Coefficient column that correspond to the model terms for the effect. The power calculation reflects the differences in response means determined by the anticipated coefficients.

Calculations use the specified Significance Level and Anticipated RMSE. For more information about the power calculation, see “Power for a Categorical Effect” on page 826 in the “Technical Details” appendix.

**Power Plot**

The Power Plot shows the power values from the Power Analysis in graphical form. The plot shows the power for each effect and for each design in a side-by-side bar chart.
Figure 16.21  Power Plot for Three Designs

The Power Plot in Figure 16.21 is for the main effects of the three designs constructed in “Designs of Different Run Sizes” on page 478.

Power versus Sample Size

The Power versus Sample Size plots appears only when the designs that you are comparing differ in run size. The plots enables you to see how sample size affects power for each effect in the model. It conveys the same information as is in the Power Plots graph, but in a different format. The power values at integer sample sizes are connected with line segments.

Figure 16.22  Power versus Sample Size Profiler for Three Designs

Prediction Variance Profile

The Prediction Variance Profile outline shows profilers of the relative variance of prediction for each design being compared. Each plot shows the relative variance of prediction as a function of each factor at fixed values of the other factors.
To find the maximum value of the relative prediction variance over the design space for the reference design, select the **Maximize Variance** option from the red triangle next to Prediction Variance Profile. See “Maximize Variance” on page 495.

**Figure 16.23** Prediction Variance Profile for Three Designs

![Prediction Variance Profile](image)

The Prediction Variance Profile plot in Figure 16.23 is for the three designs constructed in “Designs of Different Run Sizes” on page 478. Two two-way interactions, \(X_1 \times X_3\) and \(X_2 \times X_3\), have been added to the Model outline. The initial value for each continuous factor in the plot is the midpoint of its design settings. The Variance values to the left indicate that, as the number of runs increases, the variance decreases at the center point.

**Relative Prediction Variance**

For given settings of the factors, the prediction variance is the product of the error variance and a quantity that depends on the design and the factor settings. Before you run your experiment, the error variance is unknown, so the prediction variance is also unknown. However, the ratio of the prediction variance to the error variance is not a function of the error variance. This ratio, called the **relative prediction variance**, depends only on the design and the factor settings. Consequently, the relative variance of prediction can be calculated before acquiring the data. See “Relative Prediction Variance” on page 827 in the “Technical Details” appendix.

After you run your experiment and fit a least squares model, you can estimate the error variance using the mean squared error (MSE) of the model fit. You can estimate the actual variance of prediction at any setting by multiplying the relative variance of prediction at that setting.

Ideally, the prediction variance is small throughout the design space. Generally, the error variance drops as the sample size increases. In comparing designs, a design with lower prediction variance on average is preferable.
Maximize Variance

You can also evaluate a design or compare designs in terms of the maximum relative prediction variance. Select the **Maximize Variance** option from the red triangle next to Prediction Variance Profile. JMP uses a desirability function that maximizes the relative prediction variance. The value of the Variance in the Prediction Variance Profile is the worst (least desirable from a design point of view) value of the relative prediction variance.

**Figure 16.24** Prediction Variance Profile Showing Maximum Variance for Three Designs

Figure 16.24 shows the Prediction Variance Profile after Maximize Variance was selected for the three designs constructed in “Designs of Different Run Sizes” on page 478. As expected, the maximum relative prediction variance decreases as the run size increases. The plot also shows values of the factors that give this worst-case relative variance. However, keep in mind that many settings can lead to this same maximum relative variance.

**Fraction of Design Space Plot**

The Fraction of Design Space Plot shows the proportion of the design space over which the relative prediction variance lies below a given value.
Figure 16.25 Fraction of Design Space Plot for Three Designs

Figure 16.25 shows the Fraction of Design Space plot for the three designs constructed in “Designs of Different Run Sizes” on page 478. Note the following:

- The X axis in the plot represents the proportion of the design space, ranging from 0 to 100%.
- The Y axis represents relative prediction variance values.
- For a point \((x, y)\) that falls on a given curve, the value \(x\) is the proportion of design space with variance less than or equal to \(y\).
- Red dotted crosshairs mark the value that bounds the relative prediction variance for 50% of design space for the reference design.

Figure 16.25 shows that the relative prediction variance for the 24-run design is uniformly smaller than for the other two designs. The 20-run design has uniformly smaller prediction variance than the 16-run design. The red dotted crosshairs indicate that the relative prediction variance for the 20-run design is less than about 0.23 over about 50% of the design space.

You can use the crosshairs tool to find the maximum relative prediction variance that corresponds to any Fraction of Space value. For example, use the crosshairs tool to see that for the 24-run design, 90% of the prediction variance values are below approximately 0.20.

**Note:** Plots for the same design might vary slightly, since Monte Carlo sampling of the design space is used in constructing the Fraction of Design Space Plot.
Relative Estimation Efficiency

The Relative Estimation Efficiency report compares designs in terms of the standard errors of parameter estimates for parameters in the assumed model. The standard errors control the length of confidence intervals for the parameter estimates. This report provides an efficiency ratio and the relative standard errors.

The relative estimation efficiency values are colored according to a color gradient shown under the table of relative estimation efficiency values. You can control the color legend using the options in the Relative Estimation Efficiency red triangle menu. See “Color Dashboard” on page 489.

Figure 16.26  Relative Estimation Efficiency Comparing Two Split-Plot Designs

Figure 16.26 shows the Relative Estimation Efficiency outline for the split-plot designs compared in “Split Plot Designs with Different Numbers of Whole Plots” on page 482.

Relative Estimation Efficiency

For a given term, the estimation efficiency of the reference design relative to a comparison design is the relative standard error of the term for the comparison design divided by the relative standard error of the term for the reference design. A value less than one indicates that the reference design is not as efficient as the comparison design. A value greater than one indicates that it is more efficient.
Relative Standard Error of Estimates

The Relative Std Error of Estimates report gives the ratio of the standard deviation of a parameter’s estimate to the error standard deviation. These values indicate how large the standard errors of the model’s parameter estimates are, relative to the error standard deviation. For the \( i \)th parameter estimate, the Relative Std Error of Estimate is defined as follows:

\[
SE = \sqrt{(X'X)_{ii}^{-1}}
\]

where:

- \( X \) is the model matrix defined in “The Alias Matrix” on page 823 in the “Technical Details” appendix, and
- \((X'X)^{-1}\) is the \( i \)th diagonal entry of \((X'X)^{-1}\).

Alias Matrix Summary

The alias matrix addresses the issue of how terms that are not included in the model affect the estimation of the model terms, if they are indeed active. In the Alias Terms outline, you list potentially active effects that are not in your assumed model but that might bias the estimates of model terms. The alias matrix entries represent the degree of bias imparted to model parameters by the Alias Terms effects. See “Alias Terms” on page 489 and “Alias Matrix” on page 499.

The Alias Matrix Summary table lists the terms in the assumed model. These are the terms that correspond to effects listed in the Model outline. Given a design, for each entry in the Term column, the square root of the sum of the squared alias matrix entries for the terms corresponding to effects in the Alias Terms outline is computed. This value is reported in the Root Mean Squared Values column for the given design. For an example, see “Example of Calculation of Alias Matrix Summary Values” on page 499.

Note: The Alias Matrix Summary report appears only if there are effects in the Alias Terms list.
Figure 16.27 Alias Matrix Summary for Two Designs

Figure 16.27 shows the Alias Matrix Summary report for the Plackett-Burman and Definitive Screening designs constructed in “Designs of Same Run Size” on page 473, with only main effects in the Model outline. All two-factor interactions are in the Alias Terms list. The table shows that, for the Definitive Screening Design, main effects are uncorrelated with two-factor interactions.

The Root Mean Squares Values are colored according to a color gradient shown under the Alias Matrix Summary table. You can control the color legend using the options in the Alias Matrix Summary red triangle menu. See “Color Dashboard” on page 489.

Alias Matrix

The rows of the Alias Matrix are the terms corresponding to the model effects listed in the Model outline. The columns are terms corresponding to effects listed in the Alias Terms outline. The entry in a given row and column indicates the degree to which the alias term affects the parameter estimate corresponding to the model term.

In evaluating your design, you ideally want one of two situations to occur relative to any entry in the Alias Matrix. Either the entry is small or, if it is not small, the effect of the alias term is small so that the bias is small. If you suspect that the alias term might have a substantial effect, then that term should be included in the model or you should consider an alias-optimal design. In fact, alias-optimality is driven by the squared values of the alias matrix.

For additional background on the Alias Matrix, see “The Alias Matrix” on page 823 in the “Technical Details” appendix. See also Lekivetz, R. (2014).

Example of Calculation of Alias Matrix Summary Values

This example illustrates the calculation of the values that appear in the Alias Matrix Summary outline. In this example, you compare the two designs assuming that only main effects are active.

1. Select Help > Sample Data, click Open the Sample Scripts Directory, and select Compare Same Run Size.jsl.
2. Right-click in the script window and select **Run Script**.

   Two 13-run design tables are constructed:
   – Definitive Screening Design
   – Plackett-Burman

   You are interested only in the Plackett-Burman design. This is the active table.

3. From the Plackett-Burman table, select **DOE > Design Diagnostics > Evaluate Design**.
4. Select X1 through X6 and click **X, Factor**.
5. Click **OK**.
6. Open the Alias Terms outline to confirm that all two-factor interactions are in the Alias Terms list.
7. Open the Alias Matrix outline.

   For each model term listed in the Effect column, the entry in that row for a given column indicates the degree to which the alias term affects the parameter estimate corresponding to the model term.

   For example, to obtain the Alias Matrix Summary entry in Figure 16.27 corresponding to X1, square the terms in the row for X1 in the Alias Matrix, average these, and take the square root. You obtain 0.2722.

### Absolute Correlations

The Absolute Correlations report summarizes information about correlations between model terms and alias terms.
Figure 16.28 Absolute Correlations Report for Three Designs

The table in the Absolute Correlations report is divided into three sections:

- Model x Model considers correlations between terms corresponding to effects in the Model list.
- Model x Alias considers correlations between terms corresponding to effects in the Model list and terms corresponding to effects in the Alias list.
- Alias x Alias considers correlations between terms corresponding to effects in the Alias list.

Note: If there are no alias terms, only the Model x Model section appears.
Compare Designs
Chapter 16

For each section of the report, the following are given:

**Average Correlation**  The average of the correlations for all pairs of terms considered in this section of the report.

**Number of Confoundings**  The number of pairs of terms consisting of confounded terms.

**Number of Terms**  The total number of pairs of terms considered in this section of the report.

The values in the Absolute Correlations table are colored according to a color gradient shown under the table. You can control the color legend using the options in the Absolute Correlations red triangle menu. See “Color Dashboard” on page 489.

**Color Map on Correlations**

The Color Map on Correlations outline shows plots for each of the designs. The cells of the color map are identified above the map. There are cells for all terms that correspond to effects that appear in either the Model outline or the Alias Terms outline. Each cell is colored according to the absolute value of the correlation between the two terms.

By default, the absolute magnitudes of the correlations are represented by a white to gray to black intensity color theme. In general terms, the color map for a good design shows a lot of white off the diagonal, indicating orthogonality or small correlations between distinct terms. Large absolute correlations among effects inflate the standard errors of estimates.

To see the absolute value of the correlation between two effects, hover over the corresponding cell. To change the color scale, click the Color Map on Correlations red triangle and select **Blue to Gray to Red**. For a custom color scale, right-click in the plot and select **Color Theme**. To save a table of the correlations, right-click to the right of the plot below the legend and select **Table of Correlations**.

**Absolute Correlations and Color Map on Correlations Example**

Figure 16.28 shows the Absolute Correlations report for the Plackett-Burman and Definitive Screening designs constructed in “Designs of Different Run Sizes” on page 478. The Model outline contains only main effects, so the Alias Terms outline contains all two-factor interactions. All main effects and two-way interactions are shown in the color maps.

In the Color Map on Correlations for the 16-run design, the black cells off the main diagonal indicate that the corresponding terms have correlation one and therefore are completely confounded. There are nine instances where model terms (main effects) are confounded with alias terms (two factor interactions), and six instances where alias terms are confounded with each other. This is shown in the report under Pairwise Confoundings.
The color maps for the 20- and 24-run designs have no off-diagonal cells that are solid black. It follows that these designs show no instances of confounding between any pair of main or two-way interaction effects. However, it is interesting to note that the 20- and 24-run designs both have a higher Average Correlation for Model x Alias terms than does the 16-run design. Although the 16-run design shows confounding, the average amount of correlation is less than for the 20- and 24-run designs.

**Design Diagnostics**

The Design Diagnostics outline shows \( D \)-, \( G \)-, \( A \)-, and \( I \)-efficiencies for the reference design relative to the comparison designs. It also shows the Additional Run Size. Given two designs, the one with the higher relative efficiency measure is better.

**Figure 16.29** Design Diagnostics for Three Designs

![Design Diagnostics Table]

Figure 16.29 shows the Design Diagnostics report for the three designs constructed in “Designs of Different Run Sizes” on page 478, with only main effects in the Model outline.

The values in the Design Diagnostics table are colored according to a color gradient shown under the table. You can control the color legend using the options in the Design Diagnostics red triangle menu. See “Color Dashboard” on page 489.

**Efficiency and Additional Run Size**

Relative efficiencies for each of \( D \)-, \( G \)-, \( A \)-, and \( I \)-efficiency are shown in the Design Diagnostics report. These are obtained by computing each design’s efficiency value and then taking the appropriate ratio. The descriptions of the relative efficiency measures are given in “Relative Efficiency Measures” on page 504.

Additional Run Size is the number of runs in the reference design minus the number of runs in the comparison design. If your reference design has more runs than your comparison design, then the Additional Run Size tells you how many additional runs you need to achieve the efficiency of the reference design.
Relative Efficiency Measures

Notation

- $X$ is the model matrix
- $p$ is the number of terms, including the intercept, in the model
- $\text{Var}(\hat{y}|\bar{x})$ is the relative prediction variance at the point $\bar{x}$. See “Relative Prediction Variance” on page 827 in the “Technical Details” appendix.

Relative Efficiencies

The relative efficiency of the reference design ($\text{Ref}$) to the comparison design ($\text{Comp}$) is given by the following expressions:

**D Efficiency**  $\frac{\text{Eff}_{\text{Ref}}}{\text{Eff}_{\text{Comp}}}$ where $\text{Eff}$ for each design is given as follows:

\[ \text{Eff} = |X'X|^{1/p} \]

**G Efficiency**  $\frac{\text{Eff}_{\text{Comp}}}{\text{Eff}_{\text{Ref}}}$ where $\text{Eff}$ for each design is given as follows:

\[ \text{Eff} = \text{Var}(\hat{y}|\bar{x})_{\text{max}} = \text{maximum}[\bar{x}'(X'X)^{-1}\bar{x}] \]

Here, D denotes the design region.

**Note:** G-Efficiency is calculated using Monte Carlo sampling of the design space. The reported value is based on the larger of $\text{Var}(\hat{y}|\bar{x})_{\text{max}}$ or the prediction variance from the Monte Carlo sampling. Therefore, calculations for the same design might vary slightly.

**A Efficiency**  $\frac{\text{Eff}_{\text{Comp}}}{\text{Eff}_{\text{Ref}}}$ where $\text{Eff}$ for each design is given as follows:

\[ \text{Eff} = \text{Trace}[(X'X)^{-1}] \]

**I Efficiency**  $\frac{\text{Eff}_{\text{Comp}}}{\text{Eff}_{\text{Ref}}}$ where $\text{Eff}$ for each design is given as follows:

\[ \text{Eff} = \frac{\int \bar{x}'(X'X)^{-1}\bar{x} d\bar{x}}{\int d\bar{x}} \]

For more information about the calculation, see Section 4.3.5 in Goos and Jones (2011).
Compare Designs Options

**Advanced Options > Split Plot Variance Ratio**  Specify the ratio of the variance of the random whole plot and the subplot variance (if present) to the error variance. Before setting this value, you must define a hard-to-change factor for your split-plot design, or hard and very-hard-to-change factors for your split-split-plot design. Then you can enter one or two positive numbers for the variance ratios, depending on whether you have specified a split-plot or a split-split-plot design.
Use the Sample Size and Power platform to investigate the impact of sample size on your ability to answer specific questions when planning experiments or studies.

- How many units should I test?
- Will I be able to detect a difference in my treatment means?
- How many units must I test to estimate failure time?

The Sample Size and Power platform is a collection of calculators. The calculators have fields for data entry and calculated values. You can select values to specify and those to calculate. For example, you might specify power and the effect size that you want to detect and then calculate the necessary sample size. Alternatively, you might specify a sample size and power to calculate the effect size that you can detect.

Sample size calculations for hypothesis tests are based on the trade off between Type I and Type II errors. The Type I error, or $\alpha$, is the probability of rejecting the null hypothesis when it is true. The Type II error, or $\beta$, is the probability of not rejecting the null hypothesis when it is false. Generally you would like $\alpha$ and $\beta$ to be small. Power, or $1 - \beta$, is the probability of rejecting the null hypothesis when it is false.

For more information about power and sample size in JMP, see Barker (2011).

Launch the Sample Size and Power Platform

The Sample Size and Power platform is a collection of calculators for planning experiments or studies. Launch the Sample Size and Power platform by selecting **DOE > Design Diagnostics > Sample Size and Power**.

**Figure 17.2** Sample Size and Power Launch Window

Choose from the following calculators:

- "One Sample Mean Calculator" on page 511
- "Two Sample Means Calculator" on page 518
- "k Sample Means Calculator" on page 521
- "One Sample Standard Deviation Calculator" on page 525
- "One Sample Proportion Calculator" on page 528
- "Two Sample Proportions Calculator" on page 531
- "Counts per Unit Calculator" on page 534
- "Sigma Quality Level Calculator" on page 537
- "Reliability Test Plan Calculator" on page 539
- "Reliability Demonstration Calculator" on page 544
One Sample Mean Calculator

Use the One Sample Mean calculator to evaluate sample size for a hypothesis test about one mean. Study the trade offs between sample size, power, significance, and the hypothesized difference to detect. Sample size and power are associated with the following hypothesis test:

\[ H_0: \mu = \mu_0 \]

versus the two-sided alternative:

\[ H_a: \mu \neq \mu_0 \]

where \( \mu \) is the true mean and \( \mu_0 \) is the null mean or reference value. The difference to detect is an amount, \( \delta \), away from \( \mu_0 \) that one considers as important to detect based on a set of samples. For the same significance level and power, a larger sample size is needed to detect a small difference than to detect a large difference. It is assumed that the population of interest is normally distributed with mean \( \mu \) and standard deviation \( \sigma \).

**Figure 17.3** Initial Sample Size and Power Calculator for One Mean
Examples of the One Sample Mean Calculator

In the following examples, suppose you are interested in demonstrating that the flammability of a new fabric being developed by your company has improved performance over current materials. Previous testing indicates that the standard deviation for time to burn of this fabric is 2 seconds.

Example of Sample Size Calculation

In this initial example, you would like to design an experiment that has 90% power to detect a difference of 1.5 seconds at a significance level of $\alpha = 0.05$. Use the One Sample Mean calculator to calculate the number of fabric samples you need to test.

2. Click the One Sample Mean button.
3. Leave Alpha set to 0.05.
4. Enter 2 for Std Dev.
5. Leave Extra Parameters set to 0.
6. Enter 1.5 for Difference to detect.
7. Leave Sample Size blank.
8. Enter 0.9 for Power.
9. Click Continue.

Figure 17.4 One-Sample Mean Calculator

At a significance level of 0.05, 21 fabric samples are needed to have a 90% chance of detecting a significant difference of 1.5 seconds in the burn time.
Example of Power versus Sample Size Plot

To explore tradeoffs between sample size and power in your fabric experiment, use the plot of power versus sample size.

1. Select **DOE > Design Diagnostics > Sample Size and Power**.
2. Click **One Sample Mean**.
3. Leave **Alpha** set to 0.05.
4. Enter 2 for **Std Dev**.
5. Leave **Extra Parameters** set to 0.
6. Enter 1.5 for the **Difference to detect**.
7. Leave **Sample Size** blank.
8. Leave **Power** blank.
9. Click **Continue** to launch the power by sample size plot.

**Figure 17.5**  Power by Sample Size

The plot shows a range of sample sizes for which the power varies from about 0.1 to about 0.95. You could reduce the number of tests in your experiment to about 15 and maintain power above 75%. However, if you ran only 10 tests, the power to detect a significant difference of 1.5 would drop to about 50%.

**Tip:** Use the crosshair tool to obtain sample size and power combinations from the plot.
Example of Power versus Difference Plot

To explore trade offs between power and the magnitude of the difference that you can detect with 21 observations in your fabric experiment, use the plot of power versus difference.

2. Click One Sample Mean.
3. Leave Alpha set to 0.05.
4. Enter 2 for Std Dev.
5. Leave Extra Parameters set to 0.
7. Enter 21 for Sample Size.
8. Leave Power blank.
9. Click Continue.

Figure 17.6 Plot of Power by Difference to Detect for a Sample Size of 21

At a significance level of 0.05 and 21 observations, you can detect a difference of 1.5 seconds with 90% power. If the difference is only one second smaller, then with 21 fabric samples, you have about 50% power of detecting the difference.

Example of an Animation Script

Use an animation script to explore how changing the sample size affects power.

2. Click **One Sample Mean**.
3. Leave **Alpha** set to 0.05.

**Tip:** You can change the Alpha level after the animation is launched by clicking the Alpha value in the animation window.

4. Enter 2 for **Std Dev**.
5. Leave **Extra Parameters** set to 0.
6. Enter 1.5 as **Difference to detect**.
7. Leave **Sample Size** blank.

**Tip:** When you leave the sample size blank, the default sample size is set to 20. You will see the default of 20 after the animation script is launched. You can change the sample size before or after the animation is launched. To change it after the animation is launched, click the Sample Size value in the animation window.

8. Leave **Power** blank.
9. Click **Animation Script**.

**Figure 17.7** Initial Animation Script to Illustrate Power

The initial animation plot shows two $t$-density curves:

- The red curve shows the $t$-distribution when the true mean is zero.
- The blue curve shows the $t$-distribution when the true mean is 1.5, which is the difference to be detected.
– The blue shading indicates the probability of committing a type II error. A type II error is the probability of not detecting a difference when there is a difference. The probability of a type II error is often denoted by $\beta$.

– The red shading indicates the probability of committing a type I error. A type I error is the probability of concluding that the difference in means is significant when there is no difference. The probability of a type I error is often denoted by $\alpha$.

Select and drag the square handles to see the changes in statistics based on the positions of the curves. To change the values of Sample Size and Alpha, click their values beneath the plot.

By default, the animation shows a two sided test. Use the Two Sided, Low Side, and High Side buttons to toggle between not equal, less than, or greater than alternative hypotheses.

**One Sample Mean Calculator Fields**

Specify the following quantities:

**Alpha** The probability of a type I error, which is the probability of rejecting the null hypothesis when it is true. It is commonly referred to as the significance level of the test. The default alpha level is 0.05.

**Tip:** For a one-sided test, use $\alpha = \alpha \times 2$. For a one sided test with $\alpha = 0.05$, use the two-sided calculator with $\alpha = 0.10$. The resulting values are those needed for a one-sided test with $\alpha = 0.05$.

**Std Dev** The assumed standard deviation. An estimate of the error standard deviation could be the root mean square error (RMSE) from a previous model fit.

**Tip:** Use a standard deviation of 1 to estimate the sample size needed to detect differences measured in standard deviation units.

**Extra Parameters** The number of parameters other than $\mu$ in the hypothesis test. This option can be used for multi-factor designs. Leave the default zero in this field for simple cases.

In a multi-factor design where effects are orthogonal, you can specify the number of additional model parameters here. For example, in a three-factor, two-level design with all three two-factor interactions, the number of additional parameters is five: two parameters for the other main effects, and three parameters for the interactions.

Specify two of the following values to calculate the third value, or specify one value to obtain a plot of the relationship between the other two:

**Difference to Detect** The smallest difference between the true mean and the hypothesized or reference mean you want to be able to declare statistically significant.
Sample Size  The total number of observations (runs, experimental units, or samples) in your experiment.

Power  The probability of rejecting the null hypothesis when it is false. With all other parameters fixed, power increases as sample size increases.

Calculator Buttons

Continue  Evaluates the missing value when two parameters are specified, or launches a plot comparing two missing parameters if only one parameter is specified.

Back  Returns to the previous Sample Size and Power launch window.

Animation Script  Launches an interactive plot to illustrate and explore the relationship between power and the difference to detect. See “Example of an Animation Script” on page 514.

Statistical Details for the One Sample Mean Calculator

The one sample mean calculations are based on the traditional full versus reduced F test for the following hypothesis test:

\[ H_0: \mu = \mu_0 \text{ vs } H_a: \mu \neq \mu_0 \]

JMP calculates power as follows:

\[
\Pr(\text{reject } H_0 \mid \mu = \mu_0 + \delta) = 1 - F \left( f_{1-\alpha}, 1, n - p - 1, \frac{n\delta^2}{\sigma^2} \right)
\]

where:

\( \alpha \) is the significance level.
\( n \) is the sample size.
\( p \) is the number of extra parameters.
\( \delta \) is the difference to detect.
\( f_{1-\alpha} \) is the \((1 - \alpha)\)th quantile of the \(F(1, n - p - 1)\) distribution.
\( F(x, df_1, df_2, nc) \) is the cumulative distribution function of the non-central \( F \) distribution with degrees of freedom \( df_1 \) and \( df_2 \) and non-centrality parameter \( nc \) evaluated at \( x \).

Because analytical solutions for \( \delta \) and \( n \) do not exist, numerical solutions are used to solve for them.

For more information about calculations in JMP, see Barker (2011, Section 2.1).
Two Sample Means Calculator

Use the Two Sample Means calculator to evaluate sample size for a hypothesis test about two means. Explore questions such as how large a treatment effect is detectable for a given sample size, significance level, desired power, and assumed variability in the data. Sample size and power are associated with the following hypothesis test:

\[ H_0: \mu_1 - \mu_2 = 0 \]

versus the two-sided alternative:

\[ H_a: \mu_1 - \mu_2 \neq 0 \]

where \( \mu_1 \) and \( \mu_2 \) are the true means of the two populations. It is assumed that the populations of interest are normally distributed and that you want to detect a difference of \( \delta \) between the means.

Example of the Two Sample Means Calculator

Suppose you are comparing two groups and want to detect a 1 standard deviation difference between the group means at a 0.05 significance level with 80% power.

2. Click Two Sample Means.
3. Leave Alpha as 0.05.
4. Enter 1 for Std Dev.
5. Leave Extra Parameters as 0.
6. Enter 1 as Difference to detect.
7. Leave Sample Size blank.
8. Enter 0.8 for Power.
9. Click Continue.
The sample size is calculated as 34. With 17 samples in each group, you have an 80% chance of detecting a 1 standard deviation difference between the two sample means at a significance level of $\alpha = 0.05$.

**Two Sample Means Calculator Fields**

Specify the following quantities:

**Alpha**  The probability of a type I error, which is the probability of rejecting the null hypothesis when it is true. It is commonly referred to as the significance level of the test. The default alpha level is 0.05.

**Std Dev**  The assumed standard deviation where both groups are assumed to have equal standard deviation.

**Extra Parameters**  The number of parameters other than $\mu_1$ and $\mu_2$ in the hypothesis test. This option can be used for multi-factor designs. Leave the default zero in this field for simple cases.

In a multi-factor balanced design, the number of additional model parameters can be specified here. For example, in a three-factor two-level design with all three two-factor interactions, the number of additional parameters is four: one parameter for the other main effects, and three parameters for the interactions.

Specify two of the following parameters to calculate the third value, or specify one value to obtain a plot of the relationship between the other two parameters:

**Difference to Detect**  The smallest difference between the two means that you want to be able to declare statistically significant.
Sample Size  The total number of observations (runs, experimental units, or samples) in your experiment. Use half of this sample size in each group.

Power  The probability of rejecting the null hypothesis when it is false. With all other parameters fixed, power increases as sample size increases.

Calculator Buttons

Continue  Evaluates the missing value when two parameters are specified, or launches a plot comparing two missing parameters if only one parameter is specified.

Back  Returns to the previous Sample Size and Power launch window.

Statistical Details for the Two Sample Means Calculator

The two sample mean calculations are based on the traditional full versus reduced $F$ test for the following hypothesis test:

$$H_0: \mu_1 - \mu_2 = 0 \text{ vs } H_a: \mu_1 - \mu_2 \neq 0$$

JMP calculates power as follows:

$$\text{power} = \Pr(\text{reject } H_0 \mid \mu_1 - \mu_2 = \delta) = 1 - F(f_{1 - \alpha}, 1, 2n - p - 2, \frac{n\delta^2}{2\sigma^2})$$

where:

$\alpha$ is the significance level.

$n$ is the sample size per group.

$p$ is the number of extra parameters.

$\delta$ is the difference to detect.

$f_{1 - \alpha}$ is the $(1 - \alpha)^{th}$ quantile of the $F(1, 2n - p - 2)$ distribution.

$F(x, df_1, df_2, nc)$ is the cumulative distribution function of the non-central $F$ distribution with degrees of freedom $df_1$ and $df_2$ and non-centrality parameter $nc$ evaluated at $x$.

Because analytical solutions for $\delta$ and $n$ do not exist, numerical solutions are used to solve for them.

For more information about calculations in JMP, see Barker (2011, Section 2.2).
k Sample Means Calculator

Use the k Sample Means calculator to determine an appropriate sample size for a hypothesis test about two to ten means. Sample size and power are associated with the following hypothesis test:

\[ H_0: \mu_1 = \mu_2 = \ldots = \mu_k \]

versus the two-sided alternative:

\[ H_a: \text{not all means equal} \]

where:

\[ X_{ij} \sim N(\mu_j, \sigma^2) \text{ for } i = 1, \ldots, n, \ j = 1, \ldots, k \]

Example of the k Sample Means Calculator

Suppose you have 4 observations from each of 4 groups and you want to test to see whether all of the group means are equal. You expect the group means to be 10, 11, 12, and 13 with a standard deviation of 0.9. Calculate the power of detecting a difference in one or more means at a 0.05 significance level.

1. Select \textbf{DOE > Design Diagnostics > Sample Size and Power}.
2. Click \textbf{k Sample Means}.
3. Leave \textbf{Alpha} as 0.05.
4. Enter 0.9 for \textbf{Std Dev}.
5. Leave \textbf{Extra Parameters} as 0.
6. Enter 10, 11, 12, and 13 as the four levels of prospective means.
7. Enter 16 for \textbf{Sample Size}.
8. Leave \textbf{Power} blank.
9. Click \textbf{Continue}.
Figure 17.9 Prospective Power for 4 Means

The Power is calculated as approximately 0.95. This means that there is a 95% chance of detecting that at least one of the means is different at a 0.05 significance level, assuming that the population means are 10, 11, 12, and 13, with a standard deviation of 0.9 and a total sample size of 16.

10. Click the 16 for Sample Size and delete it.
11. Click the 0.95 for Power and delete it.
12. Click **Continue** to launch a plot of power versus sample size.
From the plot of power versus sample size, you can confirm that a sample size of 16 is acceptable. Hover over the Sample Size axis and drag to extend the axis beyond 16. You can see that the increase in power for sample sizes above 16 is slight.

The plot also reports the difference in means, which is calculated as the square root of the sum of squared deviations from the grand mean. In this case, it is the square root of \((-1.5)^2 + (-0.5)^2 + (0.5)^2 + (1.5)^2\), which is the square root of 5. Therefore, the difference in means in this example is approximately 2.236.

**k Sample Means Calculator Fields**

Specify the following quantities:

**Alpha**  
The probability of a type I error, which is the probability of rejecting the null hypothesis when it is true. It is commonly referred to as the significance level of the test. The default alpha level is 0.05.

**Std Dev**  
The assumed standard deviation where all groups are assumed to have equal standard deviation.

**Extra Parameters**  
The number of parameters other than the \(\mu\) in the hypothesis test. This option can be used for multi-factor designs. Leave the default 0 in this field in simple cases.

**Prospective Means**  
The assumed values for the means. At least two means must be specified.
Specify one of the following values to calculate the second, or leave both values blank to obtain a plot of the relationship between the two:

**Sample Size** The total number of observations (runs, experimental units, or samples) in your experiment. Use a sample size of \( n/k \) in each group, where \( n \) is the total number of observations.

**Power** The probability of rejecting the null hypothesis when it is false. With all other parameters fixed, power increases as sample size increases.

**Calculator Buttons**

**Continue** Evaluates the missing value when one parameter is specified, or launches a plot comparing two parameters if no parameters are specified.

**Back** Returns to the previous Sample Size and Power launch window.

### Statistical Details for the k Sample Means Calculator

The \( k \) sample mean calculations are based on the following:

\[
\text{power} = 1 - F \left( f_{1-\alpha}, 1k - 1, 2kn - p - 2k, \sum_{i=1}^{k} \frac{(\mu_j - \bar{\mu})^2}{\sigma^2} \right)
\]

where:

- \( \alpha \) is the significance level
- \( \sigma \) is the common standard deviation among the \( k \) groups.
- \( n \) is the sample size per group.
- \( p \) is the number of extra parameters.
- \( \bar{\mu} \) is the mean of the \( k \) group prospective means
- \( f_{1-\alpha} \) is the \((1 - \alpha)\)th quantile of the \( F(k - 1, kn - p - k) \) distribution.
- \( F(x, df_1, df_2, nc) \) is the cumulative distribution function of the non-central \( F \) distribution with degrees of freedom \( df_1 \) and \( df_2 \) and non-centrality parameter \( nc \) evaluated at \( x \).

Numerical solutions are used to solve for \( n \).
Difference in Means

The difference in means is calculated as follows:

\[
\sqrt{k \sum_{j=1}^{k} (\mu_j - \mu)^2}
\]

For more information about calculations in JMP, see Barker (2011, Section 2.3).

One Sample Standard Deviation Calculator

Use the One Sample Standard Deviation calculator to evaluate sample size for a hypothesis test about one standard deviation. Sample size and power are associated with the following hypothesis test:

\[
H_0: \sigma = \sigma_0
\]

versus the one-sided alternative:

\[
H_a: \sigma > \sigma_0 \text{ or } H_a: \sigma < \sigma_0
\]

where \( \sigma \) is the population standard deviation and \( \sigma_0 \) is the hypothesized value. The difference to detect is an amount, \( \delta \), away from \( \sigma_0 \) that one considers as important to detect based on a set of samples.

Example of the One Sample Standard Deviation Calculator

**Note:** This example is from the online manual of The National Institute of Standards and Technology (NIST). You can access the NIST manual examples at [https://www.itl.nist.gov/div898/handbook/prc/section2/prc232.htm](https://www.itl.nist.gov/div898/handbook/prc/section2/prc232.htm).

The variance for resistivity measurements on a lot of silicon wafers is claimed to be 100 ohm-cm squared. The buyer is unwilling to accept a lot if the variance is greater than 155 ohm-cm squared. How many wafers must you test to estimate the lot variance with precision to detect an increase in 55 ohm-cm squared from the target of 100 ohm-cm squared? In terms of standard deviation, the hypothesized standard deviation, \( \sigma_0 \), is 10 (the square root of 100) and \( \sigma \) is 12.4499 (the square root of 100 + 55 = 155). The difference to detect is 12.4499 – 10 = 2.4499. The desired power is 0.99 and the significance level is 0.05.

1. Select **DOE > Design Diagnostics > Sample Size and Power**.
2. Click **One Sample Standard Deviation**.
3. Leave **Alpha** as 0.05.
4. Enter 10 for **Hypothesized Standard Deviation**.
5. Select **Larger** for **Alternative Standard Deviation**.
6. Enter 2.4499 for **Difference to Detect**.
7. Leave **Sample Size** blank.
8. Enter 0.99 for **Power**.
9. Click **Continue**.

**Figure 17.11 One-Sample Standard Deviation Calculator**

You must test 171 wafers in order to have a 99% chance of detecting an increase in the standard deviation of 2.4499 from a standard deviation of 10, with an alpha of 0.05.

**One Sample Standard Deviation Calculator Fields**

Specify the following:

**Alpha**  The probability of a type I error, which is the probability of rejecting the null hypothesis when it is true. It is commonly referred to as the significance level of the test. The default alpha level is 0.05.

**Hypothesized Standard Deviation**  The hypothesized or baseline standard deviation to which the sample standard deviation is compared.

**Alternative Standard Deviation**  The direction of the change that you want to detect, either Larger or Smaller.

**Note:** If you select Smaller from the Alternative Standard Deviation menu, enter a negative Difference to Detect.
Specify two of the following values to calculate the third value:

**Difference to Detect**  The smallest detectable difference (how small a difference you want to be able to declare statistically significant). This is the difference between the hypothesized value and the true value.

**Sample Size**  The total number of observations (runs, experimental units, or samples) in your experiment.

**Power**  The probability of rejecting the null hypothesis when it is false. With all other parameters fixed, power increases as sample size increases.

**Calculator Buttons**

**Continue**  Evaluates the missing value.

**Back**  Returns to the previous Sample Size and Power launch window.

### Statistical Details for the One Sample Standard Deviation Calculator

The formula that JMP uses to calculate power depends on the setting of the Alternative Standard Deviation option.

For cases where the alternative standard deviation is larger, JMP calculates power as follows:

\[
power = 1 - F \left( \frac{\sigma_0^2 \cdot \chi_{1-\alpha}}{(\sigma_0 + \delta)^2}, n - 1 \right)
\]

\[
\delta = \sigma_0 \sqrt{\chi_{1-\alpha} - \chi_\beta} - \sigma_0
\]

where:

- \( \sigma_0 \) is the hypothesized standard deviation.
- \( \sigma \) is the true standard deviation.
- \( X_p \) is the \((1 - p)^{th}\) quantile of the \(X_{n-1}^2\) distribution.
- \( F(x, n-1) \) is the cumulative distribution function of the \(X_{n-1}^2\) distribution evaluated at \( x \).

For cases where the alternative standard deviation is smaller, JMP calculates power as follows:

\[
power = 1 - F \left( \frac{\sigma_0^2 \cdot \chi_{\alpha}}{(\sigma_0 + \delta)^2}, n - 1 \right)
\]
Prospective Sample Size and Power

Chapter 17

One Sample Proportion Calculator Design of Experiments Guide

where:

- $\sigma_0$ is the hypothesized standard deviation.
- $\sigma$ is the true standard deviation.
- $X_p$ is the $(1 - p)^{th}$ quantile of the $X_{n-1}^2$ distribution.
- $F(x, n-1)$ is the cumulative distribution function of the $X_{n-1}^2$ distribution evaluated at $x$.

Numerical solutions are used to solve for $n$.

For more information about calculations in JMP, see Barker (2011, Section 2.4).

---

One Sample Proportion Calculator

Use the One Sample Proportion calculator to evaluate sample size for a hypothesis test about one proportion. Sample size and power are associated with the following hypothesis test:

$H_0: p = p_0$

versus the two-sided alternative:

$H_a: p \neq p_0$

or versus a one-sided alternative:

$H_a: p < p_0$ or $H_a: p > p_0$

where $p$ is the population proportion and $p_0$ is the null proportion.

The One Proportion Calculator also provides the actual test size. This is the actual Type I error rate for the specified assumptions. Since the binomial distribution is discrete, the actual test size can differ significantly from the stated Alpha level for small samples or proportions near 0 or 1. To guarantee an alpha level equal to or greater than your stated level, use the Exact Clopper-Pearson method.

Example of the One Sample Proportion Calculator

Suppose that an assembly line has a historical proportion of defects equal to 0.1. Given a sample size of 100 and an alpha level of 0.05, you want to calculate the power to detect a defect rate that differs by 0.1 or more from the historical rate.

2. Click **One Sample Proportion**.

3. Leave **Alpha** as 0.05.

4. Leave 0.1 as the value for **Proportion**.

5. Leave the **Method** as Exact Agresti-Coull.

6. Leave the test type as **Two-Sided**.

7. Leave 0.2 as the value for **Null Proportion**.

8. Enter 100 as the **Sample Size**.

9. Click **Continue**.

Figure 17.12 One Sample Proportion Calculator

For a sample size of 100, the power is approximately 70%. The Actual Test Size is approximately 0.0467, which is slightly less than the desired 0.05. With a sample size of 100, if the defect rate is 0.2, the probability of a Type I error of rejecting the null hypothesis is 5%. Alternatively, the probability of a Type II error of not rejecting the null hypothesis is 30% (1 - power).

**One Sample Proportion Calculator Fields**

Specify the following quantities and test settings:

**Alpha**  The probability of a type I error, which is the probability of rejecting the null hypothesis when it is true. It is commonly referred to as the significance level of the test. The default alpha level is 0.05.

**Proportion**  The true proportion, which could be known or hypothesized. The default value is 0.1.
Tip: For all other parameters fixed, the largest sample size occurs when the proportion is 0.5.

Method  Select a method. Choices are Exact Agresti-Coull or Exact Clopper-Pearson. The Clopper-Pearson method tends to be more conservative (larger sample size) than the Agresti-Coull method.

One-Sided or Two-Sided  Select either a one-sided or a two-sided test.

Specify two of the following parameters to calculate the third value, or specify one value to obtain a plot of the relationship between the other two parameters.

Note: The plot uses the normal approximation method rather than an exact method.

Null Proportion  The proportion to test against ($p_0$). The default value is 0.2.

Sample Size  The total number of observations (runs, experimental units, or samples) in the experiment.

Power  The probability of rejecting the null hypothesis when it is false. With all other parameters fixed, power increases as sample size increases.

Calculator Buttons

Continue  Evaluates the missing value when two parameters are specified, or launches a plot comparing two missing parameters if only one parameter is specified.

Back  Returns to the previous Sample Size and Power launch window.

Statistical Details for the One Proportion Calculator

The one proportion sample size computations use exact methods based on the binomial distribution. Exact calculations guarantee that the stated power level is obtained.

Agresti-Coull Method

The exact Agresti-Coull method uses the adjusted Wald-based test statistic. JMP calculates power under the two-sided null hypothesis as follows:

$$\text{Power} = \sum_{y=0}^{n} \Pr\{ Y = y | Y \sim \text{binomial}(n, p) \} I\{ T(y) \geq \chi_1 - \alpha \}$$
where:

\[
T(y) = \frac{(\hat{p} - p_0)^2}{p(1-p)} \frac{1}{n+4}
\]

\[
\hat{p} = \frac{y + 2}{n + 4}
\]

\[
I\{T(y_1,y_2) \geq \chi_{1-\alpha}^2\} = 1 \text{ if } (T(y_1,y_2) \geq \chi_{1-\alpha}^2) \text{ and } 0 \text{ otherwise, and}
\]

\[
\chi_{1-\alpha}^2 \text{ is the } (1 - \alpha)\text{-th quantile of the } \chi_1^2 \text{ distribution.}
\]

Because there is not a closed-form expression for \( n \) or \( p_0 \), numerical techniques are used to solve for \( n \) or \( p_0 \).

For more information about the adjusted Wald test statistic, see Agresti and Coull (1998). For more information about calculations in JMP, see Barker (2011, Section 3.3).

**Clopper-Pearson Method**

The exact Clopper-Pearson method is based on the binomial distribution. This method results in an alpha level equal to or greater than the stated level. The Clopper-Pearson method is more conservative (larger sample size) than the Agresti-Coull method.

The exact Clopper-Pearson method uses the binomial distribution directly. Numerical techniques are used to solve for the unknown parameter.

For more information about the Clopper-Pearson exact method, see Clopper and Pearson (1934) or Agresti and Coull (1998, Section 1).

**Two Sample Proportions Calculator**

Use the Two Sample Proportions calculator to evaluate sample size for a hypothesis test about two proportions. Sample size and power are associated with the following hypothesis test:

\[
H_0: p_1 - p_2 = D_0
\]

versus the two-sided alternative:

\[
H_a: p_1 - p_2 \neq D_0
\]

or versus either of the following one-sided alternatives:

\[
H_a: (p_1 - p_2) < D_0 \text{ or } H_a: (p_1 - p_2) > D_0
\]
where $p_1$ and $p_2$ are the population proportions from two populations, and $D_0$ is the hypothesized difference in proportions.

The Two Proportions Calculator also provides the actual test size. This is the actual Type I error rate for the specified assumptions. Since the binomial distribution is discrete, the actual test size can differ significantly from the stated Alpha level for small samples or proportions near 0 or 1.

**Example of the Two Sample Proportions Calculator**

Suppose you are responsible for two silicon wafer assembly lines. Based on the knowledge from many runs, one of the assembly lines has a defect rate of 8% and the other line has a defect rate of 6%. You want to know the sample size necessary to have 80% power to conclude there is a difference in defect rates.

1. Select **DOE > Design Diagnostics > Sample Size and Power**.
2. Click **Two Sample Proportions**.
3. Leave **Alpha** set at 0.05.
4. Enter 0.08 for **Proportion 1**.
5. Enter 0.06 for **Proportion 2**.
6. Select a **Two-Sided** test.
7. Enter 0 for **Null Difference in Proportion**.
8. Leave **Sample Size 1** and **Sample Size 2** blank.
9. Enter 0.8 for **Power**.
10. Click **Continue**.

**Figure 17.13** Difference between Two Proportions for a Two-Sided Test
The calculator shows that you should test a sample size of 2,554 wafers from each production line in order to detect a difference in defect rates.

**Two Sample Proportions Calculator Fields**

Specify the following quantities and test settings:

**Alpha**  The probability of a type I error, which is the probability of rejecting the null hypothesis when it is true. It is commonly referred to as the significance level of the test. The default alpha level is 0.05.

**Proportion 1**  The proportion for population 1, which could be known or hypothesized. The default value is 0.5.

**Proportion 2**  The proportion for population 2, which could be known or hypothesized. The default value is 0.1.

**One-Sided or Two-Sided**  Select either a one-sided or a two-sided test.

Specify two of the following parameters to calculate the third where the sample sizes are considered as one parameter. The sample sizes must both be entered or both be left blank for calculation.

**Null Difference in Proportion**  The difference in proportions under the null hypothesis. The default value is 0.2.

**Sample Size 1**  The total number of observations (runs, experimental units, or samples) in the experiment to estimate Proportion 1.

**Sample Size 2**  The total number of observations (runs, experimental units, or samples) in the experiment to estimate Proportion 2.

**Note:** When sample size is calculated, Sample Size 1 = Sample Size 2. If you enter sample sizes, they do not have to be equal.

**Power**  The probability of rejecting the null hypothesis when it is false. High power is desired. With all other parameters fixed, power increases with sample size.

**Calculator Buttons**

**Continue**  Evaluates the missing value.

**Back**  Returns to the previous Sample Size and Power launch window.
Statistical Details for the Two Proportions Calculator

Two proportions calculations are based on exact methods similar to those used for the one proportion calculator. For the two-sided hypothesis

\[ H_0: p_1 - p_2 = D_0 \text{ vs } H_a: p_1 - p_2 \neq D_0 \]

JMP calculates power under the null hypothesis as follows:

\[
\text{Power} = \sum_{y_1 = 0}^{n_1} \sum_{y_2 = 0}^{n_2} \text{Pr}(Y_1 = y_1)\text{Pr}(Y_2 = y_2)I\{T(y_1,y_2) \geq \chi_{1-\alpha}^2\}
\]

where the adjusted Wald statistic is defined as follows:

\[
T(y_1,y_2) = \frac{(\hat{p}_1 - \hat{p}_2 - \delta_0)^2}{\frac{\hat{p}_1(1-\hat{p}_1)}{n_1 + 2} + \frac{\hat{p}_2(1-\hat{p}_2)}{n_2 + 2}}
\]

and:

\[
I\{T(y_1,y_2) \geq \chi_{1-\alpha}^2\} = 1 \text{ if } (T(y_1,y_2) \geq \chi_{1-\alpha}^2) \text{ and 0 otherwise}
\]

and \(\chi_{1-\alpha}\) is the \((1 - \alpha)\)th quantile of the \(\chi^2\) distribution.

Because there are no closed-form expressions for the \(n_i\) or \(\delta_0\) numerical techniques are used to solve for the \(n_i\) and \(\delta_0\).

For more information about the adjusted Wald test statistic, see Agresti and Coull (1998). For more information about calculations in JMP, see Barker (2011, Section 3.3).

Counts per Unit Calculator

Use the Counts per Unit Calculator to evaluate sample size for a one-sided hypothesis test about the defects (counts) per unit. Sample size and power are associated with the following hypothesis test:

\[ H_0: \lambda \leq \lambda_0 \]

versus a one-sided alternative:

\[ H_a: \lambda > \lambda_0 \]

where \(\lambda\) is the rate of a Poisson distribution.
Example of the Counts per Unit Calculator

Consider a wafer manufacturing process with a target of 4 or fewer defects per wafer. You want to verify that a new process meets that target. How many wafers should you test to detect a difference of 1 that the count of defects per wafer is on target with 90% power at the significance level of 0.05?

1. Select **DOE > Design Diagnostics > Sample Size and Power**.
2. Click **Counts per Unit**.
   1. Leave **Alpha** as 0.05 (the chance of failing the test if the new process is as good as the target).
   2. Enter 4 as the **Baseline Counts per Unit**, indicating the target of 4 defects per wafer.
   3. Enter 1 as the **Difference to detect**.
   4. Enter a power of 0.9.
      - This is the chance of detecting a change larger than 1, which is equivalent to 5 or more defects per wafer. In this type of situation, the significance level (alpha) is sometimes called the *producer’s risk* and the power (beta) is called the *consumer’s risk*.
3. Click **Continue**.

**Figure 17.14** Counts per Unit Calculator

You must test 38 wafers. The process meets the target if there are fewer than 173 defects.

**Note:** The 173 defects are the maximum number of defects that can occur in 38 wafers without rejecting the null hypothesis.
Counts per Unit Calculator Fields

Specify the following quantities:

**Alpha**  The probability of a type I error, which is the probability of rejecting the null hypothesis when it is true. It is commonly referred to as the significance level of the test. The default alpha level is 0.05.

**Baseline Count per Unit**  The number of targeted defects per unit. The default value is 0.1. Specify two of the following quantities to calculate the third quantity:

**Difference to detect**  The smallest detectable difference to test against specified in defects per unit.

**Sample Size**  The number of units.

**Power**  The probability of rejecting the null hypothesis when it is false. With all other parameters fixed, power increases as sample size increases.

**Calculator Buttons**

**Continue**  Evaluates the missing value.

**Back**  Returns to the previous Sample Size and Power launch window.

Statistical Details for the Counts per Unit Calculator

Calculations for the counts per unit calculator are based on applying a normal approximation to the Poisson distribution. The test uses the following hypothesis:

\[ H_0 : \lambda \leq \lambda_0 \text{ vs } H_a : (\lambda > \lambda_0) \]

The above hypothesis uses the following test statistic:

\[ T = \frac{\bar{d} - \lambda_0}{\sqrt{\lambda_0 / n}} \]

where \( n \) is the sample size and \( \bar{d} \) is the mean number of defects per unit in the sample. We assume \( T \) to be approximately normally distributed. The power calculation is based on the distribution of \( T \) under the null and alternative hypotheses.
power = Pr(reject \( H_0 \) | \( \lambda = \lambda_0 + \delta \))

= Pr\[ T > Z_{1-\alpha} | (\lambda = \lambda_0 + \delta) \] = 1 - \Phi \left( \frac{Z_{1-\alpha} - \delta \sqrt{n/\lambda_0}}{\sqrt{(\lambda_0 - \delta)/\lambda_0}} \right)

where \( \Phi() \) is the standard normal cumulative distribution function and \( Z_{1-p} \) is the \((1 - p)\)th quantile of the standard normal distribution.

Using \( 1 - \beta \) to denote the desired power to reject the null hypothesis, the sample size is calculated as follows:

\[
n = \frac{\lambda_0}{\delta^2 \left( Z_{1-\alpha} - Z_{\beta} \frac{\lambda_0 + \delta}{\lambda_0} \right)^2} \]

Because an analytical solution for \( \delta \) does not exist, numerical methods are used to solve for \( \delta \) given power and \( n \).

For more information about calculations in JMP, see Barker (2011, Section 2.5).

Sigma Quality Level Calculator

Use the Sigma Quality Level Calculator to explore relationships between the number of defects, number of opportunities for defects, and the Sigma Quality Level. The Sigma Quality Level is a statistic that relates a given defect rate to a six-sigma scale. For example, a defect rate of 3.4 per one million opportunities results in a six-sigma process.

Example of the Sigma Quality Level Calculator

Suppose you want to estimate the Sigma Quality Level for 50 defects in 1,000,000 opportunities at your plant. An opportunity is the unit for the defect count. It could be a single item or you might have multiple defects on a single item where each potential defect is an opportunity.

1. Select **DOE > Design Diagnostics > Sample Size and Power**.
2. Click the **Sigma Quality Level**.
3. Enter 50 for the **Number of Defects**.
4. Enter 1000000 as the **Number of Opportunities**.
5. Click **Continue**.
**Example Computing the Number of Defects**

To calculate the maximum number of defects you can have out of a million opportunities and still have a six-sigma quality level process, follow these steps:

1. Select **DOE > Design Diagnostics > Sample Size and Power**.
2. Click the **Sigma Quality Level** button.
3. Leave **Number of Defects** blank.
4. Enter 1000000 as the **Number of Opportunities**.
5. Enter 6 as **Sigma Quality Level**.
6. Click **Continue**.

The computation shows that the **Number of Defects** cannot be more than 3 in 1,000,000 opportunities to achieve a six-sigma quality level process.
**Sigma Quality Level Calculator Fields**

Specify two of the following quantities to calculate the third quantity:

- **Number of Defects** The number of defects.
- **Number of Opportunities** The number of opportunities for a defect.
- **Sigma Quality Level** The defect rate in standard deviation units.

**Calculator Buttons**

- **Continue** Evaluates the missing value.
- **Back** Returns to the previous Sample Size and Power launch window.

**Statistical Details for the Sigma Quality Calculator**

Calculations for the sigma quality calculator are based on the definition of sigma quality level $\sigma_q$ for $d$ defects in $n$ opportunities:

\[
\sigma_q = Z \frac{d}{1 - \frac{d}{n}} + 1.5
\]

From this definition, $d$ and $n$ can be calculated as follows:

\[
d = n [1 - \Phi(\sigma_q - 1.5)]
\]

\[
n = d [1 - \Phi(\sigma_q - 1.5)]^{-1}
\]

where $\Phi()$ is the standard normal cumulative distribution function and $Z_{1-d/n}$ is the $(1 - d/n)^{th}$ quantile from the standard normal distribution.

**Reliability Test Plan Calculator**

Use the Reliability Test Plan Calculator to determine the sample size, study length, or precision needed for a reliability study. Reliability studies are used to estimate failure times and failure probabilities of a product. The test plan calculator uses expected confidence intervals to define the precision of the estimates. These estimates are based on a fitted failure distribution. To fit a failure distribution, a minimal number of failures must be observed.
Example of the Reliability Test Plan Calculator

A company has developed a new product and wants to calculate how many units to test to estimate the time until 20% of units fail, using a 95% confidence interval with two-sided absolute precision of 200 hours. In other words, when a confidence interval is created for the estimated time, the difference between the upper and lower limits should be approximately 200 hours. The company can run the test for 2,500 hours. In addition, from studies of similar products, they believe the approximate failure distribution to be a Weibull distribution with location parameter $\alpha = 2000$ and scale parameter $\beta = 3$.

To compute the required sample size:

2. Click Reliability Test Plan.
3. Leave Alpha set at 0.05.
4. Select Weibull from the Distribution list.
5. Enter 2000 for the Weibull $\alpha$ parameter.
6. Enter 3 for the Weibull $\beta$ parameter.
7. Select Two-sided Interval Absolute Width from the Precision Measure list.
8. Select Estimate time associated with specified failure probability and enter 0.2 for $p$.

Note: The cumulative distribution function plot is labeled according to the study objective. Here, Time = 1213 is the time estimate for 20% of unit failures.

10. Enter 2500 for Censor Time.
11. Enter 200 for Precision.
12. Click Continue.
Figure 17.17 Reliability Test Plan Calculator

To estimate the time until 20% of units fail with a precision of 200 hours requires 217 units on test for 2,500 hours. The expected number of failures in this test is approximately 186, much larger than the minimum of 3 needed to estimate the failure distribution.

Reliability Test Plan Calculator Fields

Specify the following quantities and test settings:

**Alpha**  The significance level of the confidence interval used to define the precision measure.
Distribution  The assumed failure distribution. Distributions available are: Weibull, Lognormal, Frechet, Loglogistic, SEV, Normal, LEV, and logistic. For more information about these distributions, see Reliability and Survival Methods.

Location  The location parameter for the failure distribution.

Note: The Location field is denoted Weibull $\alpha$ when the Distribution is set to Weibull.

Scale  The scale parameter for the failure distribution.

Note: The Scale field is denoted Weibull $\beta$ when the Distribution is set to Weibull.

Precision Measure  The definition of the precision measure. Definitions are based on the expected confidence interval of the quantity being estimated (failure time or probability). The choices for the precision measure are as follows:

Interval Ratio  Defines precision as the square root of the ratio of the upper limit to the lower limit. This ratio is always greater than one since the upper limit is greater than or equal to the lower limit. The interval ratio decreases as the precision in the estimate increases.

Two-sided Interval Absolute Width  Defines precision as the width of the confidence interval or the difference between the upper and lower limits.

Lower One-sided Interval Absolute Width  Defines precision as the width of the lower side of the interval or the difference between the estimate and the lower limit of the confidence interval for the estimate.

Two-sided Interval Relative Width  Defines precision as the width of the confidence interval relative to the estimate. This is the difference between the upper and lower limits divided by the estimate.

Lower One-sided Interval Relative Width  Defines precision as the width of the lower side of the interval relative to the estimate. This is the difference between the estimate and the lower limit divided by the estimate.

Objective  The objective of the study. Select one of the following objectives and enter the corresponding value:

– Estimate time associated with specified failure probability $p$.
– Estimate failure probability at time $t$.

Note: The plot is the cumulative distribution function of the failure distribution. The plot is labeled with the estimate of time or probability based on the study objective.
Specify two of the following quantities to calculate the third quantity:

**Sample Size**  The number of units to include in the reliability test.

**Censor Time**  The amount of time available to run the reliability test.

**Precision**  The level of precision. The definition of the units on this value corresponds to the chosen Precision Measure.

**Calculator Buttons**

**Continue**  Evaluates the missing value.

**Back**  Returns to the previous Sample Size and Power launch window.

**Additional Reliability Test Plan Calculations**

In addition to calculating the sample size, censor time, or precision, the following quantities are also calculated:

**Expected number of failures**  The expected number of failures for the specified reliability test.

**Probability of fewer than 3 failures**  The probability that the specified reliability test results in fewer than three failures. This is important because a minimum of three failures is required to obtain stable estimates for the location and scale parameters of the failure distribution. With only one or two failures, the estimates are unstable. If this probability is large, you risk not observing enough failures to reliably estimate the distribution parameters. Increasing the sample size or censor time are both ways to lower the probability of fewer than three failures.

**Large-sample approximate covariance matrix**  Provides the approximate variances and covariance for the location and scale parameters of the failure distribution.

**Statistical Details for the Reliability Test Plan Calculator**

The reliability test plan is designed to estimate either a quantile:

\[ q(p) = \exp[\sigma \Phi^{-1}(p) + \mu] \]

or a failure probability:

\[ p(t) = \Phi\left[\frac{\log(t) - \mu}{\sigma}\right] \]
at a specified level of significance with an assumed failure time distribution and precision measure. \( \Phi() \) is the standard cumulative distribution function of the assumed failure time distribution with location parameter \( \mu \) and scale parameter \( \sigma \). Wald confidence intervals and the precision measure define precision as a function of \( t \) (time) and \( n \) (sample size). Numerical methods are used to solve for the desired quantity.

For more information about calculations in JMP, see Barker (2011, Section 6).

## Reliability Demonstration Calculator

Use the Reliability Demonstration calculator to test a specified number of units for a specified period of time. If fewer than \( k \) units fail, the demonstration passes, and you can conclude that the product reliability meets or exceeds a reliability standard. We pose the reliability demonstration as a hypothesis test:

\[
H_0: p < p^* \quad \text{vs} \quad H_a: p \geq p^*
\]

where \( p \) is the probability of survival time at \( t^* \) for the new product and \( p^* \) is the standard probability of survival at time \( t^* \).

### Example of the Reliability Demonstration Calculator

A company wants to estimate the sample size needed for assessing the reliability of a new product against a historical reliability standard of 90% survival after 1,000 hours. From prior studies on similar products, it is believed that the failure time distribution is Weibull, with a \( \beta \) parameter of 3. The company can afford to run the demonstration for 800 hours, and wants the experiment to result in no more than 2 failures.

To compute the required sample size:

1. Select \textit{DOE} > \textit{Design Diagnostics} > \textit{Sample Size and Power}.
2. Click \textit{Reliability Demonstration}.
3. Leave Alpha set at 0.05.
4. Select \textit{Weibull} from the Distribution list.
5. Enter 3 for the \textit{Weibull} \( \beta \).
6. Enter 2 for \textit{Max Failures Tolerated}.
7. Enter 1000 for \textit{Time}.
8. Enter 0.9 for \textit{Probability of Surviving}.
9. Enter 800 for \textit{Time of Demonstration}.
10. Leave \textit{Number of Units Tested} blank.
11. Click **Continue**.

**Figure 17.18** Reliability Demonstration Calculator

The company needs to run 118 units in the demonstration. Furthermore, if they observe 2 or fewer failures by 800 hours, they can conclude that the new product reliability is at least as reliable as the standard.

The plot shows that as the true probability of a unit surviving to the time in the reliability standard increases, the probability of passing the demonstration increases. In this example, if a unit has only a 92% chance of surviving to the standard time, then the chance of the new product passing the demonstration is only about 12.5%.
Reliability Demonstration Calculator Fields

Specify the following quantities and test settings:

**Alpha**  The probability of a type I error, which is the probability of rejecting the null hypothesis when it is true. It is commonly referred to as the significance level of the test. The default alpha level is 0.05.

**Distribution**  The assumed failure time distribution. Distributions available are: Weibull, Lognormal, Frechet, Loglogistic, SEV, Normal, LEV, and logistic. For more information about these distributions, see *Reliability and Survival Methods*.

**Scale**  The scale parameter for the failure time distribution.

**Max Failures Tolerated**  The maximum number of failures allowed for a successful test demonstration.

**Reliability Standard**  The definition of the standard that you are testing. This standard is based on a length of time and the probability of an item's survival to that time.

**Time**  The minimum length of time that an item under test should survive.

**Probability of Surviving**  The probability that the item under test survives until the defined Time of the reliability standard

Enter one of the following two values to calculate the other:

**Time of Demonstration**  The length of the demonstration in time.

**Number of Units Tested**  The number of units needed for the demonstration.

**Calculator Buttons**

**Continue**  Evaluates the missing value.

**Back**  Returns to the previous Sample Size and Power launch window.

Statistical Details for the Reliability Demonstration Calculator

The reliability demonstration depends on the assumed failure time distribution with scale parameter \( \sigma \). The reliability standard, or probability of survival at time \( t \) and location \( \mu \) is stated as follows:

\[
p = 1 - \Phi \left[ \frac{\log t - \mu}{\sigma} \right]
\]
where \( \mu \) is solved for using the following:

\[
\mu = \log(t) - \sigma \Phi^{-1}(1 - p) .
\]

To calculate sample size and the size of the test, the probability of survival at time \( t \) is posed as a hypothesis test:

\[
H_0: p < p^* \text{ vs } H_a: p \geq p^*
\]

where \( p^* \) is the standard probability of survival at time \( t^* \).

We want to test the hypothesis at the \( \alpha \) level or as follows:

\[
\alpha = \Pr(k \text{ or few failures} \mid H_0 \text{ true}).
\]

Since the test is of \( n \) independent units, the number of failures has a binomial \((n, p)\) distribution where \( p \) is the probability of a unit failing before time \( t \). Therefore, we can express \( \alpha \) as a function of \( t \) and \( n \):

\[
\alpha = \Pr(x \leq k \mid x \sim \text{Bin}(n, \Phi\left[\frac{\log t - \mu^*}{\sigma^*}\right]))
\]

where \( \mu^* \) and \( \sigma^* \) are from the assumed reliability standard.

Properties of the binomial and beta distributions result in being able to solve for \( t \) using:

\[
t = \frac{t^* \exp\{\sigma^* \Phi^{-1}[1 - B^{-1}(\alpha; n - k, k + 1)]\}}{\exp[\sigma^* \Phi^{-1}(1 - p^*)]}
\]

For \( n \), Brent’s method is used to find the root of:

\[
B^{-1}(\alpha; n - k, k + 1) - 1 + \Phi\left[\frac{\log t - (\log t^*) + \sigma^* \Phi^{-1}(1 - p^*)}{\sigma^*}\right] = 0
\]

where:

- \( B^{-1}(\alpha; n - k, k + 1) \) is the \( \alpha \) quantile of the Beta\((n - k; k + 1)\) distribution
- and \( \Phi() \) is the cumulative distribution function of the assumed failure time distribution.

For more information about calculations in JMP, see Barker (2011, Section 5).
A choice (or discrete choice) experiment provides data for modeling discrete preferences. Study participants are presented with sets of potential products (or product profiles) with varying attributes. From each set of profiles, a participant selects a preferred profile. For example, in designing a high-end laptop, a computer company might be interested in the relative importance of key features such as: processor speed, hard disk size, screen size, battery life, and price. A choice experiment addresses the relative values of these features to a customer and indicates an optimal set of trade-offs among product features.

The results of a choice experiment are analyzed using conjoint analysis methods. See Consumer Research.

Overview ofChoice Designs

Discrete choice experiments support the process of designing a product. They help prioritize product features for a company’s market so that the company can design a product that people want to buy. The Choice Design platform creates experiments using factors that are attributes of a product. Selecting the attributes to be studied and their values is of critical importance. You must include all attributes that are likely to influence a consumer’s decision to buy the product. For more information and guidelines for designing a choice experiment, see Sall (2008).

Choice Design Terminology

The following terminology is associated with choice designs:

- An attribute is a feature of a product.
- A profile is a specification of product attributes.
- A choice set is a collection of profiles.
- A survey is a collection of choice sets.
- A partial profile is a profile in a choice design where only a specified number of attributes are varied within each choice set. The remaining attributes are not varied.

In a discrete choice experiment, respondents are presented with a survey containing several choice sets. Choice sets usually contain only a small number of profiles to facilitate the decision process. Within each choice set, each respondent specifies which of the profiles he or she prefers. For example, attributes for a laptop experiment might include speed, storage, screen size, battery life, and price. Different combinations of these attributes comprise product profiles. A choice set might consist of two profiles. From each choice set, a respondent chooses the profile that he or she prefers.

In cases where many attributes are involved, you can construct surveys where each choice set contains partial profiles. In a choice set with partial profiles, only a specified number of attributes are varied and the remaining attributes are held constant. This reduces the complexity of the choice task.
Bayesian D-Optimality

Because discrete choice models are nonlinear in their parameters, the efficiency of a choice design depends on the unknown parameters. The Choice Design platform uses a Bayesian approach, optimizing the design over a prior distribution of likely parameter values that you specify. The Bayesian D-optimality criterion is the expected logarithm of the determinant of the information matrix, taken with respect to the prior distribution. The Choice Design platform maximizes this expectation with respect to the prior probability distribution. See “Bayesian D-Optimality and Design Construction” on page 569 and Kessels et al. (2011).

You can also generate the following types of designs:

- Utility-neutral designs - In a utility-neutral design, all choices within a choice set are equally probable. The prior mean is set to 0.
- Local D-optimal designs - A local D-optimal design takes into account the prior on the mean, but does not include any information from a prior covariance matrix.

For more information about utility neutral and local D-optimal designs, see “Utility-Neutral and Local D-Optimal Designs” on page 570.

Example of a Choice Design

About the Experiment

In this example, a coffee shop is interested in making an ideal cup of coffee to satisfy the majority of its customers. The manager has asked you to determine which factors affect customer preferences. Specifically, you need to determine which settings of the following factors (attributes) result in an ideal cup of coffee:

- Grind size (medium or coarse)
- Temperature (195°, 200°, 205°)
- Brewing time (3 minutes, 3.5 minutes, or 4 minutes)
- Charge (1.6 grams/ounce, 2 grams/ounce, or 2.4 grams/ounce)

Each combination of factor levels is a profile. Trying to obtain information about preferences by having every respondent sample every possible profile is not practical. However, you can ask a respondent to select a preferred profile from a choice set consisting of a small number of profiles.

In this example, you design an experiment where each respondent indicates his or her preference in several choice sets. Your design will have the following structure:

- ten respondents
• twelve choice sets
• two profiles per choice set
• one survey per respondent containing all 12 choice sets

The experiment results in 12 responses per respondent. Analysis of these preferences can be used to draw conclusions about how to make a cup of coffee that pleases most customers.

Create the Design

You can enter factors either manually or automatically using a preexisting table that contains the factors and settings. In this example, for convenience, you use a preexisting table. But, if you are designing a new experiment, you must first enter the factors manually. For more information about entering factors manually, see “Attributes” on page 563.

1. Select DOE > Consumer Studies > Choice Design.
2. Select Help > Sample Data Library and open Design Experiment/Coffee Choice Factors.jmp.
3. Click the Choice Design red triangle and select Load Factors.

4. Click Continue.

5. (Optional) Open the DOE Model Controls outline.

Notice that there only main effects. In this example, you are only interested in a model that contains the main effects of your four factors. However, if you wanted your design to be capable of estimating additional effects, you add them in this outline.

6. In the Design Generation panel:
   - Keep the **Number of attributes that can change within a choice set** at 4.
   - Keep the **Number of profiles per choice set** at 2.
   - Type 12 for the **Number of choice sets per survey**.

   In this example, the respondents evaluate 12 choice sets.
– Keep the **Number of surveys** at 1.
– Type 10 for the **Expected number of respondents per survey**.

In this example, there are ten respondents.

**Figure 18.3** Completed Design Generation Panel

</tbody>
</table>

**Note:** Setting the Random Seed in step 7 reproduces the exact results shown in this example. In constructing a design on your own, this step is not necessary.

7. (Optional) Click the Choice Design red triangle and select **Set Random Seed**. Type 12345 and click **OK**.
8. Click **Make Design**.

There are 12 choice sets, each consisting of two coffee profiles.

9. Select **Output separate tables for profiles and responses**.

This places the descriptions of the choice sets in a data table called Choice Profiles. A second data table (called Choice Runs) is constructed to facilitate entry of the response information.

10. Click **Make Table**.

The Choice Profiles table shows the 12 choice sets, each consisting of two profiles. The Choice Runs table enables you to record the preferred profile in the column **Response** using the profile ID. Enter 1 if Choice1 is the preferred profile or 2 if Choice 2 is the preferred profile. Alternatively, if the respondent has no preference, leave the response missing.

The **Choice** script in the Choice Profiles table facilitates analysis of experimental results. It opens a completed launch window for a Choice Model. For information about Choice Models, see **Consumer Research**.

The **DOE Dialog** script in the Choice Profiles table relaunches the design dialog.
Example of a Choice Design with Analysis

In this example, a computer manufacturer is interested in manufacturing a new laptop and wants information about customer preferences before beginning an expensive development process. The manufacturer decides to construct a design consisting of two sets of profiles that will be administered to ten respondents. The goal of the choice design is to understand how potential laptop purchasers view the advantages of a collection of four attributes:

- size of hard drive disk (40 GB or 80 GB)
- speed of processor (1.5 GHz or 2.0 GHz)
- battery life (4 Hrs or 6 Hrs)
- cost of computer ($1000, $1200 or $1500)

To construct the design for the ten respondents, you first conduct a small pilot study using only one respondent. Then you analyze the results and use the parameter estimates as prior information in designing the final study for the ten respondents.

Create a Choice Design for a Pilot Study

In this section, you construct a choice design for a one-respondent study.

Define Factors and Levels

In this example, you load the factors from an existing table. When designing a new experiment on your own, enter the factors manually.

1. Select **DOE > Consumer Studies > Choice Design**.
2. Select **Help > Sample Data Library** and open Design Experiment/Laptop Factors.jmp.
3. Click the Choice Design red triangle and select **Load Factors**.

Figure 18.4  Choice Design Window with Attributes Defined
Create the Design

1. Click **Continue**.

2. This pilot survey will be given to a single respondent. The default values in the DOE Model Controls, Prior Specification, and Design Generation panels are appropriate as is.

3. (Optional) Click the Choice Design red triangle and select **Set Random Seed**. Type 12345 and click **OK**.

4. Click **Make Design**.

   **Note:** Setting the Random Seed in step 3 reproduces the exact results shown in this example. In constructing a design on your own, this step is not necessary.

---

**Figure 18.5** Pilot Design

The single survey contains eight choice sets, each consisting of two laptop profiles.

5. Verify that the **Combine profiles and responses in one table** option is selected.

   This places the choice sets and the survey results in the same table.

6. Click **Make Table**.

This survey was designed assuming no prior information. For this reason, some choice sets might not elicit useful information. The plan is to obtain survey results from the single respondent, analyze the results, and then use the results from the pilot survey as prior information in designing the final survey.
Chapter 18
Choice Designs
557
Design of Experiments Guide
Example of a Choice Design with Analysis

Analyze the Pilot Study Data

Now that the pilot survey design is complete, it is administered to single respondent. The respondent chooses one profile from each set, entering 1 for the chosen profile and 0 for the rejected profile. You will analyze the results using the Choice platform.

Note: For more information about the Choice platform, see Consumer Research.

1. Select Help > Sample Data Library and open Design Experiment/Laptop Design.jmp.
2. Run the Choice script.

Figure 18.6 Choice Model Launch Window

The only grouping variable is Choice Set because there is a single survey and a single respondent.

3. Click Run Model.
To construct the final choice design that you will give to ten respondents, you need prior means and variances for the parameter estimates. The analysis in Figure 18.7 gives estimates of the parameter means (Estimate) and estimates of their standard errors (Std Error). You will treat the standard errors as prior estimates of the standard deviations. Next, to calculate estimates of the variances of the attributes, construct a JMP table and square the standard errors.

4. Right-click in the Parameter Estimates report and select Make into Data Table.

5. In the new data table, right-click in the Std Error column header and select New Formula Column > Transform > Square.

A column called Std Error^2 is added to the data table. Its values will serve as your estimates of the prior variance for the choice model parameters.

**Figure 18.8** Untitled Data Table with Variance Estimates in Last Column

*Note:* Do not close the Untitled data table at this point.

**Design the Final Choice Experiment Using Prior Information**

In this section, you use the prior information obtained from the pilot laptop study to construct a final design. The final design will be administered to a set of ten participants.

1. Select Help > Sample Data Library and open Design Experiment/Laptop Factors.jmp.
2. Select DOE > Consumer Studies > Choice Design.
3. Click the Choice Design red triangle and select Load Factors.
4. Click **Continue**.

5. From the Untitled table, enter the values in the **Estimate** column into the Prior Mean outline in the Choice Design window (Figure 18.9).

   You can copy and paste the entire column from the Untitled table, then click in the **Disk Size** text box under **Prior Mean** in the Prior Mean outline, right-click, and select Paste.

6. From the Untitled table, enter the values in the **Std Error^2** column into the diagonal entries in the Prior Variance Matrix outline in the Choice Design window (Figure 18.9). Enter these one-by-one, rounded to three decimal places.

![Figure 18.9 Prior Mean and Variance Information from Pilot Study](image)

7. In the Design Generation panel, enter 2 for the **Number of surveys** and five for the **Expected number of respondents per survey**.

   This gives instruments for a total of 10 respondents and allows for two different sets of profiles.

8. Click **Make Design**.

9. Click **Make Table**.

   The design table has 160 rows. There are 16 rows for each of the ten study respondents. Each respondent has 8 choice sets, each with 2 profiles. There are two surveys, each given to 5 respondents. The 160 rows result from the following calculation: 2 profiles * 8 choice sets * 2 surveys * 5 respondents = 160 rows.

   The final design is now ready to be administered to the 10 respondents.
Run the Design and Analyze the Results

In this section, you analyze the results obtained when you obtain results from the final design. In particular, you want to know how changing the price or other characteristics of a laptop affects its desirability as perceived by potential buyers. This desirability is called the *utility value* of the laptop attributes.

Determine Significant Attributes

1. Select **Help > Sample Data Library** and open Design Experiment/Laptop Results.jmp.
2. Run the **Choice** script.

**Figure 18.10 Choice Model Launch Window**

There are three grouping variables, **Respondent**, **Survey**, and **Choice Set**, because there are multiple surveys and respondents.

3. Click **Run Model**.
The Effect Summary and Likelihood Ratio Tests outlines indicate that Disk Size, Speed, and Price are significant at the 0.05 level, and that Battery Life is marginally significant.

**Find Unit Cost and Trade Off Costs**

Next, use the Profiler to see the utility value and how it changes as the laptop attributes change.

1. Click the Choice Model red triangle and select **Utility Profiler**.

**Figure 18.12 Utility Profiler at Price = $1000**

When each attribute value is set to its lowest value, the Utility value is –0.3406. The first thing that you want to do is determine the unit utility cost.

2. Move the slider for **Price** to $1,500.
When Price changes from $1,000 to $1,500, the Utility changes from –0.3406 to –2.3303. That is, raising the price of a laptop by $500.00 lowers the utility (or desirability) approximately 2 units. Therefore, you can estimate the unit utility cost to be approximately $250.00.

With this unit utility cost estimate, you can now vary the other attributes, note the change in utility, and find an approximate monetary value associated with attribute changes. For example, the most significant attribute is Speed (Figure 18.11).

3. In the Utility Profiler, set Price back to $1,000, its lowest value, and change Speed to 2.0 GHz, its higher value.

The Utility value changes from the original value shown in Figure 18.12 of –0.3406 to 0.9886, for a total change of 1.3292 units. Using the utility cost estimate or $250.00, the increase in price for a 2.0 GHz laptop over a 1.5 GHz laptop can be computed to be 1.3292*$250.00 = $332.30. This is the dollar value that the Choice study indicates that the manufacturer can use as a basis for pricing this laptop attribute. You can make similar calculations for the other attributes.

**Choice Design Window**

The Choice Design window walks you through the steps to construct a choice design for modeling attribute preferences. You can specify an assumed model and prior information.
The Choice Design window updates as you work through the design steps. The outlines, separated by buttons that update the outlines, follow the flow in Figure 18.15.

**Figure 18.15** Choice Design Flow

```
Attribute → Continue → Model Design Generation → Make Design → Design → Make Table
```

### Attributes

Attributes in a choice design can only be categorical.

**Tip:** When you have completed the Attributes outline, consider selecting **Save Factors** from the red triangle menu. This saves the attribute names, roles, and levels in a data table that you can later reload and reuse.

**Figure 18.16** Attributes Outline

<table>
<thead>
<tr>
<th>Name</th>
<th>Role</th>
<th>Attribute Levels</th>
</tr>
</thead>
<tbody>
<tr>
<td>X1</td>
<td>Categorical</td>
<td>L1, L2</td>
</tr>
<tr>
<td>X2</td>
<td>Categorical</td>
<td>L1, L2, L3</td>
</tr>
</tbody>
</table>

The Attributes outline contains the following buttons:

**Add Factor** Adds an attribute with the selected number of levels.

**Remove** Removes the selected attributes.

**Add N Factors** Adds multiple attributes. Enter the number of attributes to add, click **Add Factor**, and then select the number of levels. Repeat **Add N Factors** to add multiple attributes with different numbers of levels.

The Attributes outline contains the following columns:

**Name** The name of the attribute. Attributes are given default names of X1, X2, and so on. To change a name, double-click it and type the desired name.

**Role** Specifies the Design Role of the attribute as Categorical.
Attribute Levels  The attribute name or description. To insert Attribute Levels, click the default levels and type the desired names.

Editing the Attributes Outline
- To edit the Name of an attribute, double-click the attribute name.
- To edit an Attribute Level, click the level.

Attribute Column Properties
For each attribute, JMP saves the Value Order column property to the data tables constructed by the Choice platform. The Value Order column property specifies that levels appear in reports using the ordering specified in the Attributes outline. See “Value Order” on page 811 in the “Column Properties” appendix.

Model
The model outline consists of two parts:
- You can specify your assumed model, which contains all the effects that you want to estimate. See “DOE Model Controls” on page 564.
- You can specify prior knowledge about the attribute levels, which can result in a better design. See “Prior Specification” on page 565.

DOE Model Controls
Specify your assumed model in the DOE Model Controls outline. All main effects are included by default. Click the Interactions button to add all two-way interactions.

Figure 18.17  DOE Model Controls Outline

When you construct your design table, JMP saves a Choice script to the data table. The Choice script launches the Choice Platform with the model selected in the DOE Model Controls outline.
The DOE Model Controls outline contains the following buttons:

**Main Effects**  Adds main effects for all attributes in the model.

**Interactions**  Adds all second-order interactions. If you do not want to include all of the interactions, select the interactions that you want to remove and click **Remove Term**.

**Remove Term**  Removes selected effects.

**Prior Specification**

Enter specifications for a multivariate normal prior distribution on the model parameters. Enter the prior distribution’s mean in the Prior Mean outline and its covariance matrix in the Prior Variance outline.

**Figure 18.18**  Prior Specification Outline

You can ignore the prior specifications using these options:

**Ignore prior specifications. Generate the Utility Neutral design.**  Sets the prior means to 0 and generates a locally D-optimal design. This design is called a *utility-neutral* design. See Huber and Zwerina (1996).

**Ignore prior variance. Generate the local design for the prior mean.**  Generates a locally D-optimal design. The local design takes into account the prior on the mean but ignores the covariance matrix. See Huber and Zwerina (1996).

**Design Generation**

Enter specifications that define the structure for your design in the Design Generation panel.
Figure 18.19  Design Generation Panel for Coffee Example

Note: Figure 18.19 is taken from the coffee example. See “Example of a Choice Design” on page 552.

Enter a number for each of the following items:

**Number of attributes that can change within a choice set**  Enter a number less than or equal to the total number of attributes. This is often set to the total number of attributes. However, if you are comparing many attributes and want to simplify the selection process for respondents, set this to a number that is smaller than the total number of attributes.

**Number of profiles per choice set**  Enter the number of profiles that a respondent must choose from in stating a preference.

**Number of choice sets per survey**  Enter the number of preferences that you want to obtain from each respondent.

**Number of surveys**  Enter the number of distinct collections of choice sets. This is useful if you want to administer surveys to multiple respondents.

**Expected number of respondents per survey**  Enter the total number of respondents divided by the number of surveys.

**Make Design**

Once you have completed the Design Generation outline, click Make Design to generate the design. The design appears in the Design outline.

**Design**

The Design outline shows the runs for a design that is optimal, given your selections. Review the design to ensure that it meets your needs.

</tbody>
</table>

**Note:** Figure 18.20 is taken from the coffee example. See “Example of a Choice Design” on page 552.

**Note:** The algorithm for finding an optimal design is based on a random starting design. Because of this, the design you obtain is not unique. The design algorithm will generate different designs when you click the **Back** and **Make Design** buttons repeatedly.

**Output Options**

Select one of the following output options:

**Output separate tables for profiles and responses** Displays two data tables:
- The Choice Profiles table lists the profiles in each row, identified by Survey and Choice Set columns. Within a choice set, the profiles are identified by Choice ID. This table is useful for constructing the survey instruments.
- The Choice Runs table provides an empty Response column where you can enter respondent preferences. Each row corresponds to a single choice set. The rows are sorted by Respondent, Survey, and Choice Set. The choice set IDs are given in the next columns, followed by the Response column. Enter the choice set ID for the respondent’s preference in the Response column.

**Combine profiles and responses in one table** Provides a single Choice Profiles table with an empty Response Indicator column where you can enter respondent preferences. Each
row corresponds to a single profile. The table is sorted by Respondent, Survey, and Choice Set. Enter the value 1 (or another nonzero numerical indicator) for the respondent’s preferred profile and a 0 indicator for the other profiles in that choice set.

Note: The values you enter in the Response Indicator column must be numerical.

Make Table

Click **Make Table** to construct the table or tables that you selected in “Output Options” on page 567. In the table panel of the Choice Profiles table, there is a Choice script. Run the script and then click **Run Model** to analyze your experimental results.

For information about the Choice Model report, see *Consumer Research*.

Choice Design Options

**Save Factors**  Saves the information in the Factors panel to a new data table. Each factor’s column contains its levels. Other information is stored as column properties. You can then quickly load the factors and their associated information into most DOE windows.

Note: It is possible to create a factors table by entering data into an empty table, but remember to assign each column an appropriate Design Role. Do this by right-clicking on the column name in the data grid and selecting Column Properties > Design Role. In the Design Role area, select the appropriate role.

**Load Factors**  Loads factors that you saved using the Save Factors option.

**Set Random Seed**  Sets the random seed that JMP uses to control actions that have a random component. These actions include one or more of the following:

- initializing search algorithms for design generation
- randomizing Run Order for design construction
- selecting a starting design for designs based on random starts

To reproduce a design, enter the random seed that generated the design before clicking **Make Design**.

Note: The random seed associated with a design is included in the DOE Dialog script that is saved to the design data table.

**Simulate Responses**  Adds response probabilities and a column containing a choice simulation formula to the design table. Select this option before you click Make Table.
When you click Make Table, the following occur:

- A new column that contains a simulated choice response formula is added to the design table. The formula and values are based on the model that is specified in the design window.
- A Model window appears where you can set the values of the marginal utilities for model effects.
- A script called **Choice Simulate** is saved to the design table. This script reopens the Model window, enabling you to re-simulate values or to make changes to the marginal utilities.

When you click Apply, the formula for the simulated choice response values is updated in the Choice Simulated column. If you click Apply again, the formula and values in this column are updated.

See “Simulate Responses” on page 112 in the “Custom Designs” chapter.

**Note:** You can use Simulate Responses to conduct simulation analyses using the JMP Pro Simulate feature. For more information and DOE examples, see Basic Analysis.

**Number of Starts** Enables you to specify the number of random starts used in constructing the design. See “Bayesian D-Optimality and Design Construction” on page 569.

**Advanced Options** Not available for Choice Designs.

**Save Script to Script Window** Creates the script for the design that you specified in the Choice Design window and saves it in an open script window.

**Technical Details**

**Bayesian D-Optimality and Design Construction**

The Bayesian D-optimality criterion is the expected logarithm of the determinant of the information matrix of the maximum likelihood of the parameter estimators in the multinomial logit model, taken with respect to the prior distribution. The Choice Design platform maximizes this expectation with respect to a sample of parameter vectors that represents the prior probability distribution. See Kessels et al. (2011).

For partial profile designs, JMP uses a two-stage design algorithm:

1. The constant attributes in each choice set are determined using an attribute balance approach.
2. The levels of the non-constant attributes are determined using Bayesian D-optimality.
Attribute balance means that the algorithm attempts to balance the number of times each attribute is held constant in the entire design. If two or more attributes are held constant, the algorithm attempts to balance the occurrence of pairs of attributes held constant in the design.

The levels of the non-constant attributes are determined to optimize the Bayesian D-optimal criterion. A random starting design is found. Then levels of the non-constant attributes are generated using a coordinate-exchange algorithm and evaluated until the Bayesian D-optimality criterion is optimized. The calculations, which involve integration with respect to a multivariate normal prior, use the quadrature method described in Gotwalt et al. (2009).

**Note:** The Bayesian D-optimality criterion can result in choice sets where some non-constant attributes have identical levels. This situation occurs when varying the non-constant levels within a profile would result in uninformative choice sets where all profiles have very high or very low probabilities.

**Utility-Neutral and Local D-Optimal Designs**

You can use the Choice Design platform to generate a utility-neutral design by setting prior means to 0. In a utility-neutral design, all choices within a choice set are equally probable. See Huber and Zwerina (1996).

You can also generate a local D-optimal design. The local design takes into account the prior of the mean, but does not include any information from a prior covariance matrix. See Huber and Zwerina (1996).
MaxDiff (maximum difference scaling) studies are an alternative to studies that use standard preference scales to determine the relative importance of items being rated. In a MaxDiff study, a respondent reports only the most and least preferred options from among a small set of choices. This forces respondents to rank options in terms of preference, which often results in rankings that are more definitive than rankings obtained using standard preference scales.

Use the MaxDiff platform when you need to construct a design consisting of choice sets for one factor that can be presented to respondents as part of a MaxDiff study. Conduct your study and then analyze your data use the MaxDiff analysis platform.

Overview of the MaxDiff Design Platform

A choice set is a collection of items from which a respondent must select an item that is most preferred (best item) and one that is least preferred (worst item). Use the MaxDiff platform to specify the number of items that appear in a choice set and the number of choice sets to be presented to a respondent.

The MaxDiff platform provides you with a single survey. If you have several respondents, you can administer the same survey to all respondents or construct a survey for each respondent.

The MaxDiff design is constructed to match the incidence matrix of a balanced incomplete block design as closely as possible. This implies that each pair of items occurs equally often in the design. If the number of choice sets allows a balanced incomplete block to be constructed for the specified number of items in a choice set, the design that is constructed is a balanced incomplete block design.

The items or profiles are considered to be the levels of the treatment factor. The choice sets are considered to be blocks. In a MaxDiff study, the block size is smaller than the number of treatments.

Example of a MaxDiff Design

You are the purchaser for your company’s office supplies and you need to buy candy for a holiday party. First, you want to determine which candy types people prefer. To figure this out, you conduct a MaxDiff study.

You ask five randomly chosen associates to rate seven types of candies. Based on your experience with previous studies, you realize that it is difficult for raters to rank seven types of items in order of preference. Instead, you create a design that consists of choice sets of size four. To keep the study manageable, you structure the survey as a MaxDiff study: you ask each associate to specify his or her most preferred and least preferred candy in each of the seven choice sets. (These selections result in a balanced incomplete block design. See Cochran and Cox (1957).) You administer the same survey to each associate.

Create the Design

Construct a table that lists the items or profiles for your choice sets. In this example, your table of items, Candy Profiles.jmp, is already constructed.

1. Select Help > Sample Data Library and open Design Experiment/Candy Profiles.jmp.
    The table lists the seven candy types of interest.
2. Select DOE > Consumer Studies > MaxDiff Design.
3. From the Select Columns list, select Candy and click X, Factor.
4. Click OK.
5. In the Design Options outline, do the following:
   - Set the Number of Profiles per Choice Set to 4.
   - Set the Number of Choice Sets to 7.

**Note:** Setting the Random Seed in step 6 reproduces the exact results shown in this example. In constructing a design on your own, this step is not necessary.

6. (Optional) Click the MaxDiff Study red triangle and select Set Random Seed. Type 12345 and click OK.
7. Click Make Design.
   The Design outline shows 7 choice sets, each consisting of 4 candy types. The Pairwise Incidence Matrix provides a matrix of the number of choice sets in which each pair of candy types appear together. The diagonal of the matrix is the number of choice sets each candy type appears in. For this example, each candy appears in 4 choice sets and appears with each other candy types in two of the four choice sets.
8. Click Make Table.

</tbody>
</table>

The design table contains a Choice column for recording preferences. For each choice set, record a 1 for the most preferred candy, a -1 for the least preferred, and a 0 for the other two candies.
Analyze the Study Results

You conduct the study and record your data in Candy Survey.jmp.

1. Select Help > Sample Data Library and open Design Experiment/Candy Survey.jmp.
   The table shows the results of presenting the survey to each of five respondents, listed in the Subject column.

2. Select Analyze > Consumer Research > MaxDiff.

3. Click Select Data Table, select Candy Survey, and click OK.

4. Assign column roles:
   - Select Choice and click Response Indicator.
   - Select Subject and click Subject ID.
   - Select Choice Set and click Choice Set ID.
   - Select Candy and click Add in the Construct Profile Effects panel.

Figure 19.3 Completed MaxDiff Analysis Launch Window

Because you designated the Best choice as 1 and the Worst choice as -1, you make no change to the Best and Worst choice indicators at the bottom left of the launch window.

5. Click Run Model.
The report indicates that Candy is significant. The three candy types with the highest utilities are Plain M&Ms, Reese’s Cups, and Peanut M&Ms.

6. Click the MaxDiff Model red triangle and select **All Levels Comparison Report**.

The comparison report indicates which pairs of candy types differ significantly in terms of utility. The third entry in each cell is the *p*-value for the difference defined by the row item’s utility minus the column item’s utility. The intensity of the color for the *p*-value indicates how significant a difference is. The shading, blue or red, indicates whether the difference (row - column) is negative or positive. The *p*-values are not adjusted to control the multiple comparison error rate and should be used only as a guide. For more information about the All Level Comparisons Report, see *Consumer Research*. 
MaxDiff Design Launch Window

To use the MaxDiff Design platform, you need a starting data table. Your starting data table must contain a column of character data that lists the items to be presented to respondents for rating.

With your starting data table active in JMP, select **DOE > Consumer Studies > MaxDiff Design**. If you have no active data tables, you are prompted to navigate to your starting data table.

**Figure 19.6** MaxDiff Launch Window using Candy Profiles.jmp

X, Factor  The character column that contains the items that respondents will rate.

MaxDiff Window

The MaxDiff Study window updates as you work through the design steps. The outlines, separated by buttons that update the outlines, follow the flow in Figure 19.7

**Figure 19.7** MaxDiff Design Flow

Design Options → Make Design → Design → Make Table

The MaxDiff Study window opens showing the Design Options outline. Once you click Make Design, the Design outline appears. To construct the design table, click Make Table.

Design Options Outline

Specify the following:

**Number of Profiles per Choice Set**  The number of items to be included in each choice set.
Number of Choice Sets  The total number of sets of items to be presented to and rated by respondents.

Design Outline

The Design outline identifies the choice sets using consecutive positive integers. The items that comprise each choice set are listed.

Pairwise Incidence Matrix

The Pairwise Incidence Matrix outline provides a matrix of the number of choice sets in which each pair of factor levels appear together. The diagonal of the matrix is the number of choice sets each factor level appears in.

Make Table

The Make Table button creates the design table. The design table consists of four columns:

Subject  Initially populated by ones. Replace with appropriate identifiers for respondents.

Tip: To easily add respondent identifiers, see Using JMP. Use Columns > Recode to change the identifiers to names.

Choice Set  A designator for each choice set.

Factor  The levels of the factor that you specified. These are the items in the choice set.

Choice  A column where you can enter results. Use a numeric value to indicate the best choice, the worst choice, and choices in between. The values 1, -1, and 0 are typically used and are required for analysis by the MaxDiff analysis platform (located at Analyze > Consumer Research > MaxDiff).

MaxDiff Options

Set Random Seed  Sets the random seed that JMP uses to control actions that have a random component. These actions include one or more of the following:

- initializing search algorithms for design generation
- randomizing Run Order for design construction
selecting a starting design for designs based on random starts

To reproduce a design, enter the random seed that generated the design before clicking Make Design.

Note: The random seed associated with a design is included in the DOE Dialog script that is saved to the design data table

Simulate Responses Select this option to simulate response values. When you click Make Table, a Simulate Choice window opens along with the design table, and Probability and Choice Simulated columns are added to the design table. The Choice Simulated formula column contains random responses and the Probability formula column contains their probabilities.

Caution: To change the model used in simulating the responses, enter values in the Marginal Utility column in the Simulate Choice window for all factor levels but the last. Because the marginal utilities must sum to zero, you are not permitted to edit the Marginal Utility for the last level. Once you have specified the remaining Marginal Utility values, the last level of the factor is adjusted accordingly.

Number of Starts The number of random starts used in constructing the design. This value is set to 10 by default.

Advanced Options Not applicable for MaxDiff Designs.

Save Script to Script Window Creates the script for the design that you specified and places in an open script window.
Covering arrays are used in testing deterministic systems where failures occur as a result of interactions among components or subsystems. The design goal is to reveal if any interaction induces a failure in the system. Application areas include software, circuit, and network design.

Since the tests are deterministic, the emphasis driving the design is the need to cover all required interactions. The Covering Arrays platform constructs highly efficient covering arrays. You can also exclude factor level combinations that are not feasible for your testing protocol.

Overview of Covering Arrays

You can use covering arrays to test systems where failures occur as a result of interactions among components or subsystems. Covering arrays are often used in areas such as software, circuit, and network design, where the following conditions are likely to be true:

- The cost of testing is usually high.
- Testing focuses on revealing interactions for which failures occur.
- A test run is typically deterministic and results in either success or failure.
- Replicate runs are wasteful because they yield identical results.
- The efficiency of a design is based on how many of the possible conditions are covered without including redundant runs.

Because systems testing is expensive, reducing the amount of testing is critical. Testing all possible interactions is usually prohibitive and often unnecessary. Experience shows that most failures result from the interaction of a small number of components. The size of the largest combination of components likely to drive a failure, called the strength, drives the size of the design.

In the Covering Array platform, you specify the required strength of your design. If appropriate, you define factor level combinations that are not permitted. The Covering Array platform constructs a highly efficient design that meets your requirements. It provides metrics that you can use to assess the quality of the design in terms of its coverage. It also provides a script in the data table for the design that enables you to analyze your results.

Covering arrays are often used in situations where certain combinations of factor level settings are not feasible. The Covering Array platform is able to find very efficient covering arrays even when restrictions are placed on factor level combinations.

For background on the structure of covering arrays and algorithms for computing them, see Colbourn (2004), Colbourn et al. (2011), Hartman and Raskin (2004), and Martirosyan (2003). For more information about covering arrays with restrictions on factor levels, see Cohen et al. (2007) and Morgan (2009).

Covering Arrays and Strength

A covering array of strength \( t \) is a design that tests all combinations of \( t \) factor level settings. Consider an interaction defined by specific settings for \( k \) factors. If failures occur for all tests involving that interaction, then that interaction detects a failure. Using this terminology, a strength \( t \) design enables you to detect failures associated with any interaction of up to \( t \) factors.
In the literature, covering arrays are also referred to as factor covering designs. For background and more information, see Yilmaz et al. (2014), Cohen et al. (2003), and Dalal and Mallows (1998).

To illustrate the nature of covering arrays, consider a situation involving seven categorical factors each with two levels. You want to test all pairwise combinations of factor levels.

A design that might be used in this situation is the 8-run resolution III main effects design:

**Figure 20.2** A Resolution III Design with Strength 2

Note that this factorial design is a strength 2 covering array because all pairwise combinations of levels of any two factors appear. For example, for \(X_1\) and \(X_2\), the following combinations each appear twice:

- L2 and L1
- L2 and L2
- L1 and L1
- L1 and L2

However, a strength 2 covering array needs only 6 runs:

**Figure 20.3** Strength 2 Covering Array

All pairwise combinations of levels of any two factors appear at least once in the six runs. The Covering Array design is more efficient than the Resolution III design because it achieves strength 2 coverage with fewer runs.

The efficiency of a covering array is measured by the number of runs required to achieve the required coverage. The smaller the number of runs, the more efficient the design.
Example of a Covering Array with No Factor Level Restrictions

The data in this example pertain to interoperability in the area of software testing. There are four factors of interest:

- Web Browser (Safari, IE, Firefox, Chrome, Other)
- Operating System (Windows or macOS)
- RAM (4, 8, or 16 MB)
- Connection Speed at three settings (0-1, 1-5, or greater than 5 Mbps)

You are interested in finding out which combinations of these factors are likely to cause failures.

The response is whether the system functions properly for each combination of factor settings.

Testing each combination of settings would require 90 (5x2x3x3) trials. To keep the run size manageable, you decide to require Strength 3 coverage, indicating that all combinations of any three factors are tested.

Create the Design

Create the Strength 3 covering array by following these steps.

1. Select Help > Sample Data Library and open Design Experiment/Software Factors.jmp.
   - The Software Factors.jmp data table contains the factors and their settings.
2. Select DOE > Special Purpose > Covering Array.
3. From the menu next to Strength: t = , select 3.
4. Click the Covering Array red triangle, select Load Factors.
   - The Factors outline is populated with the four factors and their levels.
5. Click **Continue**.

The Restrict Factor Level Combinations outline opens, where you can enter restrictions on the design settings. Because there are no restrictions for this design, do not change the default selection of **None**.

6. Click **Make Design**.

The Design outline opens to show a 45-run design.

**Figure 20.5** Design and Metrics Outlines for Software Factors

In the Metrics outline, consider the row that corresponds to $t = 3$. The Coverage is 100%, indicating that the design covers 100% of the three-factor interactions. This is what you want, because you requested a Strength 3 design. For $t = 3$, the Diversity column indicates that 68.33% of the three-factor interactions that appear are distinct. There is some minor repetition of three-factor combinations.
For $t = 4$, the Coverage is 50%, indicating that the design covers half of the four-factor interactions. There are 90 possible distinct combinations of the four factor settings. The 45 runs in the design comprise one-half of these distinct combinations. The Diversity value of 100% reinforces the fact that none of the four-way interactions are repeated.

7. Click Make Table.

Figure 20.6 Partial Design Table for Software Factors

The design is presented in a data table. Notice the following in the Table panel at the top left:

- The Design note indicates that this is a strength 3 covering array.
- The DOE Dialog script reproduces the Covering Array window settings.
- The Analysis script analyzes the experimental data.

**Analyze the Experimental Data**

Now that you have your design table, you can conduct your experiment and record your data in the Response column of the design table (Figure 20.6). Your experimental results are in the Software Data.jmp sample data table.

1. Select Help > Sample Data Library and open Design Experiment/Software Data.jmp.
2. In the Table panel, click the green triangle next to the Analysis script.
The Summary outline indicates that three tests failed and four tests did not result in a pass or fail outcome.

The Failure Analysis Details outline gives a breakdown of failures in terms of the associated three-way interactions. The outline lists only combinations of factor levels where all tests resulted in failure. If any test that involves a given three-way combination of settings results in success, then that three-way combination of settings cannot be responsible for system failure.

Two failures were associated with Web Browser set to Firefox, Operating System set to macOS, and RAM set to 8 MB. Notice that this combination led to failure regardless of the setting of Connection Speed.

3. Select the first line in the 3 Factor Interactions report.

This action selects the corresponding rows and columns in the data table.
Three failures were associated with combinations of Web Browser, RAM, and Connection Speed. Note that two of these failures, Firefox, 8 MB, 1-5 Mbps and Firefox, 8 MB, >5 Mbps, are among the two failures for the Web Browser, Operating System, and RAM interaction. Selecting any of these rows in the report selects the corresponding rows and columns in the data table.

Example of a Covering Array with Factor Level Restrictions

This example is patterned after an example described in Dalal and Mallows (1998). An originating phone (Near Phone) calls a receiving phone (Far Phone). Each phone call goes through an interface of type A or B. Five factors are of interest:

- Market: USA, UK, Canada, France, Mexico
- Near Phone: ISDN, Bus (Business), Coin, Res (Residential)
- Near Interface: A or B
- Far Phone: ISDN, Bus (Business), Coin, Res (Residential)
- Far Interface: A or B

You are interested in which combinations of pairs of these factors are likely to cause failures. However, certain combinations are not possible:

- An ISDN line on either phone (Near or Far) cannot use interface A.
• Business and Residential lines on the originating phone (Near) cannot use interface B.

Create the Design

The factors and their settings are given in the data table Phone Factors.jmp. Create a Strength 2 covering array by following these steps.

Load Factors

1. Select **Help > Sample Data Library** and open Design Experiment/Phone Factors.jmp. The Phone Factors.jmp data table contains the factors and their settings.
2. Select **DOE > Special Purpose > Covering Array**. Notice that the menu next to **Strength: \( t = \)** is set to 2 by default.
3. Click the Covering Array red triangle and select **Load Factors**. The Factors outline is populated with the five factors and their levels.

**Figure 20.10** Factors Outline for Phone Factors

4. Click **Continue**. The Restrict Factor Level Combinations outline opens.

Restrict Factor Level Combinations

You can specify disallowed combinations in two ways:

- Use Disallowed Combinations Filter
- Use Disallowed Combinations Script
The filter gives an intuitive way to specify disallowed combinations. The script provides a quick and easy way to specify disallowed combinations, but requires that you have written or saved a script. In this example, if you do not want to specify combinations using the filter, skip to “Specify Disallowed Combinations Using a Script” on page 592.

Recall that the restrictions are the following:

- An ISDN line on either phone (Near or Far) cannot use interface A.
- Business and Residential phones on the originating phone (Near) cannot use interface B.

### Specify Disallowed Combinations Using the Filter

Use this approach to enter disallowed combinations using the filter interface. Alternatively, you can paste a script as shown in “Specify Disallowed Combinations Using a Script” on page 592.

1. Select **Use Disallowed Combinations Filter**.
2. From the Add Filter Factors list, select **Near Phone** and **Near Interface** and click the **Add** button.
3. Press Ctrl and click ISDN under **Near Phone** and A under **Near Interface**.
   
   Both blocks should turn dark. You have added the constraint that an ISDN line on the originating phone (Near) cannot use interface A.

4. Click **OR**.
5. From the Add Filter Factors list, select **Far Phone** and **Far Interface** and click the **Add** button.
6. Press Ctrl and click ISDN under **Far Phone** and A under **Far Interface**.
   
   You have added the constraint that an ISDN line on the receiving phone (Far) cannot use interface A.

7. Click **OR**.
8. From the Add Filter Factors list, select Near Phone and Near Interface and click the Add button.

9. Press Ctrl and click Bus and Res under Near Phone and B under Near Interface.

You have added the restriction that Business and Residential lines on the originating phone (Near) cannot use interface B.

Figure 20.12 Completed Disallowed Combinations Filter

Specify Disallowed Combinations Using a Script

Alternatively, you can specify disallowed combinations by constructing a script. After loading your factors ("Load Factors" on page 590), do the following:

1. Click Continue.

2. Select Use Disallowed Combinations Script.

3. Copy the following script and paste it in the Disallowed Combinations Expression script box:

   ```
   (Near Phone == "ISDN" & Near Interface == "A") | 
   (Far Phone == "ISDN" & Far Interface == "A") | 
   (Near Phone == "Bus" & Near Interface == "B") | 
   (Near Phone == "Res" & Near Interface == "B") 
   ```
Figure 20.13  Completed Disallowed Combinations Script Window

Construct the Design Table

Note: Setting the Random Seed in the next two steps reproduces the exact results shown in this example. When constructing a design on your own, these steps are not necessary.

1. Click the Covering Array red triangle and select Set Random Seed.
2. Enter 632 and click OK.
3. Click Make Design.
   The Design outline opens to show a 20-run design. A Metrics outline is added to the window.

Figure 20.14  Metrics Outline for Phone Design

The Metrics outline indicates that Strength 2 coverage is 100%. This means that all permissible two-factor combinations are represented in the design. The design also covers 65% of all three-factor combinations.

4. Click Make Table.
   The design is placed in a design table. A column for the response is provided, as well as various scripts.
Figure 20.15 Covering Array Design Table

</table>

Analyze the Experimental Data

Now that you have your design table, you can conduct your experiment and record your data in the Response column of the design table. Your experimental results are in the Phone Data.jmp sample data table.

1. Select Help > Sample Data Library and open Design Experiment/Phone Data.jmp.
2. In the Table panel, click the green triangle next to the Analysis script.
The Summary outline indicates that three tests failed.

The Failure Analysis Details outline contains a 2 Factor Interactions report, because a two-way interaction is the lowest level interaction that detects a failure.

The 2 Factor Interactions report shows the combinations that might have caused the three failures. It is possible that one combination, Near Interface set to A and Far Phone set to Coin, is responsible for all three failures. Or it is possible that two or three other combinations caused the three failures.

3. Select the first line in the 2 Factor Interactions report.

In the data table, rows 4, 16, and 19 are selected. Failures occur for these combinations, regardless of the settings for Market, Near Phone, and Far Interface. But note that other combinations of factor settings could account for these failures as well.
Factors

Add factors in the Factors outline.

Figure 20.18 Factors Outline

Add Factor  Enters the number of factors specified in Add N Factors. All factors are categorical. Select or specify the number of levels.

Remove  Removes the selected factors.

Add N Factors  Adds multiple factors with a specific number of levels. Enter the number of factors to add, click Add Factor, and select or specify the number of levels. Repeat Add N Factors to add multiple factors with different numbers of levels.

Strength t =  Select a value to specify the strength of the array.

Tip: When you have completed your Factors panel, select Save Factors from the red triangle menu. This saves the factor names and values in a data table that you can later reload. See “Covering Array Options” on page 604.

Factors Table

The Factors table contains the following columns:

Name  The name of the factor. When a factor is added, it is given a default name of X1, X2, and so on. To change this name, double-click it and enter the desired name.

Role  Specifies the Design Role of the factor. The Design Role for all covering array factors is Categorical. The Design Role column property for the factor is saved to the data table. This property ensures that the factor is modeled appropriately.

Values  The settings for the factors. To insert Values, click the default values and enter the desired values. The value ordering in the design table is the order of the values as entered from left to right.
**Editing the Factors Table**

In the Factors outline, notice the following:

- To edit a factor name, double-click the factor name.
- Categorical factors have a down arrow to the left of the factor name. Click the arrow to add a level.
- To remove a factor level, click the value, click **Delete**, and click outside the text box.
- To edit a value, click the value in the **Values** column.

**Factor Column Properties**

For each factor, the Value Labels column property is saved to the design table. The Value Labels column property represents values in a column with specified labels. These labels are shown in the data table and are used in plots and reports. See “Value Labels” on page 815 in the “Column Properties” appendix.

**Restrict Factor Level Combinations**

When you complete the Factors outline and click Continue, the Restrict Factor Level Combinations outline appears. This outline enables you to specify factor level combinations that are prohibited. Unless you have loaded a constraint or included one as part of a script, the **None** option is selected. To specify constraints, select one of the other options:

**Use Disallowed Combinations Filter**  Defines sets of constraints based on restricting values of individual factors. You can define both AND and OR constraints. See “Use Disallowed Combinations Filter” on page 597.

**Use Disallowed Combinations Script**  Defines disallowed combinations and other constraints as Boolean JSL expressions in a script editor box. See “Use Disallowed Combinations Script” on page 599.

**Use Disallowed Combinations Filter**

This option uses an adaptation of the Data Filter to facilitate specifying disallowed combinations. For detailed information about using the Data Filter, see *Using JMP*.

To add disallowed combinations:

1. Select factors from the Add Filter Factors list and click **Add**.
2. Specify the disallowed combinations by selecting levels.
Note: The red triangle options in the Add Filter Factors menu are the same as those found in the Select Columns panel of many platform launch windows. See Using JMP.

When you click Add, the initial panel is updated. The Disallowed Combinations control panel shows the selected factors and provides options for further control.

The Covering Array platform allows only categorical factors. For categorical factors, the possible levels are shown either as labeled blocks or, when the number of levels is large, as list entries. Select a level to disallow it. To select multiple levels, press Ctrl. The block or list entries are highlighted to indicate the levels that have been disallowed. When you add a factor to the Disallowed Combinations panel, the number of levels of the categorical factor is given in parentheses following the factor name.

Disallowed Combinations Options

Clear  Clears all disallowed factor level settings that you have specified. This does not clear the selected factors.

AND  Opens the Add Filter Factors list. Selected factors become an AND group. Any combination of factor levels specified within an AND group is disallowed.

To add a factor to an AND group later on, click the group's outline to see a highlighted rectangle. Select AND and add the factor.

To remove a single factor, select Delete from its red triangle menu.

OR  Opens the Add Filter Factors list. Selected factors become a separate AND group. For AND groups separated by OR, a combination is disallowed if it is specified in at least one AND group.

Red Triangle Options for Factors

A factor can appear in several OR groups. An occurrence of the factor in a specific OR group is referred to as an instance of the factor.

Delete  Removes the selected instance of the factor from the Disallowed Combinations panel.

Clear Selection  Clears any selection for that instance of the factor.

Invert Selection  Deselects the selected values and selects the values not previously selected for that instance of the factor.

Display Options  Changes the appearance of the display.

Blocks Display  Shows each level as a block.

List Display  Shows each level as a member of a list.
**Single Category Display**  Shows each level.

**Check Box Display**  Adds a check box next to each value.

**Radio Box Display**  Adds a radio selection next to each value for a single selection.

**Find**  (Available for categorical factors.) Provides a text box beneath the factor name where you can enter a search string for levels of the factor. Press Enter or click outside the text box to perform the search. Once **Find** is selected, Find options appear in the search panel black triangle menu. Options include Contain Terms, Contain Phrase, Starts with Phrase or Ends with Phrase, and Invert Result.

---

**Use Disallowed Combinations Script**

This option opens a script window where you insert a script that identifies the combinations that you want to disallow. The script must evaluate as a Boolean expression. When the expression evaluates as true, the specified combination is disallowed.

When creating the expression, use the name of the level in quotation marks. Do not use the ordinal value of the level. For example, Figure 20.19 shows the script that you entered in the phone interface example, “Specify Disallowed Combinations Using a Script” on page 592.

**Figure 20.19**  Script Window Showing Names of Levels in Quotes

---

**Design**

When you click Make Design, the Design and Metrics outlines appear. For designs that require extensive computation, a progress bar appears.

The Design outline shows the design that you have constructed. The first column lists a Run order. You might need to use the scroll bar to view all the runs. The remaining columns show factor settings for each run.
Optimize

Select Optimize to reduce the size of a design that was constructed by the Covering Array platform or that you have loaded using the Load Design red triangle option. Optimize is not available for designs constructed by the Covering Array platform that are known to be optimal. In particular, all unconstrained strength 2 designs for two-level factors constructed by the platform are optimal. Also, any unconstrained strength \( t \) design for \( t+1 \) factors is optimal for any \( t \).

For more information about the algorithm, see “Algorithm for Optimize” on page 606.

**Note:** Optimize is time intensive, but can be run repeatedly to yield incrementally better designs.

Use the **Maximum iterations** option to specify a maximum number of iterations to be used in optimizing the design.

Unsatisfiable Constraints

If a set of constraints prohibits the construction of a covering array where all required factor levels are represented, it is said to be *unsatisfiable.*

Example of Unsatisfiable Constraints

Consider a strength 2 design for three factors, each at three levels.

1. Select **DOE > Special Purpose > Covering Array.**
2. Next to **Add N Factors**, type 3.
3. From the **Add Factor** menu, select **3 Level**.
4. Click **Continue**.
5. Select **Use Disallowed Combinations Filter**.
6. From the **Add Filter Factors** list, select all three factors and click the **Add** button.
7. Press Ctrl and select the following levels:
   - For X1, select L1.
   - For X2, select L1, L2, and L3.
   - For X3, select L3.
Figure 20.20 Completed Restrict Factor Level Combinations Panel

![Completed Restrict Factor Level Combinations Panel]

**Note:** Setting the Random Seed in the next two steps reproduces the exact results shown in this example. When constructing a design on your own, these steps are not necessary.

8. Click the Covering Array red triangle and select **Set Random Seed**.
9. Enter 12345 and click **OK**.
10. Click **Make Design**.

Figure 20.21 Design and Metrics Outlines

![Design and Metrics Outlines]

A note beneath the Design outline indicates that one run has a missing setting due to the constraints. That run is run 9. To ensure that the covering array has strength 2, the
combination of X1 set to L1 and X3 set to L3 is required. But for these settings, the constraints prohibit all settings for X2.

**Metrics**

The Metrics outline gives you information about how well the design meets the strength requirements. See Dalal and Mallows (1998) for background on these metrics for unconstrained designs.

- \( t \) The number of factors.

**Coverage** The ratio of the number of distinct \( t \)-factor settings that appear in the design to the total possible number of \( t \)-factor settings, expressed as a percentage. A \( t \)-coverage of 100% indicates that all possible \( t \)-factor settings are covered by the design. Note that each \( t \)-factor setting can appear multiple times.

For constrained and unsatisfiable designs, the definition of Coverage is adjusted for the number of \( t \)-factor settings that are possible once the constraints have been applied to all \( t \)-factor combinations. See “Formulas for Metrics” on page 606.

**Diversity** The ratio of the number of distinct \( t \)-factor settings in the design to the total number of occurrences of \( t \)-factor settings in the design, expressed as a percentage. The \( t \)-diversity measures how well the design avoids replication. A \( t \)-diversity of 100% indicates that no \( t \)-factor settings are repeated. A \( t \)-diversity of 50% indicates that the average number of times that distinct \( t \)-factor settings appear is two.

For constrained and unsatisfiable designs, the definition of Diversity is adjusted for the number of runs with missing settings. See “Formulas for Metrics” on page 606.

**Output Options**

- **Make Table** Constructs the Covering Array data table.

- **Back** Takes you back to the Factors outline. You can make changes to the previous outlines and regenerate the design.

**Note:** If you have defined Disallowed Combinations in the Restrict Factor Level Combinations outline, these are retained as a script. The script is shown in the Use Disallowed Combinations Script panel when you click Continue.
The Covering Array Data Table

The Covering Array data table contains a first column where you can enter the response. The remaining columns give the factor settings.

The Table panel in the upper left contains a Design note indicating that the design is a Covering Array and giving the Strength of the design. The Table panel also contains the following scripts.

**DOE Dialog**  Re-creates the Covering Array window that you used to generate the design table.

**Disallowed Combinations**  Shows factor level restrictions that you entered in the Restrict Factor Level Combinations outline.

**Analysis**  Provides an analysis of your experimental data. For more information about the script, see “Analysis Script” on page 603. For background, see Zhang and Zhang (2011).

**Tip:** To run a script, click the green triangle next to the script name.

---

**Figure 20.22**  Partial View of Covering Array Table for Software Data.jmp Showing Scripts

---

**Analysis Script**

The Analysis script assumes the following about the Response column:

- The responses are recorded as 0 for failure and 1 for success.
- Missing values are permitted.
- The Response column is continuous.
- You can rename or move the Response column.
The Analysis script produces a report with two outlines:

- The Summary outline gives the number of runs resulting in Success, Failure, and the number of runs for which the response is Missing.
- The Failure Analysis Details report contains a \(<k\) Factor Interactions report. The value of \(k\) is the smallest number of interactions that detect a failure. (For a definition of detect, see “Covering Arrays and Strength” on page 583.) The three columns contain the following:
  - The **Factors** column lists all \(k\)-factor combinations that detect failures.
  - The **Failure Levels** column lists the values of the \(k\) factors in the **Factors** column that detect failures.
  - The **Failure Count** column gives the number of failures corresponding to the \(k\)-factor combination of **Failure Levels**.

  **Note:** A failure observation can appear in more than one of the \(k\)-factor combinations listed in the **Failure Levels** column.

The rows in the \(<k\) Factor Interactions report are dynamically linked to the data table. If you select one or more rows in the report, the corresponding rows are selected in the data table.

---

### Covering Array Options

The red triangle menu in the Covering Array platform contains these options:

- **Save Factors**  Creates a data table containing a column for each factor that contains its factor levels. Each factor’s column contains these column properties: Design Role, Value Order, and Factor Changes. Saving factors enables you to quickly load them into a DOE window.

  **Note:** You can create a factors table for a Covering Array by entering data into an empty table, but remember to assign each column an appropriate Design Role of Categorical. Right-click the column name in the data grid and select **Column Properties > Design Role**. In the Design Role area, select Categorical.

- **Load Factors**  Loads factors that you have saved using the Save Factors option into the Factors outline.

- **Load Design**  Loads a design from the active data table. If no data table is active, you are prompted to open one. When you select Load Design, a menu appears that enables you to select the columns that you want to specify as factors in the design. All columns are imported as categorical. Columns and their values are listed in the Factors outline. The
Design outline shows a Run for each row in the data table and gives the values of the factors for each run.

The Load Design options enables you to obtain metrics, modify, or construct an Analysis script for an existing design:

- The Metrics outline shows $t$-Coverage and $t$-Diversity for the specified design.
- You can click Back to impose factor level restrictions and then construct a new design.
- Clicking Make Table constructs a design table where you can enter responses. The table contains an Analysis script for the design.

**Set Random Seed**  Sets the random seed that JMP uses to control certain actions that have a random component. For Covering Arrays, the seed selects a starting design and an iteration count. For most designs, the random seed guarantees reproducibility of the design, but not of the run order.

**Note:** Upper limits on time as well as iteration count are used to limit design construction time. For some large and high strength designs, depending on the machine, the time limit might override the iteration limit. For such designs, the random seed does not guarantee reproducibility.

To reproduce a design, enter the random seed used to generate it before clicking Make Design.

**Note:** The random seed associated with a design is included in the DOE Dialog script that is saved to the design data table.

**Advanced Options**  Not available for Covering Arrays.

**Save Script to Script Window**  Creates the script for the design that you specified in the Covering Array window and places it in an open script window.

---

**Technical Details for Covering Arrays**

- “Algorithm for Optimize”
- “Formulas for Metrics”
Algorithm for Optimize

The Optimize button invokes an algorithm that is conceptually similar to a class of covering array optimizers sometimes referred to as post-construction randomized optimizers (Nayeri et al., 2013). However, the algorithm in JMP differs from most in that it also addresses designs with constraints. In particular, it optimizes constrained covering arrays as well as unsatisfiable, constrained covering arrays.

The algorithm assumes that the design to be optimized is a covering array of the specified strength. For a $K$ factor design of strength $t$, the algorithm iteratively examines all $\binom{K}{t}$ factor projections to determine whether runs can be eliminated or merged. Consequently, as $K$ or $t$ increases, the run time of the algorithm quickly escalates. To improve performance, the JMP implementation is threaded to use as many CPU cores as are available on your workstation.

Formulas for Metrics

The formulas for Coverage and Diversity depend on whether there are constraints. The following notation is used:

- $u \binom{v}{u}$ is the number of combinations of $u$ things taken $v$ at a time
- $t$ is the strength of the design
- $K$ is the number of factors
- $M = \binom{K}{t}$
- $i = 1, 2, \ldots, M$ is an index that orders all combinations, or projections, of $t$ factors
- $v_{ik}$ is the number of levels for the $k$th factor
- $n_i$ is the number of distinct $t$ tuples in the design for the $i$th projection
- $p_i$ is the product of the $v_{ik}$ for the factors in the $i$th projection
- $r$ is the number of runs in the design

Unconstrained Design

Coverage and Diversity are given by the following:

Coverage  \[
\frac{1}{M} \sum_{i=1}^{M} \frac{n_i}{p_i}
\]

Diversity  \[
\frac{1}{M} \sum_{i=1}^{M} \frac{n_i}{r}
\]
Constrained Design

In a constrained design, certain tuples are not allowed. This can result in missing values for some tuples. For some combinations of factors, there might be no valid tuples whatsoever. Coverage and diversity must be defined in terms of the possible valid combinations. For this reason, the formulas for constrained designs require additional notation:

- $a_i$ is the number of invalid tuples arising from factors in the $i^{th}$ projection
- $m$ is the number of projections where there are no valid tuples
- $q_i$ is the number of runs in the design with missing values for any factor in the $i^{th}$ projection
- $r_i = r - q_i$
- $M' = M - m$

Coverage and Diversity are given by the following:

\[
\text{Coverage} = \frac{1}{M'} \sum_{i=1}^{M'} \frac{n_i}{(p_i - a_i)}
\]

\[
\text{Diversity} = \frac{1}{M'} \sum_{i=1}^{M'} \frac{n_i}{r_i}
\]

If there are no invalid tuples ($M' = M$) and if there are no missing values ($r_i = r$, for all $i$), then the definitions for coverage and diversity for constrained designs reduce to the definitions for unconstrained designs. See Morgan (2014).
Space-filling designs are useful in situations where run-to-run variability is of far less concern than the form of the model. Consider a sensitivity study of a computer simulation model. In this situation, and for any mechanistic or deterministic modeling problem, any variability is small enough to be ignored. For systems with no variability, replication, randomization, and blocking are irrelevant.

The Space Filling platform provides designs for situations with both continuous and categorical factors. For continuous factors, space-filling designs have two objectives:

- maximize the distance between any two design points
- space the points uniformly

Overview of Space-Filling Designs

Space-filling designs are useful for modeling systems that are deterministic or near-deterministic. One example of a deterministic system is a computer simulation. Such simulations can be very complex involving many variables with complicated interrelationships. A goal of designed experiments on these systems is to find a simpler empirical model that adequately predicts the behavior of the system over limited ranges of the factors.

In experiments on systems where there is substantial random noise, the goal is to minimize the variance of prediction. In experiments on deterministic systems, there is no variance but there is bias. Bias is the difference between the approximation model and the true mathematical function. The goal of space-filling designs is to bound the bias.

One approach to bound the bias is to spread the design points out as far from each other as possible while staying inside the experimental boundaries. The other approach is to space the points out evenly over the region of interest.

The Space Filling designer supports the following design methods:

**Sphere Packing**  Maximizes the minimum distance between pairs of design points. See “Sphere-Packing Designs” on page 623 and “Create the Sphere-Packing Design for the Borehole Data” on page 648.

**Latin Hypercube**  Maximizes the minimum distance between design points but requires even spacing of the levels of each factor. This method produces designs that mimic the uniform distribution. The Latin Hypercube method is a compromise between the Sphere-Packing method and the Uniform design method. See “Latin Hypercube Designs” on page 626.

**Uniform**  Minimizes the discrepancy between the design points (which have an empirical uniform distribution) and a theoretical uniform distribution. See “Uniform Designs” on page 630.

**Minimum Potential**  Spreads points out inside a sphere around the center. See “Minimum Potential Designs” on page 633.

**Maximum Entropy**  Measures the amount of information contained in the distribution of a set of data. See “Maximum Entropy Designs” on page 636.

**Gaussian Process IMSE Optimal**  Creates a design that minimizes the integrated mean squared error of the Gaussian process over the experimental region. See “Gaussian Process IMSE Optimal Designs” on page 637.

**Fast Flexible Filling**  The Fast Flexible Filling method forms clusters from random points in the design space. These clusters are used to choose design points according to an optimization criterion. This is the only method that can accommodate categorical factors.

**Note:** If the number of runs is 500 or less, a Gaussian Process model is saved to the data table. If the number of runs exceeds 500, a Neural model is saved to the data table.

---

**Build a Space Filling Design**

Build a Space Filling Design by selecting **DOE > Special Purpose > Space Filling Design**. First define your responses and factors. Next, continue to the design options, generation, and evaluation. The design process follows the flow in Figure 21.2.

**Figure 21.2 Space Filling Design Flow**

![](image)

---

**Responses**

Use the Responses outline to specify one or more responses.

**Tip:** When you have completed the Responses outline, consider selecting **Save Responses** from the red triangle menu. This option saves the response names, goals, limits, and importance values in a data table that you can later reload in DOE platforms.

**Figure 21.3 Responses Outline**

<table>
<thead>
<tr>
<th>Responses</th>
<th>Add Response</th>
<th>Remove</th>
<th>Number of Responses</th>
</tr>
</thead>
<tbody>
<tr>
<td>Response Name</td>
<td>Goal</td>
<td>Lower Limit</td>
<td>Upper Limit</td>
</tr>
<tr>
<td>Y</td>
<td>Maximize</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

**Add Response** Enters a single response with a goal type of Maximize, Match Target, Minimize, None, or Functional. If you select Match Target, enter limits for your target value. If you select Maximize or Minimize, entering limits is not required but can be useful if you intend to use desirability functions.
**Functional** (Available only in JMP Pro.) Adds multiple Y columns with FDE column properties to the design data table. These columns can be used in the Functional Data Explorer platform with the DOE factors as supplementary factors.

**Remove** Removes the selected responses.

**Number of Responses** Enters additional responses so that the number that you enter is the total number of responses. If you have entered a response other than the default Y, the Goal for each of the additional responses is the Goal associated with the last response entered. Otherwise, the Goal defaults to Match Target. Click the Goal type in the table to change it.

The Responses outline contains the following columns:

**Response Name** The name of the response. When added, a response is given a default name of Y, Y2, and so on. To change this name, double-click it and enter the desired name.

**Goal, Lower Limit, Upper Limit** The Goal tells JMP whether you want to maximize your response, minimize your response, match a target, or that you have no response goal. JMP assigns a Response Limits column property, based on these specifications, to each response column in the design table. It uses this information to define a desirability function for each response. The Profiler and Contour Profiler use these desirability functions to find optimal factor settings. For further details, see the Profiler chapter in Profilers and “Response Limits” on page 784 in the “Column Properties” appendix.

- A Goal of Maximize indicates that the best value is the largest possible. If there are natural lower or upper bounds, you can specify these as the Lower Limit or Upper Limit.
- A Goal of Minimize indicates that the best value is the smallest possible. If there are natural lower or upper bounds, you can specify these as the Lower Limit or Upper Limit.
- A Goal of Match Target indicates that the best value is a specific target value. The default target value is assumed to be midway between the Lower Limit and Upper Limit.
- A Goal of None indicates that there is no goal in terms of optimization. No desirability function is constructed.

**Note:** If your target response is not midway between the Lower Limit and the Upper Limit, you can change the target after you generate your design table. In the data table, open the Column Info window for the response column (Cols > Column Info) and enter the desired target value.

**Importance** When you have several responses, the Importance values that you specify are used to compute an overall desirability function. These values are treated as weights for
the responses. If there is only one response, then specifying the Importance is unnecessary because it is set to 1 by default.

Detection Limits

The lower and upper detection limits are bounds beyond which the response cannot be measured. The detection limits are saved as a column property. You can use these limits to specify a censored response in the Generalized Regression platform. See the Generalized Regression chapter in Fitting Linear Models.

Editing the Responses Outline

In the Responses outline, note the following:

- Double-click a response to edit the response name.
- Click the goal to change it.
- Click on a limit or importance weight to change it.
- For multiple responses, you might want to enter values for the importance weights.

Response Limits Column Property

The Goal, Lower Limit, Upper Limit, and Importance that you specify when you enter a response are used in finding optimal factor settings. For each response, the information is saved in the generated design data table as a Response Limits column property. JMP uses this information to define the desirability function. The desirability function is used in the Prediction Profiler to find optimal factor settings. For further details about the Response Limits column property and examples of its use, see “Response Limits” on page 784 in the “Column Properties” appendix.

If you do not specify a Lower Limit and Upper Limit, JMP uses the range of the observed data for the response to define the limits for the desirability function. Specifying the Lower Limit and Upper Limit gives you control over the specification of the desirability function. For more details about the construction of the desirability function, see the Profiler chapter in Profilers.

Factors

Add factors for a space filling design in the Factors outline.
The Factors outline contains these options:

**Continuous** Enters the number of continuous factors specified in *Add N Factors*.

**Categorical** Enters the number of nominal factors specified in *Add N Factors*.

**Remove** Removes the selected factors.

**Add N Factors** Adds multiple factors of a given type. Enter the number of factors to add and click Continuous or Categorical. Repeat *Add N Factors* to add multiple factors of different types.

**Tip:** When you have completed your Factors panel, select *Save Factors* from the red triangle menu. This saves the factor names and values in a data table that you can later reload. See “Space Filling Design Options” on page 621.

**Factors Outline**

The Factors outline contains the following columns:

**Name** The name of the factor. When added, a factor is given a default name of $X_1$, $X_2$, and so on. To change this name, double-click it and enter the desired name.

**Role** Specifies the Design Role of the factor. The Design Role column property for the factor is saved to the data table. This property ensures that the factor type is modeled appropriately.

**Values** The experimental settings for the factors. To insert Values, click the default values and enter the desired values.

**Editing the Factors Outline**

In the Factors outline, note the following:

- To edit a factor name, double-click the factor name.
- Categorical factors have a down arrow to the left of the factor name. Click the arrow to add a level.
- To remove a factor level, click the value, click **Delete**, and click outside the text box.
- To edit a value, click the value in the **Values** column.

**Factor Types**

**Continuous**  Numeric data types only. A continuous factor is a factor that you can conceptually set to any value between the lower and upper limits you supply, given the limitations of your process and measurement system.

**Categorical** Either numeric or character data types. For a categorical factor, the value ordering is the order of the values as entered from left to right. This ordering is saved in a Value Order column property after the design data table is created.

**Factor Column Properties**

For each factor, various column properties are saved to the data table.

**Design Role** Each factor is assigned the Design Role column property. The Role that you specify in defining the factor determines the value of its Design Role column property. The Design Role property reflects how the factor is intended to be used in modeling the experimental data. Design Role values are used in the Augment Design platform.

**Factor Changes** Each factor is assigned the Factor Changes column property with a setting of Easy. In space-filling designs, it is assumed that factor levels can be changed for each experimental run. Factor Changes values are used in the Evaluate Design and Augment Design platforms.

**Coding** If the Role is Continuous, the Coding column property for the factor is saved. This property transforms the factor values so that the low and high values correspond to –1 and +1, respectively. The estimates and tests in the Fit Least Squares report are based on the transformed values.

**Value Order** If the Role is Categorical or Blocking, the Value Order column property for the factor is saved. This property determines the order in which levels of the factor appear.

**Define Factor Constraints**

Factor constraints can be specified only for space filling designs constructed using the Fast Flexible Filling method.
Use Define Factor Constraints to restrict the design space. Unless you have loaded a constraint or included one as part of a script, the **None** option is selected. To specify constraints, select one of the other options:

**Specify Linear Constraints**  Specifies inequality constraints on linear combinations of factors. Available only for factors with a Role of Continuous or Mixture. See *Specify Linear Constraints*.

**Note:** When you save a script for a design that involves a linear constraint, the script expresses the linear constraint as a *less than or equal to* inequality (\( \leq \)).

**Use Disallowed Combinations Filter**  Defines sets of constraints based on restricting values of individual factors. You can define both AND and OR constraints. See *Use Disallowed Combinations Filter*.

**Use Disallowed Combinations Script**  Defines disallowed combinations and other constraints as Boolean JSL expressions in a script editor box. See *Use Disallowed Combinations Script*.

**Note:** When you analyze a design that has factor constraints, the model profiler honors the constraints.

**Specify Linear Constraints**

In cases where it is impossible to vary continuous factors independently over the design space, you can specify linear inequality constraints. Linear inequalities describe factor level settings that are allowed.

Click **Add** to enter one or more linear inequality constraints.

**Add**  Adds a template for a linear expression involving all the continuous factors in your design. Enter coefficient values for the factors and select the direction of the inequality to reflect your linear constraint. Specify the constraining value in the box to the right of the inequality. To add more constraints, click **Add** again.

**Note:** The Add option is disabled if you have already constrained the design region by specifying a Sphere Radius.

**Remove Last Constraint**  Removes the last constraint.

**Check Constraints**  Checks the constraints for consistency. This option removes redundant constraints and conducts feasibility checks. A JMP alert appears if there is a problem. If constraints are equivalent to bounds on the factors, a JMP alert indicates that the bounds in the Factors outline have been updated.
Use Disallowed Combinations Filter

This option uses an adaptation of the Data Filter to facilitate specifying disallowed combinations. For detailed information, see the JMP Reports chapter in *Using JMP*.

Select factors from the Add Filter Factors list and click Add. Then specify the disallowed combinations by using the slider (for continuous factors) or by selecting levels (for categorical factors).

The red triangle options for the Add Filter Factors menu are those found in the Select Columns panel of many platform launch windows. See the Get Started chapter in *Using JMP*.

When you click Add, the Disallowed Combinations control panel shows the selected factors and provides options for further control. Factors are represented as follows, based on their modeling types:

**Continuous Factors**  For a continuous factor, a double-ended slider that spans the range of factor settings appears. You can specify disallowed settings by dragging the slider ends or by setting the endpoints by clicking on the text value under the slider. In the slider, a solid blue highlight represents the disallowed values.

**Categorical Factor**  For a categorical factor, the possible levels are displayed either as labeled blocks or, when the number of levels is large, as list entries. Select a level to disallow it. To select multiple levels, hold the Control key. The block or list entries are highlighted to indicate the levels that have been disallowed. When you add a categorical factor to the Disallowed Combinations panel, the number of levels of the categorical factor is given in parentheses following the factor name.

**Disallowed Combinations Options**

The control panel has the following controls:

- **Clear**  Clears all disallowed factor level settings that you have specified. This does not clear the selected factors.

- **Start Over**  Removes all selected factors and returns you to the initial list of factors.

- **AND**  Opens the Add Filter Factors list. Selected factors become an AND group. Any combination of factor levels specified within an AND group is disallowed.

  To add a factor to an AND group later on, click the group’s outline to see a highlighted rectangle. Select AND and add the factor.

  To remove a single factor, select **Delete** from its red triangle menu.

- **OR**  Opens the Add Filter Factors list. Selected factors become a separate AND group. For AND groups separated by OR, a combination is disallowed if it is specified in at least one AND group.
Red Triangle Options for Factors

A factor can appear in several OR groups. An occurrence of the factor in a specific OR group is referred to as an instance of the factor.

Delete  Removes the selected instance of the factor from the Disallowed Combinations panel.

Clear Selection  Clears any selection for that instance of the factor.

Invert Selection  Deselects the selected values and selects the values not previously selected for that instance of the factor.

Display Options  Available only for categorical factors. Changes the appearance of the display. Options include showing each level as a block, list, or single category, or adding a check box next to each value.

Find  Available only for categorical factors. Provides a text box beneath the factor name where you can enter a search string for levels of the factor. Press the Enter key or click outside the text box to perform the search. Once Find is selected, Find options appear in the red triangle menu, such as Does not contain, Match Case, Starts with or Ends with, or Clear Find.

Use Disallowed Combinations Script

Use this option to disallow particular combinations of factor levels using a JSL script. This option can be used with continuous factors or mixed continuous and categorical factors.

This option opens a script window where you insert a script that identifies the combinations that you want to disallow. The script must evaluate as a Boolean expression. When the expression evaluates as true, the specified combination is disallowed.

When forming the expression for a categorical factor, use the ordinal value of the level or the name of the level. If a factor’s levels are high, medium, and low, specified in that order in the Factors outline, their associated ordinal values are 1, 2, and 3. For example, suppose that you have two continuous factors, X1 and X2, and a categorical factor X3 with three levels: L1, L2, and L3, in order. You want to disallow levels where the following is true:

\[ e^{X_1} + 2X_2 < 0 \text{ and } X_3 = L2 \]

Enter the expression \((\text{Exp}(X1) + 2^*X2 < 0) \& (X3 == 2)\) into the script window.
Figure 21.5  Expression in Script Editor

(In the figure, unnecessary parentheses were removed by parsing.) Notice that functions can be entered as part of the Boolean expression. The expression 
\((\text{Exp}(X_1) + 2*X_2 < 0) \& (X_3 == \text{"L2"})\) is also valid.

Space Filling Design Methods

The following methods for constructing space-filling designs are available:

- “Sphere-Packing Designs” on page 623
- “Latin Hypercube Designs” on page 626
- “Uniform Designs” on page 630
- “Minimum Potential Designs” on page 633
- “Maximum Entropy Designs” on page 636
- “Gaussian Process IMSE Optimal Designs” on page 637
- “Fast Flexible Filling Designs” on page 639

Design

The Design outline shows the runs for the space-filling design.

Design Diagnostics

The Design Diagnostics outline shows the values for the space filling design factors scaled from zero to one. The Minimum Distance is based on these scaled values and is the minimum distance from each point to its nearest neighbor. The row number for the nearest neighbor is given in the Nearest Point column. The discrepancy value shown below the table is the integrated difference between the design points based and a uniform distribution.

The MaxPro (maximum projection) criterion is provided for the full design as well as for each level of categorical variables when used. Smaller values are better. For more information about the MaxPro criteria see “MaxPro” on page 639.
Note: If for any dimension, two points can have the same value (that is, \( x_{ik} = x_{jk} \)), the MaxPro criterion is undefined. In this case, the Design Diagnostics shows a missing value for MaxPro.

### Design Table

Use the Design Table buttons to finish your Space Filling Design construction.

- **Make Table** Constructs the Space Filling Design data table.
- **Back** Takes you back to where you were before clicking **Make Design**. You can make changes to the previous outlines and regenerate the design.

### Space Filling Design Options

The red triangle menu in the Space Filling Design platform contains these options:

- **Save Responses** Saves the information in the Responses panel to a new data table. You can then quickly load the responses and their associated information into most DOE windows. This option is helpful if you anticipate reusing the responses.

- **Load Responses** Loads responses that you saved using the Save Responses option.

- **Save Factors** Saves the information in the Factors panel to a new data table. Each factor’s column contains its levels. Other information is stored as column properties. You can then quickly load the factors and their associated information into most DOE windows.

  **Note:** It is possible to create a factors table by entering data into an empty table, but remember to assign each column an appropriate Design Role. Do this by right-clicking on the column name in the data grid and selecting **Column Properties > Design Role**. In the Design Role area, select the appropriate role.

- **Load Factors** Loads factors that you saved using the Save Factors option.

- **Save Constraints** (Unavailable for some platforms) Saves factor constraints that you defined in the Define Factor Constraints or Linear Constraints outline into a data table, with a column for each constraint. You can then quickly load the constraints into most DOE windows.

  In the constraint table, the first rows contain the coefficients for each factor. The last row contains the inequality bound. Each constraint’s column contains a column property called `ConstraintState` that identifies the constraint as a “less than” or a “greater than” constraint. See “`ConstraintState`” on page 818 in the “Column Properties” appendix.
Load Constraints  (Unavailable for some platforms) Loads factor constraints that you saved using the Save Constraints option.

Set Random Seed  Sets the random seed that JMP uses to control actions that have a random component. These actions include one or more of the following:

-  initializing search algorithms for design generation
-  randomizing Run Order for design construction
-  selecting a starting design for designs based on random starts

To reproduce a design, enter the random seed that generated the design before clicking Make Design.

Note: The random seed associated with a design is included in the DOE Dialog script that is saved to the design data table.

Simulate Responses  Adds response values and a column containing a simulation formula to the design table. Select this option before you click Make Table.

When you click Make Table, the following occur:

-  A set of simulated response values is added to each response column.
-  For each response, a new column that contains a simulation model formula is added to the design table. The formula and values are based on the model that is specified in the design window.
-  A Model window appears where you can set the values of coefficients for model effects and specify one of three distributions: Normal, Binomial, or Poisson.

Note: Not all distributions are available for all design types.

-  A script called DOE Simulate is saved to the design table. This script reopens the Model window, enabling you to re-simulate values or to make changes to the simulated response distribution.

Make selections in the Model window to control the distribution of simulated response values. When you click Apply, a formula for the simulated response values is saved in a new column called \(<Y>\) Simulated, where \(Y\) is the name of the response. Clicking Apply again updates the formula and values in \(<Y>\) Simulated.

For additional details, see “Simulate Responses” on page 112 in the “Custom Designs” chapter.

Note: You can use Simulate Responses to conduct simulation analyses using the JMP Pro Simulate feature. For more information and DOE examples, see the Simulate chapter in Basic Analysis.
**FFF Optimality Criterion**  For the Fast Flexible Filling design method, enables you to select between the MaxPro criterion (the default) and the Centroid criterion. See “FFF Optimality Criterion” on page 639.

**Number of Starts**  Specifies the number of times that the algorithm for the chosen design type initiates to construct a new design. The best design, based on the criterion for the given design type, is returned. Set to 1 by default for all design types. Not used for Fast Flexible Filling Designs.

**Advanced Options > Set Average Cluster Size**  For the Fast Flexible Filling design method, enables you to specify the average number of randomly generated points used to define each cluster or, equivalently, each design point.

**Advanced Options > MaxPro Categorical Weight**  For the Fast Flexible Filling design method, enables you to specify the weight used for categorical factors in the MaxPro calculation. Points that have the same categorical level are multiplied by the weight. This provides better space-filling properties at the sub-design for each level of a categorical factor.

**Save Script to Script Window**  Creates the script for the design that you specified in the Space Filling Design platform and saves it in an open script window.

---

**Sphere-Packing Designs**

The Sphere-Packing design method maximizes the minimum distance between pairs of design points. The effect of this maximization is to spread the points out as much as possible inside the design region.

- “Creating a Sphere-Packing Design”
- “Visualizing the Sphere-Packing Design”

**Creating a Sphere-Packing Design**

To create a sphere-packing design follow these steps:

1. Select **DOE > Special Purpose > Space Filling Design**.
2. Enter responses and factors.
   
   See “Responses” on page 612.
3. Alter the factor level values, if necessary. For example, Figure 21.6 shows the two existing factors, X1 and X2, with values that range from 0 to 1 (instead of the default –1 to 1).
4. Click **Continue**.

5. In the design specification dialog, specify a sample size *(Number of Runs)*. Figure 21.7 shows a sample size of eight.

6. Click **Sphere Packing**.

   JMP creates the design and displays the design runs and the design diagnostics. Figure 21.8 shows the Design Diagnostics panel with 0.518 as the **Minimum Distance**. Your results might differ slightly from the ones below, but the minimum distance is the same. The MaxPro statistic is undefined for Sphere Packing as points can have identical values for one dimension.
7. Click **Make Table**. Use this table to complete the visualization example, described next.

### Visualizing the Sphere-Packing Design

To visualize the sphere-packing design use the sphere-packing design table to create a plot with Graph Builder:

1. Select **Graph > Graph Builder**.
2. Specify X1 as X and X2 as Y.
3. Click the smoother icon to remove the smoother (blue line) from your graph.
4. Adjust the frame size so that the frame is square by right-clicking the plot and selecting **Graph > Size/Scale > Size to Isometric**.
5. Right-click the plot and select **Customize**. When the Customize panel appears, click the plus sign to see a text edit area and enter the following script:
   
   For Each Row(Circle({:X1, :X2}, 0.518/2))
   
   where 0.518 is the minimum distance number that you noted in the Design Diagnostics panel. This script draws a circle centered at each design point with radius 0.259 (half the diameter, 0.518), as shown on the left in Figure 21.9. This plot shows the efficient way JMP packs the design points.

6. Now repeat the procedure exactly as described in the previous section, but with a sample size of 10 instead of eight.

   Remember to change 0.518 in the graphics script to the minimum distance produced by 10 runs. When the plot appears, again set the frame size and create a graphics script using the minimum distance from the diagnostic report as the diameter for the circle. You should see a graph similar to the one on the right in Figure 21.9. Note the irregular nature of the sphere packing. In fact, you can repeat the process a third time to get a slightly different picture because the arrangement is dependent on the random starting point.
Latin Hypercube Designs

In a Latin Hypercube, each factor has as many levels as there are runs in the design. The levels are spaced evenly from the lower bound to the upper bound of the factor. Like the sphere-packing method, the Latin Hypercube method chooses points to maximize the minimum distance between design points, but with a constraint. The constraint maintains the even spacing between factor levels.

- “Creating a Latin Hypercube Design”
- “Visualizing the Latin Hypercube Design”

Creating a Latin Hypercube Design

To create a Latin hypercube design follow these steps:

1. Select **DOE > Special Purpose > Space Filling Design**.
2. Enter responses, if necessary, and factors.
   
   See “Responses” on page 612.
3. Alter the factor level values, if necessary. Figure 21.10 shows adding four factors and changing their values to 1 and 8 instead of the default –1 and 1.
4. Click **Continue**.

5. In the design specification dialog, specify a sample size (**Number of Runs**). This example uses a sample size of eight.

6. Click **Latin Hypercube** (Figure 21.7). Factor settings and design diagnostics results appear similar to those in Figure 21.11, which shows the Latin Hypercube design with four factors and eight runs.

**Note:** The purpose of this example is to show that each column (factor) is assigned each level only once, and each column is a different permutation of the levels.
Visualizing the Latin Hypercube Design

To visualize the nature of the Latin Hypercube technique, create a plot with Graph Builder:

1. Create another Latin Hypercube design using two factors.
2. Select DOE > Special Purpose > Space Filling Design.
3. Enter two factors and be sure to change the factor values so that they are 0 and 1 instead of the default –1 and 1.
4. Click Continue.
5. Specify a sample size of eight (Number of Runs).
6. Click Latin Hypercube.
Figure 21.12 Latin Hypercube Design with Two Factors and Eight Runs

7. Click **Make Table**.

8. Select **Graph > Graph Builder**.

9. Specify X1 as X and X2 as Y.

10. Click the smoother icon to remove the smoother (blue line) from your graph.

11. Right-click the plot and select **Graph > Size/Scale > Size to Isometric** to adjust the frame size so that the frame is square.

12. Right-click the plot, select **Customize** from the menu. In the Customize panel, click the large plus sign to see a text edit area, and enter the following script:

   For Each Row(Circle({:X1, :X2}, 0.404/2))

   where 0.404 is the minimum distance number that you noted in the Design Diagnostics panel (Figure 21.12). This script draws a circle centered at each design point with radius 0.202 (half the diameter, 0.404), as shown on the left in Figure 21.13. This plot shows the efficient way JMP packs the design points.

13. Repeat the above procedure exactly, but with 10 runs instead of eight (step 5). Remember to change 0.404 in the graphics script to the minimum distance produced by 10 runs.

You should see a graph similar to the one on the right in Figure 21.13. Note the irregular nature of the sphere packing. In fact, you can repeat the process to get a slightly different picture because the arrangement is dependent on the random starting point.
Figure 21.13 Comparison of Latin Hypercube Designs with Eight Runs (left) and 10 Runs (right)

Note that the minimum distance between each pair of points in the Latin Hypercube design is smaller than that for the Sphere-Packing design. This is because the Latin Hypercube design constrains the levels of each factor to be evenly spaced. The Sphere-Packing design maximizes the minimum distance without any constraints.

**Uniform Designs**

The Uniform design minimizes the discrepancy between the design points (empirical uniform distribution) and a theoretical uniform distribution.

**Note:** These designs are most useful for getting a simple and precise estimate of the integral of an unknown function. The estimate is the average of the observed responses from the experiment.

1. Select **DOE > Special Purpose > Space Filling Design**.
2. Enter responses, if necessary, and factors.
   
   See “**Responses**” on page 612.
3. Alter the factor level values to 0 and 1.
4. Click **Continue**.
5. In the design specification dialog, specify a sample size. This example uses a sample size of eight (**Number of Runs**).
6. Click the **Uniform** button. JMP creates this design and displays the design runs and the design diagnostics as shown in Figure 21.14.

**Note:** The emphasis of the Uniform design method is not to spread out the points. The minimum distances in Figure 21.14 vary substantially.

**Figure 21.14** Factor Settings and Diagnostics for Uniform Space-Filling Designs with Eight Runs

7. Click **Make Table**.

A Uniform design does not guarantee even spacing of the factor levels. However, increasing the number of runs and running a distribution on each factor (use **Analyze > Distribution**) shows flat histograms.
Comparing Sphere-Packing, Latin Hypercube, and Uniform Methods

To compare space-filling design methods, create the **Sphere Packing**, **Latin Hypercube**, and **Uniform** designs, as shown in the previous examples. The Design Diagnostics tables show the values for the factors scaled from zero to one. The minimum distance is based on these scaled values and is the minimum distance from each point to its closest neighbor. The discrepancy value is the integrated difference between the design points and the uniform distribution.

Figure 21.16 shows a comparison of the design diagnostics for three eight-run space-filling designs. Note that the discrepancy for the Uniform design is the smallest (best). The discrepancy for the Sphere-Packing design is the largest (worst). The discrepancy for the Latin Hypercube takes an intermediate value that is closer to the optimal value. The MaxPro criteria is smaller for the Latin Hypercube design as compared to the Uniform Design.

Also note that the minimum distance between pairs of points is largest (best) for the Sphere-Packing method. The Uniform design has pairs of points that are only about half as far apart. The Latin Hypercube design behaves more like the Sphere-Packing design in spreading the points out.

For both spread and discrepancy, the Latin Hypercube design represents a healthy compromise solution.
Another point of comparison is the time it takes to compute a design. The Uniform design method requires the most time to compute. Also, the time to compute the design increases rapidly with the number of runs. For comparable problems, all the space-filling design methods take longer to compute than the $D$-optimal designs in the Custom Designer.

**Minimum Potential Designs**

The Minimum Potential design spreads points out inside a sphere. To understand how this design is created, imagine the points as electrons with springs attached to every other point, as illustrated in Figure 21.17. The coulomb force pushes the points apart, but the springs pull them together. The design is the spacing of points that minimizes the potential energy of the system.
Minimum Potential designs:

- have spherical symmetry
- are nearly orthogonal
- have uniform spacing

To construct a Minimum Potential example design:

1. Select **DOE > Special Purpose > Space Filling Design**.
2. Add 3 continuous factor.
   
   See “Factors” on page 614.
3. Alter the factor level values to 0 and 1.
4. Click **Continue**.
5. In the design specification dialog (shown on the left in Figure 21.18), enter a sample size (**Number of Runs**). This example uses a sample size of 12.
6. Click the **Minimum Potential** button. JMP creates this design and displays the design runs and the design diagnostics (shown on the right in Figure 21.18).

**Figure 21.18** Space-Filling Methods and Design Diagnostics for Minimum Potential Design
7. Click **Make Table**.

You can see the spherical symmetry of the Minimum Potential design using the Scatterplot 3D graphics platform.

1. After you make the JMP design table, choose the **Graph > Scatterplot 3D** command.

2. In the Scatterplot 3D launch dialog, select \(X_1\), \(X_2\), and \(X_3\) as **Y, Columns** and click **OK** to see the initial three-dimensional scatterplot of the design points.

3. To see the results similar to those in Figure 21.19:
   - Click the Scatterplot 3D red triangle and select the **Normal Contour Ellipsoids**.
   - Right-click the plot and select **Settings**, and then increase the marker size using the **Marker Size** slider.

Now the even spread of the points on the surface of the ellipsoid can be visualized.

**Figure 21.19** Minimum Potential Design Points on Sphere
Maximum Entropy Designs

The Maximum Entropy design is an alternative to the Latin Hypercube design for computer experiments. The Latin Hypercube design is a popular design to use along with a Gaussian-Process model. Computer simulation experts like to use the Latin Hypercube design because all projections onto the coordinate axes are uniform.

However, as the example in Figure 21.20 shows, the Latin Hypercube design might not provide you with optimal space filling properties. This example is a two-factor 16 run Latin Hypercube with factor level settings set between -1 and 1. The plot of the two factors shows that this design has regions that are missing coverage. In particular, there is poor coverage for X1 near 0 and X2 near -1.

**Figure 21.20** Two-factor Latin Hypercube Design

The Maximum Entropy design optimizes a measure of the amount of information contained in an experiment. See the technical note below. With the factor levels set between -1 and 1, the two-factor Maximum Entropy design shown in Figure 21.21 covers the region better than the Latin hypercube design in Figure 21.20. The space-filling property of the design improves as the number of runs increases.
Technical Maximum Entropy designs maximize the Shannon information (Shewry and Wynn (1987)) of an experiment, assuming that the data come from a normal \((m, s^2 R)\) distribution, where

\[
R_{ij} = \exp\left(-\sum_k \theta_k (x_{ik} - x_{jk})^2\right)
\]

is the correlation of response values at two different design points, \(x_i\) and \(x_j\). Computationally, these designs maximize \(|R|\), the determinant of the correlation matrix of the sample. If \(x_i\) and \(x_j\) are far apart, then \(R_{ij}\) approaches zero. If \(x_i\) and \(x_j\) are close together, then \(R_{ij}\) is near one.

**Gaussian Process IMSE Optimal Designs**

The Gaussian process IMSE optimal design method constructs designs that are suitable for Gaussian process models. Gaussian process models fit a wide variety of surfaces. Gaussian process IMSE optimal designs minimize the integrated mean squared error of the Gaussian process model over the experimental region. The Gaussian process IMSE optimal design method uses a correlation structure similar to that of the kriging model. See Jones and Johnson (2009).
Covariance Parameter Vector

In a Gaussian Process IMSE Optimal Design formulation of the Gaussian process model, the covariance parameter vector determines the correlation structure. There is a Theta for each factor. A theta equal to 0 corresponds to a correlation of 1, causing the fitted surface to be flat in the corresponding factor’s direction. As theta increases, the correlation decreases, allowing the surface to be flexible in the factor’s direction.

In the Covariance Parameter Vector outline, in the list of values under Thetas, you can enter values that reflect your prior knowledge of the surface.

Comparison of Gaussian Process IMSE Optional Design with Latin Hypercube Design

Gaussian process IMSE optimal designs are alternatives to the Latin Hypercube design. You can compare the IMSE optimal design to the Latin Hypercube (shown previously in Figure 21.20). The table and overlay plot in Figure 21.22 show a Gaussian IMSE optimal design. You can see that the design provides uniform coverage of the factor region.

Figure 21.22 Comparison of Two-factor Latin Hypercube and Gaussian IMSE Optimal Designs

Note: Both the Maximum Entropy design and the Gaussian Process IMSE Optimal design were created using 100 random starts.
Fast Flexible Filling Designs

The algorithms for Fast Flexible Filling designs begin by generating a large number of random points within the specified design region. These points are then clustered using a Fast Ward algorithm into a number of clusters that equals the Number of Runs that you specified.

The final design points can be obtained by using the default MaxPro (maximum projection) optimality criterion or by selecting the Centroid criterion.

**Note:** If you have Categorical factors or factor constraints, then Fast Flexible Filling is the only space filling design Method available.

### FFF Optimality Criterion

The Space Filling Design red triangle menu contains optimality criteria under FFF Optimality Criterion.

**MaxPro** For \( p \) factors and \( n \) equal to the specified Number of Runs, the MaxPro criterion strives to find points in the clusters that minimize the following criterion:

\[
C_{MaxPro} = \sum_{i}^{n-1} \sum_{j=i+1}^{n} \left[ \prod_{k=1}^{p} (x_{ik} - x_{jk})^2 \right]^{1/2}
\]

The MaxPro criterion maximizes the product of the distances between potential design points in a way that involves all factors. This supports the goal of providing good space-filling properties on projections of factors. See Joseph et al. (2015). The Max Pro option is the default.

**Centroid** This method places a design point at the centroid of each cluster. It has the property that the average distance from an arbitrary point in the design space to its closest neighboring design point is smaller than for other designs.

**Note:** You can set a preference to always use a given optimality criterion. Select File > Preferences > Platforms > DOE. Select **FFF Optimality Criterion** and select your preferred criterion.
Categorical Factors

When you have categorical factors, the algorithm proceeds as follows:

- The total number of design points is balanced across the total number of combinations of levels of the categorical factors. Suppose that there are \( m \) combinations of levels and that \( k \) design points are allocated to each of these.
- A large number of points within the design space defined by the continuous variables is generated. These are grouped into \( k \) primary clusters.
- Each of the \( k \) primary clusters of points is further clustered into \( m \) sub-clusters.
- Within each primary cluster, a design point is calculated for each of the \( m \) sub-clusters using the specified FFF optimality criterion.
- For each of the \( k \) primary clusters, one of the \( m \) combinations of levels is randomly assigned to each of the \( m \) sub-cluster design points. This yields a total of \( km \) design points.
- For each of the \( k \) primary clusters, a design point is chosen for each of the \( m \) combinations of levels according to the MaxPro criterion, where points having the same level of a categorical factor are multiplied by the MaxPro Categorical Weight. (For a description of MaxPro Categorical Weight, see “Space Filling Design Options” on page 621.) This process continues through all \( k \) primary clusters 10 times, or until no improvement is found by changing the given design points.

Set Average Cluster Size for FFF Designs

The Set Average Cluster Size option enables you to specify the average number of randomly-generated points used to define each cluster or, equivalently, each design point. The option is found under Advanced Options in the Space Filling Design red triangle menu.

By default, if the Number of Runs is set to 200 or less, a total of 10,000 randomly generated points are used as the basis for the clustering algorithm. When the number of Runs exceeds 200, a default value of 50 is used. Increasing this value can be particularly useful in designs with a large number of factors or where disallowed combinations restrict the distribution of points used in the clustering algorithm.

Note: Depending on the number of factors and the specified value for Number of Runs, you might want to increase the average number of initial points per design point by selecting Advanced Options > Set Average Cluster Size.
Constraints

Once you complete the Factors outline, click **Continue**. The Define Factor Constraints outline appears. Use this outline to restrict the design region. For more information about the outline, see “Define Factor Constraints” on page 616.

You can use the Use Disallowed Combinations Filter and Use Disallowed Combinations Script options to specify disallowed factor level combinations. Or, you can use the Specify Linear Constraints option to specify bounds in terms of linear inequalities. However, the design is generated differently for these two methods.

**Use Disallowed Combinations Filter and Use Disallowed Combinations Script**

When disallowed combinations are specified, the random points that form the basis for the clustering algorithm are randomly distributed within the unconstrained design region. Then disallowed points are removed and clustering proceeds with the remaining points.

**Note:** Depending on the nature of the constraints and the specified Number of Runs, the default coverage of the unconstrained design space by the initial randomly generated points might not be sufficient to produce the required Number of Runs. In this case, you might obtain a JMP Alert indicating that the algorithm “Could not find sufficient number of points.” To increase the initial number of points that form the basis for the clustering algorithm, specify a larger average number of initial points per design point by selecting **Advanced Options > Set Average Cluster Size.** (See “Set Average Cluster Size for FFF Designs” on page 640).

**Specify Linear Constraints**

When you use the **Specify Linear Constraints** option, the random points that form the basis for the clustering algorithm are randomly distributed within the constrained design region. The clustering algorithm uses these points.

Creating and Viewing a Constrained Fast Flexible Filling Design

This example creates and views a constrained fast flexible filling design.

**Constructing the Design**

1. Select **DOE > Special Purpose > Space Filling Design.**
2. Add 2 continuous factors.
3. Alter the factor level values to 0 and 1 and click **Continue.**
4. In the Define Factor Constraints outline, select **Specify Linear Constraints.**
Notice that Fast Flexible Filling is the only available Space Filling Design Method.

5. Select **Add**.

6. Enter the following coefficients and bound:
   
   1 for X1
   1 for X2
   0.8 for the bound

**Figure 21.23** Linear Constraint

![Define Factor Constraints](image)

7. Type 200 next to **Number of Runs**.

8. Select **Fast Flexible Filling**.

   JMP creates a design that satisfies the constraints. Open the Design outline to view the design.

9. Select **Make Table** to construct the data table.

**Constructing the Plot**

1. With the data table active, select **Graph > Graph Builder**.

2. Drag X1 to the drop zone labeled X.

3. Drag X2 to the drop zone labeled Y.

4. Remove the **Smoother** by clicking the smoother icon.

5. Click the Graph Builder red triangle and click **Show Control Panel** to deselect it.

You should see a graph similar to the one in Figure 21.24. Note that the points satisfy the linear constraint $X1 + X2 \leq 0.8$. 

Creating a Space-Filling Design for a Map Shape

A fast flexible filling (FFF) design can be used to design an experiment to be executed across a region such as a map shape. For example, if you had two sample collection methods (perhaps for air or soil samples) that you wanted to compare at locations spread throughout a US state, consider a FFF design.

Supposed the US state of interest is Georgia. You want 40 samples, 20 for each sampling method, spread throughout the state. To create a FFF design for a map shape, you need a file with the latitude and longitude of the map boundaries (see “Background Maps” on page 267 in the “Maps” chapter).

In the following example, you determine the longitude and latitude for the US state of Georgia, define the shape of the state, then create the design. The design will provide the location and the sampling method for each of your 40 samples.

Find Longitude and Latitude for Georgia

1. Navigate to the Maps directory, usually found here:
   - Windows: C:/Program Files/SAS/JMP/<Version>/Maps
   - macOS: /Library/Application Support/JMP/<Version>/Maps
   Notice that in US-State-Name.jmp, Shape ID 11 corresponds to the US state of Georgia. In this example, that is the state of interest.

3. In US-State-XY.jmp, select Rows > Row Selection > Select Where...

4. Select Shape ID and enter 11 in the text box, then click OK.
   This selects all rows with a Shape ID of 11, representing Georgia.

5. Select Tables > Subset and click OK to obtain a subset of the US-State-XY.jmp table of the latitudes and longitudes data for the state of Georgia (the selected rows).

**Get the Range of Values**

To define the space for the space filling design, you need to know the range of values for the latitude and longitudes in Georgia. Then, you can create design factors with these values.

1. Select File > New > Script. In the script window, right-click and select Show Embedded Log.

2. Copy the following and paste it into the new script:
   ```
   dt = current data table();
   mymap = dt << get as matrix({X,Y});
   xx = mymap[0,1];
   yy = mymap[0,2];
   show(min(xx), max(xx));
   show(min(yy), max(yy));
   show(xx,yy);
   ```

3. With the subset of the US-State-XY.jmp table active, run the script.
   The range of values for the latitudes and longitudes in Georgia and the xx and yy matrices appear in the log.
Add Factors

1. Select **DOE > Special Purpose > Space Filling Design**.

2. Add two continuous factors to the design. Enter 2 in the **Add N Factors** text box and click **Continuous**.

3. Rename the factors longitude and latitude and enter their min and max values in the **Factor outline**:
   - For longitude, enter -85.6 and -80.9 as the values. These are the min and max longitude values from the log for $x$.
   - For latitude, enter 30.4 and 35.0 as the values. These are the min and max latitude values from the log for $y$.

4. Add a categorical factor. Click **Categorical > 2 Level**. Rename the factor **Method**.

**Figure 21.26** Factors

<table>
<thead>
<tr>
<th>Name</th>
<th>Role</th>
<th>Values</th>
</tr>
</thead>
<tbody>
<tr>
<td>Long</td>

<td>35.0</td>
</tr>
<tr>
<td></td>
<td></td>
<td>1</td>
</tr>
<tr>
<td></td>
<td></td>
<td>2</td>
</tr>
</tbody>
</table>

5. Click **Continue**.
Define the Shape

To further define the space for the space filling design, you need to define the shape of the state using a polygon.

1. Select **Use Disallowed Combinations Script** to open the Disallowed Combinations Expression text box.

   The ranges of longitude and latitude define a square. The state of Georgia is a polygon, not a square. You want to disallow points that fall outside of the state of Georgia polygon.

2. Go to your script window and copy the `xx` and `yy` matrices from your script log. Paste this into the Disallowed Combinations Expression text box.

3. At the end, add the following line:
   
   ```
   !In Polygon(longitude, latitude, xx, yy);
   ```

   This excludes points that are not in the polygon defined by the `xx` and `yy` coordinates.

Figure 21.27 Disallowed Combinations Expression

Make the Design

1. Change the **Number of Runs** to 40 and click **Fast Flexible Filling**.

2. Click **Make Table**.

3. From your design table, select **Graph > Graph Builder**.

4. Drag these columns into these zones:
   - longitude to the **X** zone
   - latitude to the **Y** zone
   - Method to the **Color** zone
5. Above the graph, click the Smoother element icon to turn it off.
6. To add the state shape, right-click the graph and select **Graph > Background Map**.
7. Under **Boundaries**, select **US States** and click **OK**.

**Figure 21.28** Example of FFF Design for the US State of Georgia

![Latitude vs. Longitude Graph](image)

**Note:** The exact location of the points on your map may differ from the one shown due to the random starting point for the FFF algorithm.

The map identifies the 40 locations where you should collect your samples. The sampling method (L1 or L2) is indicated by the color of the points.

The **Graph > Background Map** window has these additional options:
- To determine the counties for your testing, under **Boundaries**, select **US Counties**.
- To map your testing locations at the street level, under **Images**, select **Street Map Service**.
Example of a Sphere-Packing Design

Worley (1987) presented a model of the flow of water through a borehole that is drilled from the ground surface through two aquifers. The response variable $y$ is the flow rate through the borehole in m$^3$/year and is determined by the following equation:

$$y = \frac{2\pi T_u (H_u - H_l)}{\ln(r/r_w) \left(1 + \frac{2LT_u}{\ln(r/r_w)r_w^2K_w} + \frac{T_u}{T_l}\right)}$$

There are eight factors in this model:

- $r_w = \text{radius of borehole, 0.05 to 0.15 m}$
- $r = \text{radius of influence, 100 to 50,000 m}$
- $T_u = \text{transmissivity of upper aquifer, 63,070 to 115,600 m}^2/\text{year}$
- $H_u = \text{potentiometric head of upper aquifer, 990 to 1100 m}$
- $T_l = \text{transmissivity of lower aquifer, 63.1 to 116 m}^2/\text{year}$
- $H_l = \text{potentiometric head of lower aquifer, 700 to 820 m}$
- $L = \text{length of borehole, 1120 to 1680 m}$
- $K_w = \text{hydraulic conductivity of borehole, 9855 to 12,045 m/year}$

You can use a sphere-packing design to obtain a set of conditions for which to calculate the response $y$. Then you can build a model to estimate the true model over the range of inputs used in your design. Evaluation of your estimated model can help you understand the impact of each of the eight factors on the response.

Create the Sphere-Packing Design for the Borehole Data

To create a sphere-packing design for the borehole model, you can use a data table of saved factor settings.

1. Select Help > Sample Data Library and open Design Experiment/Borehole Factors.jmp
2. Select DOE > Special Purpose > Space Filling Design
3. Click the Space Filling Design red triangle and select Load Factors.
Figure 21.29 Factors Panel with Factor Values Loaded for Borehole Example

</table>

**Note:** The logarithm of $r$ and $r_{w}$ are used as factors.

4. Click **Continue**.

5. Set the Number of Runs to 32 and press Enter.

6. Click **Sphere Packing** to produce the design.

7. Click **Make Table** to make a table showing the design settings for the experiment.

**Note:** The design table includes a Model table script. This script runs a Gaussian Process model for the response $y$.

8. (Optional) To see a completed data table for this example, select **Help > Sample Data Library** and open **Design Experiment/ Borehole Sphere Packing.jmp**.

   Because the designs are generated from a random seed, the settings that you obtain can differ from those shown in the completed table.

**Guidelines for the Analysis of Deterministic Data**

It is important to remember that deterministic data have no random component. The same input values generate the same output. As a result, $p$-values from fitted statistical models do not have their usual meanings. A large $F$ statistic (low $p$-value) is an indication of an effect due to a model term. However, you cannot construct valid confidence intervals for effects or model predictions.

Residuals from a model fit to deterministic data are not a measure of noise. Instead, residuals are a measure of the model bias. Bias is the difference between the true value and the predicted value. Distinct patterns in the residuals indicate that additional terms should be considered for the model in order to reduce bias.
Analysis of the Borehole Sphere-Packing Design

Often, the true model is not available in a simple analytical form. As a result, the prediction bias is known only at observed data points. However, in this example, the functional form of the true model is known. In the Borehole Sphere Packing.jmp data table, the true model column contains the formula of the known function. This formula enables you to profile the prediction bias over the factor input region.

1. Select Help > Sample Data Library and open Design Experiment/Borehole Sphere Packing.jmp.
2. Click the green triangle next to the Model (GP from DOE) script.
   Use the Gaussian Process Model report to explore the relationships between the factors and the outcome Y.
3. Click the red triangle next to Gaussian Process Model of Y and select Save Prediction Formula.
4. Go back to the Borehole Sphere Packing.jmp data table.
5. In the data grid, select the column headings for true model and Y Prediction Formula.
6. Right-click and select New Formula Column > Combine > Difference.
   This creates a new column containing the bias.
7. From the Borehole Sphere Packing.jmp data table, select Graph > Profiler.
8. Select true model-Y Prediction Formula and click Y, Prediction Formula
   This option shows the bias as a function of the eight design factors.

Figure 21.30  Profiler Dialog for Borehole Sphere-Packing Data

10. Click OK.
The profiler defaults to the center of the design region. If there were no bias, all profile traces would be constant between the value ranges of each factor. In this example, the variables logRw, Hu, and Hl show the largest effects on the bias.

**Figure 21.31** Profiler for Bias of the Borehole GP Model with Y Axis Set at -30 to 30

You can use the profiler to explore the range of the prediction bias over the entire domain. To find points of minimum and maximum bias, select *Optimization and Desirability > Desirability Functions* from the Prediction Profiler red triangle menu. See *Profiler*. To evaluate the prediction bias over the design points, select *Analyze > Distribution* to see a distribution analysis.
Keep in mind that, in this example, the true model is known. In many applications, the response at any factor setting is unknown. The prediction bias over the experimental data can underestimate the bias throughout the design domain.
Use the Accelerated Life Test (ALT) Design platform to design plans for accelerated life testing experiments. Product reliability at normal use conditions is often so high that the time required to test the product until it fails is prohibitive. Rather than test the product at normal use conditions, you can test the product under conditions that are more severe than normal use conditions. These severe conditions can cause the product to degrade faster and fail more quickly. You can then use this accelerated failure data to predict product reliability at normal use conditions. You can design initial experiments or augment existing experiments.

Overview of Accelerated Life Test Designs

Use accelerated lift testing when product reliability at normal use conditions is high. You test the product under conditions that are more severe than normal to accelerate the time until failures occur. You use this accelerated failure data to predict product reliability at normal use conditions.

Such a test is called an accelerated life test (ALT). The factors that are set to levels that accelerate the time to failure are called acceleration factors. The models for accelerated life tests are typically nonlinear models. For more information about nonlinear models, see “Nonlinear Models” on page 700 in the “Nonlinear Designs” chapter.

The ALT Design platform creates and evaluates designs for situations involving one or two acceleration factors. You can optimize your design using D-optimality, quantile estimation, or failure probabilities.

Creating an ALT design requires initial estimates of the acceleration model parameters. Use subject matter knowledge to define starting estimates. If you do not have information to inform your starting estimates, you can specify a multivariate normal prior distribution to describe their uncertainty.

You can also use the Accelerated Life Test (ALT) Design platform to augment a current experiment. You might want to augment a current design to decrease the variance of estimates.

Example of an Accelerated Life Test Design

Use the ALT designer to construct a construct a failure probability optimal ALT test. In this example, suppose that you need to design an accelerated life test for a mechanical component. The single acceleration factor is torque, and the normal use stress is 35 Nm (newton meters). You want to estimate the time at which 10% of the units fail at the normal use stress. You.

Your test plan has the following characteristics:

- A total of 100 units are available for testing.
- The life distribution is assumed to be Weibull.
- The life-stress relationship is given by the logarithmic transformation.
- You plan to test torque at three stress levels: 50, 75, and 100 Nm.
- You have prior knowledge to predict initial failure times at the test levels. See “Obtain Prior Estimates” on page 656.
- The test runs for 5,000 cycles.
• You will monitor the process for failures on a continuous basis.

**Obtain Prior Estimates**

To create an accelerated life test design, you must provide prior estimates of the parameters. Here is an approach to obtaining prior estimates:

1. Use your process knowledge to create a table of hypothetical, but likely, failure times at a small number of stress levels.
2. Use the Fit Life by X platform to fit a model and obtain estimates of the model parameters.
3. Use these estimates as your prior values for creating a design using the ALT Design platform.

Following the approach outlined above, you create a data table containing estimates of the number of failure cycles for a balanced design. Your table consists of five units at each of the three stress levels to be used in your design. Your data table is Torque Prior.jmp, found in the Sample Data Library.

1. Select **Help > Sample Data Library** and open Design Experiment/Torque Prior.jmp.
2. Select **Analyze > Reliability and Survival > Fit Life by X**.
3. Select Cycles and click **Y, Time to Event**.
4. Select Torque and click **X**.
5. From the **Relationship** list, select **Log**.
6. Enter 35 for the **Use Condition**. Recall that 35 Nm is the normal use condition.
7. From the **Distribution** list, select **Weibull**.

**Figure 22.2** Fit Life by X Launch Window

- Models life distributions parameterized by a single regression factor.
- Cast Selected Columns into Roles
- Action

- Select Columns
- Censor Code
- Relationship
- Log
- Nested Model Tests
- Use Condition: 35
- Distribution
- Weibull
- Select Confidence Interval Method

![Image of Fit Life by X Launch Window](image-url)
8. Click **OK**.
9. Scroll down to the Weibull Results outline and open the Correlation Matrix outline.

**Figure 22.3** Fit Life by X Model for Prior Data

![Weibull Results](image)

The model for the mean is given in the Estimates outline. The Estimate column contains the parameter estimates for the intercept ($\beta_0$), the linear coefficient ($\beta_1$), and the scale ($\sigma$). The standard errors column contains the standard errors for the estimates. The estimated correlations for the parameter estimates are given in the Correlation Matrix outline. Use these parameter estimates, standard errors, and correlations as your prior values to construct your ALT design.

**Enter Basic Specifications**

To create an accelerated life test design define accelerating factors, use conditions, and test conditions.

1. Select **DOE > Special Purpose > Accelerated Life Test Design**.
   Notice that **One accelerating factor** and **Continuous Monitoring** are selected by default.
2. Click **Continue**.
3. Under **Factor Name**, click X1 and type Torque.
   Notice that the **Number of Levels** is set to 3 by default.
4. Select **Log** under Factor Transformation.
5. Enter 35 for both the **Low Usage Condition** and the **High Usage Condition**.
   Setting both the low and high usage conditions to 35 indicates that 35 is the normal usage condition.
6. Enter 50 for the **Low Test Condition** and 100 for the **High Test Condition**.

**Figure 22.4** Completed ALT Specification Window

7. Click **Continue**.

8. Notice the **Torque Level Values** are set to 50, 75, and 100.

   **Note:** JMP sets the values of the levels evenly spaced between the low and high test conditions. You can change the levels.

9. Ensure that **Weibull** is selected as the **Distribution Choice**.

**Enter Prior Information and Remaining Specifications**

Continue the construction of the example ALT design by entering prior information.

1. Under **Prior Mean**, select **Specify Intercept** and enter the prior acceleration model parameter estimates that you obtained using the Fit Life by X platform with your hypothetical data:
   - Enter 15.88 for **Intercept**.
   - Enter -1.87 for **Power (Torque)**.
   - Enter 0.05 for **1/β** (scale parameter for a Weibull model).

2. Select **Specify prior uncertainty**.

3. Enter the estimated standard errors and correlations from the prior acceleration model. Figure 22.3 shows the completed Prior Uncertainty outline:
Click the Accelerated Life Test Plan red triangle and select **ALT Optimality Criterion > Make Failure Probability Optimal**.

You plan to conduct the test over 5,000 cycles. You are interested in predictions for as many as 10,000 cycles.

4. In the Diagnostic Choices outline, enter 10,000 for both boxes for **Time range of interest**.
5. In the Design Choices outline. Enter 5,000 for **Length of test** and 100 for **Number of units under test**.

**Figure 22.6  Completed Diagnostic and Design Choices Outline**

**Make the Design**

Continue the ALT example by generating the design.

1. Click **Continue**.
The number of runs in a balanced design appears in the Candidate Runs outline. The Parameter Variance for Balanced Design outline shows the covariance matrix for the parameters for this design. The Distribution Profiler also appears. When you obtain the optimal design, you can compare the Parameter Variance and Distribution Profiler results to those for the balanced design to see the reduction in uncertainty.

2. Click **Make Design**.

The optimal experimental design appears, along with other results.

The optimal design is computed based on the levels of the test runs, the total number of units to be tested, and the prior information that you specified. The optimal design consists of testing the specified number of units at each torque level:

- 81 units at 50 Nm
- 0 units at 75 Nm
- 19 units at 100 Nm
Run Simulations

Evaluate the example ALT design with the simulator. Use the simulator to simulate the results of your test plan based on the assumptions used to build the design. This is a way to evaluate if the test plan is sufficient before running the test plan.

1. Enter 100 for the **Number of Simulations**.
2. Enter 0.1 for the **Simulation Probability of Interest**.
3. Enter 35 for the **Simulation Usage for Torque**.
4. Click **Run Simulations** to run 100 simulations of the experiment. This is to check to see whether the 100 units that you plan to test will be sufficient given your prior assumptions for the design.

Figure 22.9 Simulation Results

The simulated model fits shows that the 100 simulations of the model are all similar as they all fall close to the average shown by the red curve. The Y axis is on a log scale.

5. Double-click the Y axis and select **Linear** from the Type menu and click **OK**.

The variability in the simulated fits around the 35 normal usage condition is now easier to view. You expect variability in your estimated of the normal usage condition. The simulation helps you evaluate if your ALT plan is acceptable. If there is too much
variability, you might need to increase the number of units on test or adjust the test conditions.

Save Design

Finally, complete the Example ATL design by making a test plan and saving it to a data table.

1. Click Make Test Plan to save the design to a data table. This table is a summary of the design.
2. Click Make Table to save the design to a data table. This table has 100 rows, one for each test run.

Example of Augmenting an Accelerated Life Test Design

This example shows how to use the Accelerated Life Test Design platform to augment an existing design. In this example, 150 capacitor units were tested across three temperatures (85°C, 105°C, and 125°C Celsius) for 1500 hours. The results are recorded in the Capacitor ALT.jmp sample data table. The resulting model is used to predict the fraction of the population that is failing at 100,000 hours at a normal usage temperature of 25°C Celsius.

Review Current Predictions

1. Select Help > Sample Data Library and open Design Experiment/Capacitor ALT.jmp.
2. Click the green triangle to run the Fit Life by X table script.
3. In the Distribution Profiler, found in the Comparisons outline on the Distribution tab, change the factor settings:
   - Click 105 above Temp and change it to 25.
   - Click 750.5 above Hours and change it to 100,000.
Based on your current study, the predicted fraction of the capacitor population that fails at 25°C at 100,000 hours is 0.003575, with a 95% confidence interval of 0.00056 to 0.02268. You want to estimate the fraction of failures more precisely. To decrease the width of the confidence interval, a measure of the precision of your estimate, you can augment your study with additional tests.

**Augment the Design**

You want to augment your design to obtain a more precise estimate of the predicted fraction of failures. Your original design used temperature settings of 85, 105, and 125. In your augmented design, you want to test at temperature values of 90, 110, and 125. Note that two of these settings are new. Augment the design with optimally selected runs:

1. Select **DOE > Special Purpose > Accelerated Life Test Design**.
2. Select **One accelerating factor**, select **Continuous Monitoring**, and click **Continue**.
3. Enter **Temp** for **Factor Name**.
4. Enter 5 for **Number of Levels**.
   
   Even though your augmented runs span only three levels (90, 110, and 125), you must also specify the levels used in the original experiment for a total of five levels. The Factor Transformation is set to Arrhenius Celsius by default.
5. Enter 25 for both **Low Usage Condition** and **High Usage Condition**.
6. Enter 85 for the **Low Test Condition** and 125 for the **High Test Condition**.
7. Click **Continue**.
8. Enter 85, 90, 105, 110, and 125 for the **Temp Level Values**.

   There are three levels from the original experiment (85, 105, and 125). The augmented design has two new levels (90 and 110) and one of the levels from the first experiment (125).

**Note:** All levels must be listed.
9. Ensure that **Weibull** is selected as the **Distribution Choice**.

10. Under **Prior Mean**, select **Specify Intercept**. Enter your current acceleration model parameter estimates from the Fit Life by X Estimates outline, found in the Weibull Results outline on the Statistics tab.

**Figure 22.11** Parameter Estimates and Fitted Model from Weibull Results Outline

- Enter -35.200 for **Intercept**.
- Enter 1.389 for **Activation Energy (Temp)**.
  
  This is an estimate of the activation energy and is the coefficient of the inverse temperature, measured in degrees Kelvin, multiplied by Boltzmann’s constant.
- Enter 1.305 for **1/β**.

  For the Weibull distribution, JMP uses a parameterization that depends on a location parameter \( μ \) and scale parameter \( σ \). In terms of the usual \( α \) and \( β \) parameterization, the scale parameter is \( σ = 1/β \). See “**Weibull**” on page 677.

In the Accelerated Life Test Plan window, you can specify uncertainty about your prior means in by selecting the **Specify prior uncertainty** option. In this example, you do not specify prior uncertainty. Your design is created assuming that the values specified in the Prior Means outline are the true parameter values.

11. Under **Design Choices**, enter 1500 for **Length of test**.

  The test is conducted over 1500 hours, which was the length of the original design.

12. Enter 250 for **Number of units under test**.

  The previous experiment tested 150 units, and the augmented experiment tests an additional 100 units, for a total of 250 units.
13. Click **Continue**.

14. Under **Candidate Runs** enter 50 as the minimum number of units for the temperatures of 85, 105, and 125. These represent the runs already completed.

15. Click the Accelerated Life Test Plan red triangle and select **ALT Optimality Criterion > Make Failure Probability Optimal**.

   For more information about this criterion, see “Make Failure Probability Optimal” on page 676.

16. Click **Make Design**.

   The optimal experimental design appears along with other results.

---

**Figure 22.12** Completed Design Details Window

**Figure 22.13** Optimal Design
The optimal design is computed based on the levels of the test runs, the minimum number of units under test, the total number of units to be tested (this is the information in the Candidate Runs outline), and other information that you specified. The optimal design consists of testing the specified number of units at each temperature level:

- 50 units at 85°C. Since the previous experiment already tested 50 units at 85°C, no additional units are needed.
- 58 units at 90°C.
- 50 units at 105°C. Since the previous experiment tested 50 units at 105°C, no additional units are needed.
- 0 units at 110°C. This level is not needed.
- 92 units at 125°C. Since the previous experiment tested 50 units at 125°C, 42 additional units are needed.

**Compare the Augmented Design to the Original Study**

1. In the Distribution Profiler, enter the normal use condition of 25 for Temperature and 100,000 for Time. The estimate of the fraction of the population that is failing is 0.00357, with a 95% confidence interval of 0.00089 to 0.014525. This interval is narrower than the interval from the initial experiment, which was from 0.00056 to 0.02268 (Figure 22.10).

**Figure 22.14  Distribution Profiler for Temp = 25 and Time = 100000**

---

**Build an Accelerated Life Test Design**

Build an accelerated lift test (ALT) design by selecting **DOE > Special Purpose > Accelerated Life Test Design**. The Accelerated Life Test Plan is updated as you work through the design. The steps for building an accelerated life test design follow the flow in Figure 22.15.
Figure 22.15 Accelerated Life Test Plan Flow

This section describes the outlines in the Accelerated Life Test Plan flow.
Specify the Design Structure

Use the Accelerated Life Test Plan outline to define the model structure and the type of inspection for your design.

**Figure 22.16  Initial ALT Design Window**

**Number of accelerating Factors**

- **One accelerating factor**  Select for a design with one factor.
- **Two accelerating factors - main effects model**  Select for a two factor design for a main effects model
- **Two accelerating factors - interaction model**  Select for a two factor design for a model that contains main effects and an interaction term.

**Monitoring Type**

- **Continuous Monitoring**  Select for a design with exact failure times recorded. Failure times beyond the length of the test are right censored.
- **Monitoring at Intervals**  Select for a design with units inspected for failures at intervals. Failure times are interval censored. Enter the number of inspections, the time of the first inspection, and the time between inspections. For inspection intervals that are irregular, you can change the inspection times later in the Design Choices outline.

**Accelerated Life Test Plan**  Specify details about the acceleration factor or factors.

**Specify Acceleration Factors**

Specify details about the acceleration factor or factors.
Figure 22.17 ALT Specification Window

<table>
<thead>
<tr>

</thead>
<tbody>
<tr>
<td>X1</td>
<td>3</td>
<td>Arrhenius Celsius</td>
<td>20</td>
<td>30</td>
<td>90</td>
<td>110</td>
</tr>
</tbody>
</table>

**Factor Name**  Enter a name for each acceleration factor.

**Number of Levels**  For each acceleration factor, enter the number of proposed levels that you want to include in the experiment.

**Factor Transformation**  For each acceleration factor, select a transformation function. This transformation describes the life-stress relationship, which is the manner in which the life distribution changes across stress levels. The transformations available are Arrhenius Celsius, Reciprocal, Log, Square Root, and Linear.

**Low Usage Condition**  For each acceleration factor, enter a lower bound for its value in typical usage conditions.

**High Usage Condition**  For each acceleration factor, enter an upper bound for its value in typical usage conditions.

*Note:* The Low Usage Condition and High Usage Condition values can be equal. Use equal values when the usage condition is a single value.

**Low Test Condition**  For each acceleration factor, enter the low test condition.

**High Test Condition**  For each acceleration factor, enter the high test condition.

*Note:* The low and high test conditions define the endpoints of the acceleration factors in the design. The initial candidate uses equally spaced levels between the low and high test conditions. You can adjust the levels before constructing the design.

**Specify Design Details**

Specify the factor levels, details of the prior distribution, the time range and probability of interest, the length of the test, and the number of units to be tested.
Factors  Enter the levels for the acceleration factors. By default, the levels are evenly spaced between the low and high test conditions.

Distribution Choice  Select a life distribution (LogNormal or Weibull) for each acceleration factor. See “Statistical Details for the ALT Design Platform” on page 676.

Prior Mean  Enter prior estimates of the acceleration model parameters. The prior estimates are hyperparameters in a Bayesian prior distribution. The Prior Mean values can be a best guess based on subject matter knowledge or they can be based on a previous study.

When there is only one acceleration factor, there is a choice to specify the intercept or the quantile.

Specify Intercept  Enter the priors for the model parameters including the intercept.

Specify Quantile  Enter the priors for the acceleration factor, the expected failure proportion at a given time, and value for the acceleration factor. This information is used to calculate the intercept.

Specify prior uncertainty  Select to enter values for the standard error and correlations of the prior distribution for the acceleration model parameters. The standard errors reflect uncertainty relative to the prior estimates of the acceleration model parameters.
Note: When prior uncertainty measures are not specified, the design is created by treating the values entered under Prior Mean as the true parameter values. This design is close to optimal if the prior mean parameters are close to the true values. However, this design is not robust to misspecification of the parameter estimates. If you are unsure about your prior estimates, use the Prior Uncertainty specifications to reflect your uncertainty.

Diagnostic Choices  The choices available depend on the design optimality criteria. The design optimality criteria is found under the Accelerated Life Test Plan red triangle menu. For a D-optimal design there are no diagnostic choices.

Time range of interest  (Available only for a failure probability optimal design.) Specify the time interval over which you want to estimate the fraction of the population that is failing. Enter the lower value in the left box and the upper value in the right box. If you are interested in a specific time point, enter that value in both boxes.

Probability of interest  (Available only for a quantile estimate optimal design.) Specify the failure fraction for which you want an estimate of time. For example, if you want to estimate the time at which 10% of the units fail, then enter 0.10.

Design Choices  Specify values relating to the length of the test, inspection intervals, and the number of units being tested.

Length of test  (Available only for Continuous Monitoring.) Specify the length of time during which units are on test. When you make the design table, record each unit’s failure time or whether it was right censored.

Inspection Times  (Available only for Monitoring at Intervals.) Specify the times at which inspections are conducted. When you make the design table, these times are used to construct Start Time and End Time columns. The number of units failing in each interval is recorded.

Number of units under test  The number of units in the experiment.

- If you are designing an initial experiment, enter the number of units that you plan to test.
- If you are augmenting a previous experiment, enter the number of units tested in the previous experiment plus the number of units for the next experiment.

Review and Update Specifications for ALT Plans

After you specify the accelerated life test plan design details and click Continue, three new outlines are added to the window.
The Parameter Variance for Balanced Design outline gives \((X'X)^{-1}\), where derivatives are calculated numerically. The calculation assumes that the values specified in the Prior Mean outline are the true parameter values.

See “Nonlinear Models” on page 700 in the “Nonlinear Designs” chapter.

**Tip:** Click **Update Profiler** to update the profiler if changes are made to Distribution Choice, Prior Mean, or Design Choices.
Create and Assess the Optimal

Click Make Design to create the optimal ALT design and see results that address the quality of the design.

**Note:** By default, the optimal design is D-optimal. To change the optimality criterion click the Accelerated Life Test Plan red triangle and select **ALT Optimality Criterion**.

**Figure 22.20 Design Outlines**

**Design**  Shows the number of units to be tested at each combination of acceleration levels. For a single factor, the first column gives the levels of the factor. For two factors, the first two columns give the levels of the factors.

**N Units**  The number of units to be tested at each combination of acceleration levels.

**Expected Failures**  Expected number of failures for the design setting. The expected number is computed using the prior model specification.
All Censored Probability  Probability that none of the units tested at the combination of acceleration levels fail. The probability is computed using the prior model specification.

Failure Probability  The expected probability of failure for the design settings. The failure probability is calculated as the expected failures divided by the number of units on test.

Note: The expected failures and censoring probabilities enable you to judge whether your prior specifications are reasonable.

Parameter Variance for Optimal Design  Shows a matrix proportional to the covariance matrix for the estimates of the acceleration model parameters for the optimal design. The calculation assumes that the values specified in the Prior Mean outline are the true parameter values. See “Parameter Variance for Balanced Design” on page 672.

Note: Compare the values in the Parameter Variance for Optimal Design matrix to those in the Parameter Variance for Balanced Design matrix to determine the extent to which the optimal design reduces the variance of estimates.

Optimality Criteria  Values for three optimality criteria are provided:

D Criterion  D-optimality of the design. See “Make D-Optimal Design” on page 675.

Quantile Criterion  Time I-optimality of the design. See “Make Quantile Estimate Optimal” on page 675.

Probability Criterion  Probability I-optimality of the design. See “Make Failure Probability Optimal” on page 676.

R Precision Factor (for a 95% CI)  A profiler to evaluate the impact of sample size, level of the factor(s), and the quantile of interest on the R Precision Factor. The R Precision Factor (for a 95% CI) is a measure of the precision of the 95% CI confidence interval for the quantile of interest.

Simulator  Use the simulator to explore your accelerated model before collecting data.

Number of Simulations  The number of simulation trials to run.

Simulation Probability of Interest  The failure probability of interest.

Simulation Usage  Values for the usage conditions of the acceleration factors.

After clicking Run Simulations, a table of summary statistics and a plot of model fits appear.
Create Design Tables

Use the buttons to make the accelerated lift test design, test plan, and table.

**Make Design**  Updates the optimal design if any changes are made to the Distribution Choice, Prior Mean, Prior Variance Matrix, Design Choices, or Candidate Runs.

**Make Test Plan**  Creates a data table where each row corresponds to a distinct design setting. The table shows the acceleration factor design settings and the number of units to test at those design settings.

**Make Table**  Creates a table that you can use for recording your failure time data.

- For Continuous Monitoring, the table contains a row for each unit to be tested and the design settings for that unit. If a unit fails during the experiment, record the unit’s failure time in the Failure Time column and a 0 in the Censored column. If a unit does not fail during the experiment, record the final inspection time in the Failure Time column and a 1 in the Censored column.

- For Monitoring at Intervals, the table contains a row for each design setting and time interval combination. The time intervals are defined by the Start Time and End Time columns, which are based on the Inspection Times entered in the Design Choices outline. For each setting and time interval, record the number of units that failed in the Number Failing column.

Accelerated Life Test Options

The Accelerated Life Test Plan red triangle menu contains the following options:

**Simulate Responses**  Adds simulated responses to the table when you click **Make Table**. The simulated responses are created by taking random draws from the chosen distribution at the parameter values specified in the Prior Mean outline. If a simulated response exceeds the specified test length, the observation is censored at the test length value.

**ALT Optimality Criterion**

**Make D-Optimal Design**  Creates a Bayesian D-optimal design if the number of Monte Carlo spheres is greater than 0. The optimality criterion is the expectation of the logarithm of the determinant of the information matrix with respect to the prior distribution. If the number of Monte Carlo spheres is 0, then the design is a locally D-optimal design. It follows that D-optimality focuses on precise estimates of the coefficients.

**Make Quantile Estimate Optimal**  Default optimality criteria. Creates a design that minimizes the variance of a specified percentile at the specified usage conditions.
**Make Failure Probability Optimal**  Creates a design that minimizes the variance of the estimate of failure probability over the time range of interest at the specified usage conditions.

**Advanced Options**

**N Monte Carlo Spheres**  Enables you to set the number of nonzero radius values used in the integration. To find a nonlinear design that optimizes a given optimality criterion, JMP minimizes the integral of the log of the determinant of the Fisher information matrix with respect to the prior distribution of the parameters. Such an integral is calculated numerically. For more information about how the integration is performed, see “Nonlinear Design Options” on page 699 in the “Nonlinear Designs” chapter.

**Tip:** By default N Monte Carlo Spheres is set to four. Higher values result in better numerical accuracy but with more computation time.

**Save Script to Script Window**  Creates the script for the design that you specified in the Accelerated Life Test Plan window and places it in an open script window.

---

**Statistical Details for the ALT Design Platform**

**Failure Distributions for ALT Designs**

In the accelerated life test design platform, you can select either a lognormal or Weibull failure distribution.

This section contains the parameterizations for the probability density function (pdf) and cumulative distribution function (cdf) for each distribution. For more information about the Weibull distribution, see Reliability and Survival Methods.

**Lognormal**

Lognormal distributions are used commonly for failure times when the range of the data is several powers of 10. This distribution is often conceptualized as the multiplicative product of many small positive independently and identically distributed random variables. This distribution is appropriate when the logarithms of the data values appear normally distributed. The probability distribution function is usually characterized by strong right-skewness.
The lognormal family is parameterized by a location parameter, $\mu$, and a shape parameter, $\sigma$. The lognormal pdf and cdf are given as follows, where the logarithm is to the base $e$:

$$ f(x;\mu, \sigma) = \frac{1}{x\sigma} \phi_{\text{nor}} \left[ \log(x) - \frac{\mu}{\sigma} \right], \quad x > 0 $$

$$ F(x;\mu, \sigma) = \Phi_{\text{nor}} \left[ \log(x) - \frac{\mu}{\sigma} \right], $$

The functions

$$ \phi_{\text{nor}}(z) = \frac{1}{\sqrt{2\pi}} \exp \left( -\frac{z^2}{2} \right) $$

and

$$ \Phi_{\text{nor}}(z) = \int_{-\infty}^{z} \phi_{\text{nor}}(w) dw $$

are the pdf and cdf, respectively, for the standard normal distribution (N(0,1)).

**Weibull**

The Weibull distribution can be used to model failure time data with either an increasing or a decreasing hazard rate. It is used frequently in reliability analysis because of its tremendous flexibility in modeling many different types of data, based on the values of the shape parameter.

The Weibull pdf and cdf are commonly represented as follows:

$$ f(x;\alpha, \beta) = \frac{\beta}{\alpha} x^{(\beta - 1)} \exp \left[ -\left( \frac{x}{\alpha} \right)^\beta \right]; \quad x > 0, \alpha > 0, \beta > 0 $$

$$ F(x;\alpha, \beta) = 1 - \exp \left[ -\left( \frac{x}{\alpha} \right)^\beta \right] $$

where $\alpha$ is a scale parameter, and $\beta$ is a shape parameter. The Weibull distribution reduces to an exponential distribution when $\beta = 1$.

**Weibull Parameterization**

In JMP, the Weibull parameterization defines $\sigma$ as the scale parameter and $\mu$ as the location parameter. These are related to the $\alpha$ and $\beta$ Weibull parameterization as follows:

$$ \alpha = \exp(\mu) $$
and

$$\beta = \frac{1}{\sigma}$$

With these parameters, the pdf and the cdf of the Weibull distribution are expressed as a log-transformed smallest extreme value distribution (SEV) using a location-scale parameterization with $\mu = \log(\alpha)$ and $\sigma = 1/\beta$:

$$f(x;\mu, \sigma) = \frac{1}{x\sigma} \phi_{\text{sev}}\left[\frac{\log(x) - \mu}{\sigma}\right], \quad x > 0, \sigma > 0$$

$$F(x;\mu, \sigma) = \Phi_{\text{sev}}\left[\frac{\log(x) - \mu}{\sigma}\right]$$

where

$$\phi_{\text{sev}}(z) = \exp[z - \exp(z)]$$

and

$$\Phi_{\text{sev}}(z) = 1 - \exp[-\exp(z)]$$

are the pdf and cdf, respectively, for the standardized smallest extreme value ($\mu = 0, \sigma = 1$) distribution.

**R Precision Factor (for a 95% CI)**

The R precision factor is a measure of the precision of the estimate of $t_p$, the $p_{th}$ quantile of the failure time distribution. An approximate 95% confidence interval for $\log(t_p)$ is:

$$\log(\hat{t}_p) \pm z_{0.975}\sqrt{\text{Var}[\log(\hat{t}_p)]} = \log(t_p) \pm \log(\hat{R})$$

resulting in a confidence interval for $t_p$:

$$[\hat{t}_p/\hat{R}, \hat{t}_p\hat{R}]$$

where

$$\hat{R} = \exp\left[z_{0.975}\sqrt{\text{Var}[\log(\hat{t}_p)]}\right]$$

To obtain R, use the large sample approximation of the variance of the $\log(t_p)$:

$$R = \exp z_{0.975}\sqrt{A\text{Var}[\log(t_p)]}$$
Optimality Criterion for Accelerated Life Tests

Consider an accelerated life test (ALT) to be conducted across at most two acceleration factors $x_1$ and $x_2$ with $J_1$ and $J_2$ levels, respectively. The goal of test planning is to determine the number of samples to allocate to each combination of the factor levels.

The computation of the optimality criterion depends on the overall Fisher information matrix from the individual level-specific information matrices

$$I(\theta) = \sum_{i,j} n_{ij} I_{ij}(\theta)$$

as well as the inclusion of prior uncertainty $S$ where appropriate.

D-optimality

The D-optimal design $D_d$ is the design that minimizes the following expression across all possible values of $n_{ij}$

$$\log \left| \int_{\theta} \left[ S^{-1} + I(\theta) \right]^{-1} \pi(\theta) d\theta \right|$$

where $|\cdot|$ is the determinant operation and $\pi(\theta)$ is the prior distribution over the parameters. This distribution is usually a multivariate normal distribution. The log of the determinant is used for numerical stability.

Quantile Optimality

The quantile optimal design $D_q$ is the design that minimizes the expression:

$$\int_{\theta} [c I(\theta) c] \pi(\theta) d\theta$$

where the vector $c$ depends on the use condition.

For the single use condition

$$c' = \{1, 0, 0, 0, z_p\}$$

where $z_p$ is the $p^{th}$ quantile of the failure distribution.

For the range of use condition let

$$\varepsilon_i = \frac{G(x_{1iUh}) - G(x_{1iUL})}{G(x_{iUH}) - G(x_{iUL})}$$
where $G(\cdot)$ is the antiderivative of $g(\cdot)$, $x_{i,UH}$ is the highest use level considered for the $i^{th}$ factor, $x_{i,UL}$ is the lowest use level considered for the same factor. Then

$$c' = \{1, \varepsilon_1, \varepsilon_2, \varepsilon_1, \varepsilon_2, z_p\}$$

where $z_p$ is the $p^{th}$ quantile of the failure distribution.

**Failure Probability Optimality**

The failure probability optimal design $D_f$ is the design that minimizes the expression:

$$\int \left\{ \frac{1}{\sigma^2 \Phi(z_{UL}(\theta))} \left[ \frac{\phi(z_{UL}(\theta))}{\Phi(z_{UL}(\theta))} \right]^2 \frac{c'_f p I(\theta)c_{fp}}{-\log(\Phi(z_{UL}(\theta)))} \right\} (\pi(\theta) d\theta)$$

where $z_{UL}(\theta)$ is the standardized log-time at use conditions as defined in Quantile Optimality. $c_{fp}$ is similar to $c$ as defined in Quantile Optimality except that the last entry is $z_{UL}(\theta)$. The quantity in the numerator is based on the asymptotic variance of $\log(\Phi(z_{UL}(\theta)))$, where the log-transformation is used for numerical stability. The asymptotic variance is then standardized in terms of the original $\log(\Phi(z_{UL}(\theta)))$ for consistency and smaller is better. For a range of use conditions, the integral is taken inside of $\log(\Phi(\cdots))$ rather than over the asymptotic variance for ease of computation. It is still appropriate as an optimality metric by the property that the variance of a sum bounds the sum of variances and both the logarithmic function and cdf are monotone functions. As such, minimizing the above expression minimizes the true asymptotic variance of the failure probability by bounding it from above.
When the goal of your experiment is to fit a model that is nonlinear in the unknown parameters, use a nonlinear design to place design points in areas that are key to fitting the nonlinear model. Although you could use an orthogonal design that is optimal for a linear model, such designs, in general, do not place design points in locations that minimize the uncertainty (or maximize the precision) of the estimates of the fitted parameters.

The efficiency of a nonlinear design depends on the values of the unknown parameters. This creates a circular problem in that to find the best design, you need to know the parameters in advance. JMP uses a Bayesian approach to construct a nonlinear design that maximizes the average efficiency over specified ranges of the values of the parameter. To properly specify these ranges, you must have some insight about the system of interest.

Nonlinear designs offer these advantages compared to designs for linear models:

- Predictions using a well-chosen model are likely to be good over a wider range of factor settings.
- It is possible to model response surfaces with complex curvature and with asymptotic behavior.

Overview of Nonlinear Designs

Construct designs to fit models that are nonlinear in their parameters using the Nonlinear Design platform. You can construct optimal designs or optimally augment existing data for nonlinear models. Nonlinear designs based on information that is descriptive of the underlying process can yield more accurate estimates of model parameters and prediction of process behavior than is possible with standard designs for polynomial models. For background on nonlinear models, see “Nonlinear Models” on page 700.

The efficiency of a design for a nonlinear model depends on the unknown values of the parameters that the design is intended to estimate. For this reason, JMP uses a Bayesian approach to construct designs that are efficient over a wide range of likely parameter values. You can specify a range of values for the unknown parameters and a distribution for the prior. The prior distribution choices include Uniform, Normal, Lognormal, and Exponential.

The Nonlinear Design platform uses a Bayesian approach, optimizing the design over a prior distribution of likely parameter values that you specify. The Bayesian D-optimality criterion is the expectation of the logarithm of the determinant of the information matrix with respect to a sample of parameter vectors that represents this prior probability distribution. The information matrix entries depend on the prediction variances at the design points. Little information is contributed by observations with low variance, where the response is almost certain. It follows that an optimal design places some design settings at high-variance points. See Gotwalt et al. (2009).

A principal of optimal design is that, over the feasible region of experimentation, the optimal design places points in locations with the highest variance of prediction. Though this may seem counter-intuitive, if an alternative design put points at other locations, the prediction variance at the design points of the optimal design would be even higher. For models that are linear in the parameters, the high-variance points tend to be at the vertices of the experimental region. But this is not necessarily true for models that are nonlinear in the parameters.

Note: Nonlinear designs are computed using a random starting design. For this reason, nonlinear designs that you obtain for identical specifications usually differ.

To use the Nonlinear Design platform, you must have an existing data table. That data table must contain the following:

- A column for the response.
- A column for each factor.
- A column that contains a formula showing the relationship between the factors and the response. This formula must include the unknown parameters.
**Note:** This is the same format as is required for a data table used in the Nonlinear platform for modeling.

Your table can come in one of two forms:

- It might be a template, containing only column information and no rows. See “Create a Nonlinear Design with No Prior Data” on page 684.
- It might contain rows with predictor information. In this case, the predictor values are included in the nonlinear design. See “Augment a Design Using Prior Data” on page 689.

### Examples of Nonlinear Designs

- “Create a Nonlinear Design with No Prior Data”
- “Augment a Design Using Prior Data”
- “Create a Design for a Binomial Response”

### Create a Nonlinear Design with No Prior Data

This example shows how to create a design when you have not yet collected data, but have a guess for the unknown parameters. In this example, you model the fractional yield (Observed Yield) of an intermediate product in a chemical reaction. The fractional yield is a function of reaction time and temperature. See Box and Draper (1987).

#### Create the Design

1. Select **Help > Sample Data Library** and open **Design Experiment/Reaction Kinetics Start.jmp**.
   
   Notice the following:
   - The data table contains no rows because no data have been collected.
   - The columns for the predictors, Reaction Temperature and Reaction Time, have the Coding, Design Role, and Factor Changes properties. To see these properties, click ⚫ in the Columns panel. They tell JMP how to treat these predictors when constructing a design. For information about how to save these column properties, see the “Column Properties” chapter on page 781.
   - The Observed Yield column will contain response data obtained by running the experiment.
   - The Yield Model column contains the formula that relates the predictors to the response, Observed Yield. Click ⬇️ in the Columns panel to see the formula. The formula is nonlinear in the parameters t1 and t3.
2. Select **DOE > Special Purpose > Nonlinear Design**.
3. Select Observed Yield and click **Y, Response**.
4. Select Yield Model and click **X, Predictor Formula**.
5. Click **OK**.

In this example, the values 510 and 540 for **Reaction Temperature** and 0.1 and 0.3 for **Reaction Time** were specified using the Coding column property. Alternatively, you can specify a reasonable range of values directly in the Factors outline.

6. Change the values of the parameter t1 to 25 and 50, and t3 to 30 and 35.

These new values represent a reasonable range of parameter values for the experimental situation. The default values were constructed based on the initial parameter values that were specified in the definition of the prediction formula. For information about constructing formulas, see *Using JMP*.

Notice that the prior distribution, shown under Distribution, for each of t1 and t3 is set to Normal by default.

7. Change the number of runs to 12 in the Design Generation panel.

**Figure 23.2** Completed Outlines for Reaction Kinetics Experiment

8. Click **Make Design**.
9. Click **Make Table**.
Your design should be similar to the one shown in Figure 23.3. The runs might be in a different order, and the values for Reaction Temperature and Reaction Time, and consequently those computed for Yield Model, can be slightly different. Notice that values appear in the Yield Model column because the column contains the formula for the model. Also notice that the table contains a **Model** script that you can use to fit a nonlinear model to your observations.

Now that you have created your design table, run your experiment, and record the responses in the **Observed Yield** column. The data table Reaction Kinetics.jmp, found in the Design Experiment folder contains observed results for the design.

**Explore the Design**

Before analyzing your results, construct a plot to see the design settings.

1. Select **Help > Sample Data Library** and open Design Experiment/Reaction Kinetics.jmp.
2. Select **Graph > Graph Builder**.
3. Drag and drop Reaction Temperature into the **Y** zone.
4. Drag and drop Reaction Time into the **X** zone.
5. Click the second icon above the graph to deselect the Smoother.
Notice that the points are located in three areas. There are no points at low temperature and high time (the lower right corner of the graph). Unlike orthogonal designs, nonlinear designs do not necessarily place design points at the corners of the design region. In this example, design points at low temperature and high time would be inefficient.

To see the density of design points in the remaining three corners, use the Contour tool.

5. Click to turn on the Contour tool.
6. Click Done.
Notice that there are comparatively few points at low time and high temperature. From the design table, you can see that there are only two such points. Because of the model and the parameter specifications, the optimal design places more design points at high time and high temperature.

**Analyze the Results**

Now that you visually explored your design, analyze your results.

**Note:** Rather than conduct step 1 through step 4, you can run the Model script.

1. Select **Analyze > Specialized Modeling > Nonlinear**.
2. Select Observed Yield and click **Y, Response**.
3. Select Yield Model and click **X, Predictor Formula**.
   
   Notice that the model appears in the Options for fitting custom formulas panel.
4. Click **OK**.
5. Click **Go** in the Control Panel.
   
   The iterative search for a solution proceeds until one of the Stop Limit values is reached. Then, the Solution and Correlation of Estimates reports appear.
6. Click the Nonlinear Fit red triangle and select **Profiler > Profiler**.
7. To maximize the yield, click the Prediction Profiler red triangle and select **Optimization and Desirability > Maximize Desirability**.

**Figure 23.6** Time and Temperature Settings for Maximum Yield

The estimated maximum yield is approximately 63.5% at a reaction temperature of 540 degrees Kelvin and a reaction time of 0.1945 minutes.
Augment a Design Using Prior Data

This example shows how to create a nonlinear design when you have prior data. In this example, the data pertain to a chemical reaction. You want to model the rate of uptake (velocity) of available organic substrate as a function of the concentration of that substrate. See Meyers (1986). You have already run an experiment, but you want to leverage your results to obtain more precise estimates of the parameters.

Obtain Prior Parameter Estimates

Use your existing experimental data to obtain better estimates of the parameter values.

2. Click the plus sign next to Model (x) in the Columns panel. The formula editor opens.
3. The Parameters outline in the middle bottom of the formula editor shows the current values of the model parameters. The values (b1 = 1 and b2 = 1) are your initial estimates. They are used to compute the Model (x) values in the data table. For your next experiment, you want to replace these with better estimates.
4. Click Cancel to close the formula editor window.
5. Select Analyze > Specialized Modeling > Nonlinear.
6. Select Velocity (y) and click Y, Response.
7. Select Model (x) and click X, Predictor Formula.
   Notice that the formula given by Model (x) appears in the Options for fitting custom formulas panel.
8. Click **OK**.

9. In the Control Panel, click **Go**.

The iterative search for a solution proceeds until one of the Stop Limit values is reached. Then, the Solution and Correlation of Estimates reports appear. Also, an option appears in the Control Panel enabling you to add confidence limits to the Solution report.

10. In the Control Panel, click **Confidence Limits**.

Confidence intervals for the parameters b1 and b2 appear in the Solution report.
Figure 23.8  Nonlinear Fit Results

The Lower CL and Upper CL values for $b_1$ and $b_2$ define ranges of values for these parameters. Next, use these intervals to define a range for the prior values in your augmented nonlinear design.

**Note:** Do not close the Nonlinear Fit report because these results are needed in the next steps.

**Augment the Design**

Now, create a design to estimate the nonlinear parameters more precisely.

1. With the Chemical Kinetics.jmp data table active, select **DOE > Special Purpose > Nonlinear Design**.
2. Select Velocity (y) and click **Y, Response**.
3. Select Model (x) and click **X, Predictor Formula**.
4. Click **OK**.
In the Chemical Kinetics.jmp data, the values for Concentration range from 0.417 to 6.25. Therefore, these values initially appear as the low and high values in the Factors outline. You want to change these values to encompass a broader interval.

5. Click 0.417 and type 0.1. Click 6.25 and type 7.

6. Leave the prior Distribution for each parameter set to Normal.

   The range of Values for the parameters reflects the uncertainty of your knowledge about them. You could specify a range that you think covers 95% of possible parameter values. The confidence limits from the Nonlinear Fit report shown in Figure 23.8 provide such a range. Replace the Values for the parameters in the Parameters outline with the confidence limits, rounding to three decimal places.

7. In the DOE Nonlinear Design window, enter these values into the Parameters for $b_1$ and $b_2$:
   - $b_1$: 0.568 and 3.158
   - $b_2$: 6.858 and 45.830
8. Enter 40 for the **Number of Runs** in the Design Generation panel.

9. Click **Make Design**.

   The Design outline opens, showing the Concentration and Velocity (y) values for the original 13 runs and new Concentration settings for the additional 27 runs.

10. Click **Make Table**.

    This creates a new JMP design table that contains the settings and results for the original 13-run design and settings for 27 new runs. Instead of creating a new data table, you can add the new runs to your existing data table by clicking Augment Table instead of Make Table.

    The new runs reflect the broader interval of Concentration values and the range of values for b1 and b2 obtained from the original experiment, which are used to define the prior distribution. Both should lead to more precise estimates of b1 and b2.

---

**Create a Design for a Binomial Response**

In some applications, the measurement of interest is a pass/fail (binomial) measurement. In this example, you will construct a nonlinear design for a binomial response with one design factor. For more information on designs in nonlinear settings and the binomial case in particular, see Gotwalt et al. (2009).

You plan to model the probability of success for your binomial response as a function of a single factor $x$. using a generalized linear model with a logistic link function

$$Y(x) = \frac{1}{1 + e^{-(\beta_0 + \beta_1x)}}$$

and the variance of $Y$ as the weight.
This model is nonlinear in the unknown parameters $\beta_0$ and $\beta_1$. Use the nonlinear designer to plan an experimental design. Your goal is to model the effect of $x$ on your binomial response $Y$.

To generated the desired non-linear design you must have a data table containing columns for the predictor, a column containing a formula for the nonlinear response model that you are fitting, and a column with a formula for your weights.

Data Table for Design Construction

The One Factor Logistic Design.jmp data table, found in the Design Experiment folder, contains the following:

- Column $x$ for the predictor. The Coding property defined for this column sets the low value to 0 and the high value to 1.
- Column $Y$, for the response. This is the column for collected responses (0/1) from your testing.
- Column Linear Pred that contains a formula for the linear portion of the link function. To view the formula, click the plus sign to the right of Linear Pred in the Columns panel. The model formula includes the initial estimates for the parameters $b_0$ and $b_1$. Initial parameter values are set when you define a formula. These values are shown in the formula element panel in the lower center of the formula editor window.

Figure 23.11 Linear Predictor Formula with Initial Parameter Estimates

- Column Var Y that contains the formula for the variance of the response based on the assumed logistic model. This is $p(1-p)$ where $p$ is the logistic function. This column is used as the weight column.
- Column Pred P that contains the logistic link function.
Create the Design

1. Select Help > Sample Data Library and open Design Experiment/One Factor Logistic Design.jmp.
2. Select DOE > Special Purpose > Nonlinear Design.
4. Select Linear Pred and click X, Predictor Formula.
5. Select Var Y and click Weight.
6. Click OK.

Figure 23.12 Nonlinear Design Window

The Factors outline shows the factor x with the specified values of 0 and 1. The Parameters outline shows the two model parameters with each prior distribution set to a normal distribution. JMP computes default Values based on your initial settings for the parameter values. You can change the assumed distribution and ranges for the parameters in this outline. Leave all settings as they appear. The default number of runs is 10.

7. Click the Nonlinear Design red triangle and select Advanced Options > N Monte Carlo Spheres. Set the number of spheres to 0 to obtain a locally optimal design. Click OK.
8. Click Make Design.
9. Click Augment Table.

This adds the 10 run design to One Factor Logistic Design.jmp (Figure 23.13). Your design table will be different because the optimization algorithm has a random component.
The model saved to the data table is a nonlinear model to fit the “Linear Pred” used in the creation of the design. After you collect your data, use a generalized linear model (GLM) with a logit link function to model the effect of $x$ on $Y$.

**Nonlinear Design Launch Window**

To use the Nonlinear Design platform, you must have an existing data table that contains the following:

- A column for the response.
- A column for each factor.
- A column that contains a formula showing the relationship between the factors and the response. This formula must include the unknown parameters.

For information about formulas, see *Using JMP*.

The table can contain values for the predictors and response. If it does, the design that you construct augments the design that is implicit in the table. There can be no row containing missing predictor values.

With your starting data table active, select **DOE > Special Purpose > Nonlinear Design**.

**Figure 23.14** Nonlinear Launch Window
**Y, Response**  The numeric column for response values.

**X, Predictor Formula**  The numeric column that contains the formula for the nonlinear model. This formula must contain parameters.

**Weight**  (Optional) A numeric column that assigns weights to the observations.

---

**Nonlinear Design Window**

The Nonlinear Design window updates as you work through the design steps. The outlines, separated by buttons that update the outlines, follow the flow in Figure 23.15.

**Figure 23.15 Nonlinear Design Flow**

The initial design window shows the Factors, Parameters, and Design Generation outlines.

**Figure 23.16 Initial Design Window**

---

**Factors**

The column names used in the model formula are automatically inserted in the Name column of the Factors outline. Each factor’s role is set to Continuous.

For each factor, the Values are initially set to -1 and 1. Or, if you have defined a value using the Coding column property, those values are used instead. You can change these values in the factors outline.
Parameters

The parameter names used in the model formula are automatically inserted in the Name column of the Parameters outline.

For each parameter, the Values are initially set to a symmetric interval around the initial value specified in the parameter definition. This interval is obtained by taking the initial value’s distance to 0, and constructing an interval of this width around the initial value. These values are used in defining prior distributions for the model parameters.

**Note:** Adjust the Values for the parameters in conjunction with your choice of distribution to reflect your uncertainty about the model parameters.

Four families of prior distributions are listed under Distribution. The Values that you specify for the parameters determine which member of the family of prior distributions that is used. Denote the low value by $low$ and the high value by $high$. Then the distributions are determined as follows:

- Uniform: The distribution is uniform on the interval $(low, high)$.
- Normal, Lognormal, Exponential: The distribution is the one where $low$ is the 0.025 quantile and where $high$ is the 0.975 quantile.

Design Generation

JMP provides a suggested number of runs, determined as follows:

- If you are not augmenting a data table, the number of runs is four times the number of parameters plus two.
- If you are augmenting a data table, the number of runs is the number of runs in the data table plus two times the number of parameters.

**Note:** If you are augmenting a design, the number of runs that JMP suggests or that you specify includes those runs corresponding to observations in your data table. Adjust the number of runs appropriately.

Design

When you click Make Design, JMP constructs the design and adds a Design outline to the Nonlinear Design window. In the Design outline, you can review the factor level settings.
**Make Table or Augment Table**

The Make Table button creates a new design table. If your original table included existing runs, the new table also includes the existing runs. The Augment Table button adds the new runs to your existing table.

**Nonlinear Design Options**

The red triangle menu in the Nonlinear Design platform contains these options:

- **Save Responses** Saves the information in the Responses panel to a new data table. You can then quickly load the responses and their associated information into most DOE windows. This option is helpful if you anticipate reusing the responses.

- **Load Responses** Not available.

- **Save Factors** Saves the information in the Factors panel to a new data table. Each factor’s column contains its levels. Other information is stored as column properties. You can then quickly load the factors and their associated information into most DOE windows.

- **Load Factors** Not available.

- **Save Constraints** Not available.

- **Load Constraints** Not available.

- **Simulate Responses** Adds response values to the design table. Select this option before you click Make Table. Then, in the resulting design table, the response columns contain simulated values.

  **Note:** To set a preference to always simulate responses, select File > Preferences > Platforms > DOE and select Simulate Responses.

- **Number of Starts** Sets the number of times that a nonlinear design is created using the quadrature method. Among the designs created, the platform selects the design that maximizes the optimality criterion.

- **Advanced Options > Number of Monte Carlo Samples** Sets the number of octahedra per sphere used in computing the optimality criterion. The default value is one octahedron. See “Radial-Spherical Integration of the Optimality Criterion” on page 701.

- **Advanced Options > N Monte Carlo Spheres** Sets the number of nonzero radius values used in computing the optimality criterion. The default is two. See “Radial-Spherical Integration of the Optimality Criterion” on page 701.
Note: If N Monte Carlo Spheres (the number of radii) is set to zero, then only the center point is used in the calculations. This gives a local design that is optimal for the initial values of the parameters. For some situations, this is adequate.

---

Statistical Details for Nonlinear Designs

- “Nonlinear Models”
- “Radial-Spherical Integration of the Optimality Criterion”
- “Finding the Optimal Design”

Nonlinear Models

Denote the vector of \( n \) responses by \( Y = (Y_1, Y_2, ..., Y_n)' \). A nonlinear model is defined by the following properties:

- The \( Y_i \) are independent and identically distributed with an exponential family distribution.
- The expected value of each \( Y_i \) given a vector of predictor values \( x_i \) is a nonlinear function of parameters, \( \theta \). Denote this function as follows:
  \[
  E(Y_i(x)) = f(\theta, x_i)
  \]
- Each \( Y_i \) is expressed as follows:
  \[
  Y_i = f(\theta, x_i) + \varepsilon_i
  \]
- The vector of errors, \( \varepsilon = (\varepsilon_1, \varepsilon_2, ..., \varepsilon_n)' \) has mean \( \mathbf{0} \) and covariance matrix \( \sigma^2 I \), where \( I \) is the \( n \times n \) identity matrix.

Denote the matrix of first partial derivatives of the function \( f \) with respect to the parameters \( \theta \) by \( X \). Under general conditions, the least squares estimator of \( \theta \) is asymptotically unbiased, with asymptotic covariance matrix given as follows:

\[
\text{Cov}(\hat{\theta}) = \sigma^2 (X'X)^{-1}
\]

For the proof of this result, see Wu (1981) and Jennrich (1969).
Radial-Spherical Integration of the Optimality Criterion

The optimality criterion is the expectation of the logarithm of the determinant of the information matrix with respect to the prior distribution. Consequently, finding an optimal nonlinear design requires maximizing the integral of the log of the determinant of the Fisher information matrix with respect to the prior distribution of the parameters. This integral must be calculated numerically. The approach used in the Nonlinear Design platform is based on Gotwalt et al. (2009).

For normal distribution priors, the integral is reparameterized into a radial direction and a number of angular directions equal to the number of parameters minus one. The radial part of the integral is computed using Radau-Gauss-Laguerre quadrature with an evaluation at radius = 0. This is done by constructing a certain number of hyperoctahedra and randomly rotating each of them.

If the prior distribution is not normal, then the integral is reparameterized so that the new parameters have a normal distribution. Then the radial-spherical integration method is applied.

**Note:** If the prior distribution for the parameters does not lend itself to a solution and the process fails, a message is added to the window that the Fisher information matrix is singular in a region of the parameter space. When this occurs, consider changing the prior distribution or the ranges of the parameters.

Finding the Optimal Design

The method used to find an optimal design is similar to the coordinate exchange algorithm described in Meyer and Nachtsheim (1995). For more information about how the nonlinear optimal design is obtained, see Gotwalt et al. (2009). The general approach proceeds as follows:

- Random designs are tested until a nonsingular starting design is found.
- Iterations are conducted, where each iteration consists of a pass through all the runs.
- For each run, factors are optimized one at a time.
- The objective function is the Bayesian D-optimality criterion. This is the expectation of the logarithm of the determinant of the information matrix with respect to the prior distribution.
- Iterations terminate once the change in the objective function is small.
A Balanced Incomplete Block Design (BIBD) can be used when it is not possible to include all treatments or factor combinations in every block. Use BIBDs for testing \( a \) treatments in \( b \) blocks when only \( k \) treatments can be run in any one block (and \( k < a \)). For example, you might have a situation where there are limitations on the number of treatments that can be tested at the same time. The BIBD design is constructed such that each treatment and each pair of treatments occurs together in blocks an equal number of times. This makes the design balanced. Not including all treatments in every block makes the design incomplete.

Use the Balanced Incomplete Block Platform to construct BIBDs. In addition, you can use the platform to construct complete block designs where each treatment occurs in every block.

Balanced Incomplete Block Design Options .................................................................................. 709
Statistical Details for Balanced Incomplete Block Designs ........................................................... 710
Example of Balanced Incomplete Block Designs

In this example, you want to test three new product formulations in your plant, and you want to block by day. There is a limit of two formulations that can be run per day. In addition, you need to finish your experiment in one work week. You need a design with at most five blocks.

1. Select **DOE > Special Purpose > Balanced Incomplete Block Design**.
2. Set the Treatment Size to 3.
   
   **Tip:** Treatment size can refer to the number of levels of a single factor or combinations of levels of two or more factors.

3. Select 2 for the **Block Size**.
4. Select 3 for **Allowable Blocks**.
   
   You can select 3 or 6 blocks. In this example, each block is a day and you can have no more than 5 days or 5 blocks. The number of runs is 6 because you have 3 blocks of size 2.

**Note:** You can enter a Treatment Name, Block Name, and Treatment Labels to customize your design table.

5. Click **Make Design**.

**Figure 24.2** BIBD for 3 Treatments in 3 Blocks of Size 2
The design has six runs in three blocks with two treatments in each block as seen in the Block Design outline. For additional design details open the Design and Incidence Matrix outlines. See “Verify Design and Make Table” on page 708.

Initially, you had to select a design with 3 or 6 blocks. You selected 3 blocks because of time constraints in your plant. However, suppose you were allowed to run your experiment for 6 days. You could then update the design to use 6 blocks.

6. Select 6 in the Allowable Blocks menu.
7. Click Make Design to update the design.
8. Open the Incidence Matrix outline.

**Figure 24.3** BIBD Design Details for 3 Treatments in 6 Blocks of Size 2

Now the design has 6 blocks. The incidence matrix shows the treatments that are in each block. The Pairwise Treatment Frequencies shows that each treatment appears four times (diagonal entries) and that each treatment pair occurs twice in the design (off diagonal entries). The blocks each have two positions. The Positional Frequencies show that treatment L1 always occurs in position 1, L2 is split between the two positions, and L3 occurs in position 2.
Build a Balanced Incomplete Block Design

Build a Balanced Incomplete Block Design by selecting **DOE > Special Purpose > Balanced Incomplete Block Design**.

**Figure 24.4** Balanced Incomplete Block Design Window

For more information about the options in the Select Columns red triangle menu, see *Using JMP*.

The Balanced Incomplete Block Design window updates as you work through the design. The steps to build a BIBD follow the flow in Figure 24.5.

**Figure 24.5** Balanced Incomplete Block Design Flow

### Specify Treatments, Blocks, and Make Design

The following options are in the Design Options outline:

- **Treatment Name** The name of the treatment factor.
- **Treatment Size** The number of treatments.

  **Tip:** Treatments can be factor-level combinations.

- **Treatment Labels** Labels for the treatments. The default labeling is L1 to La where a is the total number of treatments.
- **Block Name** The name of the blocking factor.
- **Block Size** The number of treatments that can be run in any one block.
Note: Values for Block Size are determined by the number of treatments. If a value is not in the list, it is because the BIBD platform cannot create a design with that block size for the given number of treatments.

Allowable Blocks  Allowable number of blocks in the design based on the number of treatments and the block size.

Include Block Multiples  Allows for the selection of a design with the number of blocks equal to a multiple (that you specify) of the initial allowable block sizes. The additional (multiple) blocks are cyclic permutations of the original design.

Specify Multiplier  (Available when Include Block Multiples is selected.) Multiplier that you want to apply to the initial allowable block sizes.

Make Design  Generates the design.

Verify Design and Make Table

Block Design  Shows the BIBD in a traditional design layout.

Make Table  Creates the BIBD data table.

Include order column  Includes a column in the design table for the order of runs within each block.

Design  Shows the BIBD in a block layout where each row represents a block and the treatments in that block.

Incidence Matrix  Shows the treatments that occur in each block. Each row of the matrix corresponds to a block in the design with a 1 if the treatment is in the block and 0 otherwise.

Pairwise Treatment Frequencies  Shows the number of times each treatment occurs in the same block with every other treatment on the off-diagonal entries. The diagonal entries are the total number of times each treatment occurs.

Positional Frequencies  Shows the number of times each treatment occurs in each block position.
Balanced Incomplete Block Design Options

The red triangle menu in the Balanced Incomplete Block Design platform contains these options:

**Simulate Responses**  Adds response values and a column containing a simulation formula to the design table. Select this option before you click Make Table.

When you click Make Table, the following occur:

- A set of simulated response values is added to each response column.
- For each response, a new column that contains a simulation model formula is added to the design table. The formula and values are based on the model that is specified in the design window.
- A Model window appears where you can set the values of coefficients for model effects and specify one of three distributions: Normal, Binomial, or Poisson.

**Note:** Not all distributions are available for all design types.

- A script called **DOE Simulate** is saved to the design table. This script reopens the Model window, enabling you to re-simulate values or to make changes to the simulated response distribution.

Make selections in the Model window to control the distribution of simulated response values. When you click Apply, a formula for the simulated response values is saved in a new column called `<Y> Simulated`, where `Y` is the name of the response. Clicking Apply again updates the formula and values in `<Y> Simulated`.

For additional details, see “Simulate Responses” on page 112 in the “Custom Designs” chapter.

**Note:** You can use Simulate Responses to conduct simulation analyses using the JMP Pro Simulate feature. For more information and DOE examples, see the Simulate chapter in Basic Analysis.

**Save Script to Script Window**  Creates the script for the design that you specified in the Balanced Incomplete Block window and places it in an open script window.
Statistical Details for Balanced Incomplete Block Designs

The total number of observations in a BIBD is determined by the following equation:

\[ N = ar = bk \]

where

- \( a \) is the number of treatments
- \( r \) is the number of times each treatment occurs in the design
- \( b \) is the number of blocks
- \( k \) is the number of treatments in each block

The number of blocks in which each pair of treatments occurs is given by the following:

\[ \lambda = \frac{r(k - 1)}{a - 1} \]

where \( \lambda \) must be an integer.

These conditions are necessary for a BIBD to exist, but not sufficient. The BIBD platform presents values for which it can generate a BIBD.

When the Include Block Multiples is selected, the original BIBD is copied the number of times specified. The additional (multiple) blocks are cyclic permutations of the original design. The positions of treatments in the copies differs from the original.

For more information about BIBDs, see SAS Institute Inc. (2013).
Measurement system analysis experiments, also known as gage R&R studies, are based on full factorial designs. The MSA platform generates a full factorial design for a measurement systems analysis (MSA) experiment and provides design diagnostic measures. For analysis of MSA experiments, see *Quality and Process Methods*.

Statistical Details for the MSA Design Platform ......................... 721
Overview of MSA Designs

A measurement system analysis (MSA) design is a full factorial design where the factors are random effects. The focus of the study is to estimate the variation in the response due to each factor. The MSA Design platform generates a full factorial design with diagnostic measures specific to an MSA study.

Example of MSA Design

In this example, you want to study the variability in your measurement system due to instruments and operators. You have two scales in your lab and four operators who have time to participate in the study. You have a set of five standard parts to weigh and each operator makes six measurements per part per instrument. You do not have previous estimates of variability, so you design an experiment based on a variance of one, which results in diagnostics that are scaled to the true variability.

1. Select DOE > Special Purpose > MSA Design.
2. Set the Goal for the response Y, to Match Target.
3. Set the # of Levels for Operator to 4.
4. Set the # of Levels for Part to 5.
5. Set the # of Levels for Gauge to 2.
6. Set the Number of Replicates to 5 to include 6 measurements for each design run.

Figure 25.2  Factor Settings

7. Select Show Levels.
8. Edit the factor Values as shown in Figure 25.3.
Figure 25.3 Factor Values

Note: Setting the Random Seed in step 9 reproduces the design and diagnostics shown in this example.

9. (Optional) Click the MSA red triangle, select Set Random Seed, type 123.

10. Click Make Design.

   Note: Click Make Table to generate a table for data collection. See “MSA Design Table” on page 720 for analysis scripts that are included in the design table.

11. Scroll down to the Design Diagnostics outline and click the gray disclosure icon to open.

    The Design Diagnostics report contains settings for assumed variances that are then used to estimate confidence intervals, variance proportions and EMP Monitoring Classifications. These estimates are used to evaluate the strength of your MSA study design. Explore different variance assumptions, or use the Back button to make adjustments to your design.

12. Adjust the expected Variance of your factors to explore the impact on your design diagnostics. Set Operator Variance to 0.5, Part Variance to 10, and Gauge Variance to 0.25.
All diagnostics are based on simulations that are computed from the sampling distributions of the appropriate mean squares. Based on the variance estimate assumptions the study results in a 78% probability of a first class process.

Build an MSA Design

Build an MSA design by selecting **DOE > Special Purpose > MSA Design**.
For more information about the options in the Select Columns red triangle menu, see *Using JMP*.  

The MSA design window updates as you work through the design steps. The steps to build an MSA design follow the flow in Figure 25.6.

**Figure 25.6** MSA Design Flow

**Responses**

Use the Responses outline to specify one or more responses.

**Tip:** When you have completed the Responses outline, consider selecting **Save Responses** from the red triangle menu. This option saves the response names, goals, limits, and importance values in a data table that you can later reload in DOE platforms.

**Add Response**  Enters a single response with a goal type of Maximize, Match Target, Minimize, None, or Functional. If you select Match Target, enter limits for your target value. If you select Maximize or Minimize, entering limits is not required but can be useful if you intend to use desirability functions.

**JMP Pro Functional**  (Available only in JMP Pro.) Adds multiple Y columns with FDE column properties to the design data table. These columns can be used in the Functional Data Explorer platform with the DOE factors as supplementary factors.

**Remove**  Removes the selected responses.

**Number of Responses**  Enters additional responses so that the number that you enter is the total number of responses. If you have entered a response other than the default Y, the Goal for each of the additional responses is the Goal associated with the last response entered. Otherwise, the Goal defaults to Match Target. Click the Goal type in the table to change it.
The Responses outline contains the following columns:

**Response Name**  The name of the response. When added, a response is given a default name of Y, Y2, and so on. To change this name, double-click it and enter the desired name.

**Goal, Lower Limit, Upper Limit**  The Goal tells JMP whether you want to maximize your response, minimize your response, match a target, or that you have no response goal. JMP assigns a Response Limits column property, based on these specifications, to each response column in the design table. It uses this information to define a desirability function for each response. The Profiler and Contour Profiler use these desirability functions to find optimal factor settings. For further details, see the Profiler chapter in *Profiler* and “Response Limits” on page 784 in the “Column Properties” appendix.

- A Goal of Maximize indicates that the best value is the largest possible. If there are natural lower or upper bounds, you can specify these as the Lower Limit or Upper Limit.
- A Goal of Minimize indicates that the best value is the smallest possible. If there are natural lower or upper bounds, you can specify these as the Lower Limit or Upper Limit.
- A Goal of Match Target indicates that the best value is a specific target value. The default target value is assumed to be midway between the Lower Limit and Upper Limit.
- A Goal of None indicates that there is no goal in terms of optimization. No desirability function is constructed.

**Note:** If your target response is not midway between the Lower Limit and the Upper Limit, you can change the target after you generate your design table. In the data table, open the Column Info window for the response column (**Cols > Column Info**) and enter the desired target value.

**Importance**  When you have several responses, the Importance values that you specify are used to compute an overall desirability function. These values are treated as weights for the responses. If there is only one response, then specifying the Importance is unnecessary because it is set to 1 by default.

**Detection Limits**  The lower and upper detection limits are bounds beyond which the response cannot be measured. The detection limits are saved as a column property. You can use these limits to specify a censored response in the Generalized Regression platform. See the Generalized Regression chapter in *Fitting Linear Models*.

**Editing the Responses Outline**

In the Responses outline, note the following:

- Double-click a response to edit the response name.
• Click the goal to change it.
• Click on a limit or importance weight to change it.
• For multiple responses, you might want to enter values for the importance weights.

**Response Limits Column Property**

The Goal, Lower Limit, Upper Limit, and Importance that you specify when you enter a response are used in finding optimal factor settings. For each response, the information is saved in the generated design data table as a Response Limits column property. JMP uses this information to define the desirability function. The desirability function is used in the Prediction Profiler to find optimal factor settings. For further details about the Response Limits column property and examples of its use, see “Response Limits” on page 784 in the “Column Properties” appendix.

If you do not specify a Lower Limit and Upper Limit, JMP uses the range of the observed data for the response to define the limits for the desirability function. Specifying the Lower Limit and Upper Limit gives you control over the specification of the desirability function. For more details about the construction of the desirability function, see the Profiler chapter in *Profilers*.

**Factors**

The Factors outline defaults to a 5 operator, 3 part, and 3 gauge study.

**Note:** The MSA designer requires at least one factor with a part role.

- **Add Factor** Click to add one or more factors.
- **Remove** Removes the selected factors.
- **Add N Factors** Adds multiple factors. Enter the number of factors to add and click Add Factor.

**Show Levels** Select to show factor levels. When selected, the following options are available.

- **Name** Factor name with a menu to add a level.
- **Role** Fixed to a categorical factor. MSA factors are categorical by default.
- **Values** Specifies the factor levels, which you can click to edit.

**Name** Specifies the name of the factor, which you can click to edit. Initially, three factors are in the factor list; Operator, Part, and Gauge. You can add or remove factors from this list.

**MSA Role** Specifies the MSA Role of the factor. Click to select from Operator, Part, Gauge, or None.
# of Levels  Specifies the number of levels for a factor.

Variance  Specifies a prior variance due to the factor. The default is one, which results in
           diagnostics that are scaled to the true variability.

Randomize  Specifies to randomize the factor in the design table.

Number of Replicates  Specifies the number of replicates between 0 and 10 to include in your
design. The number of replicates is the number of measurements in addition to an initial
measurement. The default is two replicates, which results in three measurements for each
run. To specify a single measurement per run, set the number of replicates to zero.

MSA Design

The Design outline shows the runs for the MSA design.

MSA Design Diagnostics

All diagnostics in the Design Diagnostics report are based on simulations that are computed
from the sampling distributions of the appropriate mean squares. You can make changes to
the variance estimate for each model factor. The design diagnostics update with changes to the
variance estimates. This enables you to explore the ability of your design to measure your
system under different assumed models.

MSA Design Variance Estimates

The Variance Estimates report enables you to specify a variance estimate for each MSA model
factor. Diagnostics are based on your variance estimates and include simulated confidence
interval (CI) bounds. Simulated estimates and CI bounds are also provided for the probability
of a response falling out of specifications. The specifications are defined by the lower and
upper limits set for the response.

MSA Design Variance Proportions

The Variance Proportions report contains diagnostics for the estimated variance proportions
based on the assumed variances. The report also includes simulated approximate CI bounds
and measurement system EMP classification probability. For more information about EMP
classification see Quality and Process Methods.

MSA Design Simulation Results and Options

The Simulation report contains box plots of the distribution of the simulated variance
proportions used to estimate the variance proportions CI bounds. The simulations are based
on a large number of trials.
The Simulation Results red triangle menu contains the following options:

**Show Statistics**  Opens summary statistics for each model factor.

**Show Points**  Shows or hides the points in the box plots that fall beyond the whiskers.

**Make Data Table**  Opens a data table of the simulation results.

### MSA Design Table

Use the buttons to finish your MSA design construction.

**Make Table**  Constructs the MSA design data table. The table includes scripts for analysis:

- **EMP Measurement System Analysis**  Launches the MSA analysis platform. See *Measurement Systems Analysis*.

- **Variability Chart**  Launches the Variability Gauge Chart platform. See *Variability Gauge Charts*.

- **DOE Dialog**  Launches the MSA Design platform with the specifications used to generate the current design table.

- **Operator Worksheets**  Opens a data table for each operator to use as a worksheet for data collection.

**Back**  Takes you back to make adjustments to the design specifications.

### MSA Design Options

The MSA Design red triangle menu contains the following options:

**Save Responses**  Saves the information in the Responses panel to a new data table. You can then quickly load the responses and their associated information into most DOE windows. This option is helpful if you anticipate reusing the responses.

**Load Responses**  Loads responses that you saved using the Save Responses option.

**Save Factors**  Saves the information in the Factors panel to a new data table. Each factor’s column contains its levels. Other information is stored as column properties. You can then quickly load the factors and their associated information into most DOE windows.
**Note:** It is possible to create a factors table by entering data into an empty table, but remember to assign each column an appropriate Design Role. Do this by right-clicking on the column name in the data grid and selecting **Column Properties > Design Role**. In the Design Role area, select the appropriate role.

**Load Factors**  Loads factors that you saved using the Save Factors option.

**Save Constraints**  (Unavailable for some platforms) Saves factor constraints that you defined in the Define Factor Constraints or Linear Constraints outline into a data table, with a column for each constraint. You can then quickly load the constraints into most DOE windows.

In the constraint table, the first rows contain the coefficients for each factor. The last row contains the inequality bound. Each constraint’s column contains a column property called **ConstraintState** that identifies the constraint as a “less than” or a “greater than” constraint. See “**ConstraintState**” on page 818 in the “Column Properties” appendix.

**Load Constraints**  (Unavailable for some platforms) Loads factor constraints that you saved using the Save Constraints option.

**Set Random Seed**  Sets the random seed that JMP uses to control actions that have a random component. These actions include one or more of the following:

- initializing search algorithms for design generation
- randomizing Run Order for design construction
- selecting a starting design for designs based on random starts

To reproduce a design, enter the random seed that generated the design before clicking **Make Design**.

**Note:** The random seed associated with a design is included in the DOE Dialog script that is saved to the design data table.

---

**Statistical Details for the MSA Design Platform**

The variance and variance proportion simulations are computed using simulated mean square terms. The mean square terms are simulated from chi-square distributions scaled by the associated expected mean square. The simulated variances are computed using method of moments estimators and are then used in computing the confidence bounds for the variance proportions.

For example, consider the variance for Part. The simulation computations follow these steps:

1. Simulate the mean square for Part, the mean squares for each two-way interaction involving Part, as well as any mean squares for higher order interactions involving Part.
2. Compute the variance using inclusion-exclusion:

variance of Part = mean square of Part – mean square of two-way interactions + mean square of three-way interactions -...+/-mean square of highest order interaction

3. The simulated variance proportion for Part is then computed as Variance of Part/Total Variance.

**Note:** Only the distributions of the mean square terms are known directly. Specifically, Mean Square = Chi-Squared Distribution(df)*Expected Mean Square. The distributions of the variance and variance proportions are approximated by the simulated values. Because of this, the confidence bounds can differ each time a variance term is updated or each time the platform is run.
Group orthogonal supersaturated designs are a special case of screening designs. They are appropriate in early stage work when the number of factors to be investigated is larger than the number of feasible runs. A supersaturated design is a design with fewer observations than model parameters. That is, the design cannot estimate all main effects simultaneously. This makes detection of significant effects difficult. A group orthogonal supersaturated design is a special class of two-level supersaturated designs with properties that are desirable for model selection.

Overview of Group Orthogonal Supersaturated Designs

Group orthogonal supersaturated designs (GOSSD) are constructed to have a specific structure to facilitate model selection. The design factors are partitioned into groups such that factors within a group are correlated with other factors within the same group yet factors are orthogonal to factors in other groups. One group consists of three or more “fake” factors. These fake factors are not assigned to design factors. They are used only in the analysis of the design. The fake factors provide an unbiased estimate of the variance assuming that second-order and higher-order effects are negligible.

Practical considerations for setting up a GOSSD include:

- More groups are better than fewer groups.
- Factors that are thought to be active should be placed in separate groups.
- Choose the levels of factors so that anticipated coefficients are positive.

Example of Group Orthogonal Supersaturated Designs

In this example, you want to design an experiment to study 12 factors in at most 12 runs. You want a design with at least 16 parameters. One parameter is needed for the intercept and at least three fake factors are desired.

1. Select DOE > Special Purpose > Group Orthogonal Supersaturated > Group Orthogonal Supersaturated Design.
2. Select Number of Runs.
3. Enter 12 for the Number of Runs and click away from the text box.
4. Select the second option in the Structure window with 16 parameters in 4 groups of size 4.
5. Click on the X1 factor name and change the name to Fake 1.
6. Repeat for X2 and X3 to name them as Fake 2 and Fake 3, respectively.
7. Click Make Design.
The structure of the design is evident in the color map. Factors within a group are correlated. Factors in different groups are not correlated, which indicates that they are orthogonal.
Build a Group Orthogonal Supersaturated Design

Build a Group Orthogonal Supersaturated Design by selecting **DOE > Special Purpose > Group Orthogonal Supersaturated > Group Orthogonal Supersaturated Design.**

**Figure 26.2** Group Orthogonal Supersaturated Design Window

For more information about the options in the Select Columns red triangle menu, see *Using JMP.*

The GOSSD window updates as you work through the design. The steps to build a GOSSD follow the flow in Figure 26.3

**Figure 26.3** Group Orthogonal Supersaturated Design Flow

### Specify Factors, Structure, and Make Design

The following options are available in the Design Options outline.

**Tip:** Provide either the number of runs or the number of factors to define possible design structures.

**Number of Runs** Defines the number of design runs. The number needs to be a multiple of 2 and preferably a multiple of 4.
Number of Factors  Defines the number of factors. Include a factor for the intercept and three to five fake factors. The number of factors must be a multiple of 8.

Structure  Provides a list of possible structures for your design. The columns in this list are dependent on whether you set the number of runs or the number of factors.

Number of Groups  The number of groups in the design. The minimum is 2.

Group Size  The number of factors in each group.

Number of Runs  (Available if you set the number of factors) The number of runs in the design.

Number of Parameters  (Available if you set the number of runs.) The number of parameters in the design. The parameters include one intercept, your design factors, and the remaining parameters are assigned to fake factors.

Factors

Factor Name  The name for the intercept is fixed. The remaining factors can be renamed.

Role  Enables you to define a factor as continuous or categorical.

Lower  Enables you to set the lower limit of each factor.

Upper  Enables you to set the upper limit of each factor.

Group Structure  Shows factors that appear in each group.

Swap  Enables you to swap factors between groups.

Make Design  Generates the design.

Verify Design and Make Table

Design  Displays the design matrix.

Make Table  Creates the GOSSD data table. The design table includes the following scripts:

Model  (Executes only if the Response column is populated.) Runs the DOE > Special Purpose > Group Orthogonal Supersaturated > Fit Group Orthogonal Supersaturated platform.

Doe Dialog  Re-creates the GOSSD Design window that you used to generate the design table.

GOSSD Structure  Shows the structure of the design (number of runs, number of parameters, number of groups, group size).

Multivariate  Runs the Analyze > Multivariate platform for the design factors.
**Model Matrix**  
Contains the design matrix.

**DOE Simulate**  
(Available when you simulate responses.) Launches the simulate window.

**Design Evaluation**

**Correlation Matrix**  
Shows the matrix of correlations between effects.

**Color Map on Correlations**  
Shows the absolute correlations between effects on a plot using an intensity scale. Includes a red triangle menu that contains an option to save the correlations to a data table.

---

### Group Orthogonal Supersaturated Design Options

The red triangle menu in the Group Orthogonal Supersaturated Design platform contains the following options:

**Simulate Responses**  
Adds response values and a column containing a simulation formula to the design table. Select this option before you click Make Table.

When you click Make Table, the following occur:

- A set of simulated response values is added to each response column.
- For each response, a new column that contains a simulation model formula is added to the design table. The formula and values are based on the model that is specified in the design window.
- A Model window appears where you can set the values of coefficients for model effects and specify one of three distributions: Normal, Binomial, or Poisson.

**Note:** Not all distributions are available for all design types.

- A script called **DOE Simulate** is saved to the design table. This script reopens the Model window, enabling you to re-simulate values or to make changes to the simulated response distribution.

Make selections in the Model window to control the distribution of simulated response values. When you click Apply, a formula for the simulated response values is saved in a new column called `<Y> Simulated`, where `Y` is the name of the response. Clicking Apply again updates the formula and values in `<Y> Simulated`.

For additional details, see “Simulate Responses” on page 112 in the “Custom Designs” chapter.
Note: You can use Simulate Responses to conduct simulation analyses using the JMP Pro Simulate feature. For more information and DOE examples, see the Simulate chapter in Basic Analysis.

Save Script to Script Window  Creates the script for the design that you specified in the Group Orthogonal Supersaturated Design window and places it in an open script window.

Statistical Details for Group Orthogonal Supersaturated Designs

For statistical details of design construction see Jones, et.al. (2019).
The Fit Group Orthogonal Supersaturated Platform

Analyze Data from Group Orthogonal Supersaturated Designs

Use the Fit Group Orthogonal Supersaturated platform to analyze group orthogonal supersaturated designs. This analysis technique takes advantage of the group orthogonal structure of group orthogonal supersaturated designs.

Figure 27.1  Fit Group Orthogonal Supersaturated Results
Contents

Launch the Fit Group Orthogonal Supersaturated Platform ............................................. 736
The Fit Group Orthogonal Supersaturated Report ............................................................. 737
Fit Group Orthogonal Supersaturated Platform Options ................................................. 738
Overview of the Fit Group Orthogonal Supersaturated Platform

A group orthogonal supersaturated design (GOSSD) is constructed to facilitate the identification of active effects. These designs group factors such that within a group, factors are correlated but between groups, factors are orthogonal. This structure leads to two analysis features:

- Fake, or dummy, factors assigned to the first group are used to estimate variance, assuming that the second- or higher-order effects are negligible.
- Between-group orthogonality enables a two-step model selection procedure.

The Fit Group Orthogonal Supersaturated Platform performs a two-step model selection procedure, enables you to view a regression plot of all factors, and then provides a model for the active effects with the option to examine this model with the Fit Model platform.

Example of Fit Group Orthogonal Supersaturated

In this example, you want to design an experiment to study 12 factors in at most 12 runs. For a GOSSD, you need a design with at least 16 parameters. One parameter is needed for the intercept, at least three parameters are needed for the fake factors, and 12 parameters are needed for the design factors. Use simulated responses to fit a model.

Tip: You are not limited to three fake factors. More can be used.

Generate the Design

1. Select **DOE > Special Purpose > Group Orthogonal Supersaturated > Group Orthogonal Supersaturated Design**.
2. Select **Number of Runs**.
3. Enter 12 for the **Number of Runs** and click away from the text box.
4. Select the second option in the Structure section with 16 parameters in 4 groups of size 4.
5. Click on the X1 factor name and change the name to Fake 1.
6. Repeat for X2 and X3 to name them as Fake 2 and Fake 3, respectively.
7. Click the Group Orthogonal Supersaturated Design red triangle and select **Simulate Responses**.
8. Click **Make Design**.
9. Click **Make Table**.
Figure 27.2  Simulate Responses Window

The Simulate Responses window shows the settings that were used to generate the design table. Note that the outline box for Group 1 is closed. Group 1 contains the “fake” factors. These are all set to 0 as they are assumed to have no impact on the model. Your values might differ from those shown in Figure 27.2. This simulation has one active effect per group.

Tip: Use the Simulate Responses Window to enter new values for a different simulation.

Analyze the Simulated Response

1. Select **DOE > Special Purpose > Group Orthogonal Supersaturated > Fit Group Orthogonal Supersaturated**.
2. Select Response and click **Y**.
3. Select Fake 1 through X15 and click **X**.
4. Click **OK**.

Tip: The design table generated using the Group Orthogonal Supersaturated platform contains a script called Model. Run this script to run this analysis directly.
Your simulation set $X_7$, $X_{10}$, and $X_{13}$ as factors with effects. The Fit GOSSD procedure identified those three factors as significant. In addition, case $X_{14}$ was also identified. In practice, you would need to determine whether the size and significance of the effect warrants further attention.

**Note:** Your simulation results might differ from those shown in Figure 27.3 due to the generation of random results. You might see an alert that a group has one or more additional effects that might be active. This is a limitation of a supersaturated design; your findings might not be conclusive.

5. Click **Run Model** to run the identified model.
Launch the Fit Group Orthogonal Supersaturated Platform

Launch the Fit Group Orthogonal Supersaturated Design platform by selecting **DOE > Special Purpose > Group Orthogonal Supersaturated > Fit Group Orthogonal Supersaturated.**

**Note:** If you created your design in JMP using the Group Orthogonal Supersaturated platform, the design table contains a script called Model. Run this script to run the analysis directly.

**Figure 27.4** Fit Group Orthogonal Supersaturated Launch Window

- **Y** One or more numeric response variables.
- **X** Two-level continuous or categorical factors. Because the platform uses the unique structure of a GOSSD in performing the analysis, these factors must define a GOSSD.

For more information about the options in the Select Columns red triangle menu, see *Using JMP.*
The Fit Group Orthogonal Supersaturated Report

The Fit Group Orthogonal Supersaturated Report has two sections. The first section reports the estimates of active effects within each group, fitting one group at a time. Only active groups are shown. This is Stage 1 of the analysis. In Stage 2 a combined model is constructed.

**Figure 27.5 Stage 1 Findings**

| Term | Estimate | Std Error | t Ratio | Prob>|t| |
|------|----------|-----------|---------|-------|
| X7   | 3.1345   | 0.1542    | 20.331  | 0.0003*|
| X10  | 3.1411   | 0.1542    | 20.374  | 0.0003*|
| X13  | 3.3291   | 0.1635    | 20.359  | 0.0003*|
| X14  | 0.4143   | 0.1635    | 2.5333  | 0.0852 |

**Term** Main effects that are identified as active.

**Estimate** Parameter estimate for a regression fit of Y on the main effect.

**Std Error** The standard error of the estimate, computed using the fake factors in Group 1.

**t Ratio** The Estimate divided by its Std Error.

**Prob>|t|** The p-value computed using the t Ratio and the degrees of freedom for error (DF).

The second section of the report contains the results of Stage 2 of the analysis. Stage 2 constructs the model used to evaluate the design results.

**Figure 27.6 Stage 2 Results**

| Term | Estimate | Std Error | t Ratio | Prob>|t| |
|------|----------|-----------|---------|-------|
| X7   | 3.1345   | 0.2556    | 12.215  | <.0001*|
| X10  | 3.1411   | 0.2556    | 12.241  | <.0001*|
| X13  | 3.3291   | 0.2722    | 12.231  | <.0001*|
| X14  | 0.4143   | 0.2722    | 1.5222  | 0.1718 |

**Term** Main effects that are identified as active.

**Estimate** Parameter estimate for a regression fit of Y on the main effect.
**Std Error**  The standard error of the estimates obtained by fitting the specified model and intercept using the full data set.

**t Ratio**  The Estimate divided by its Std Error.

**Prob>|t|**  The $p$-value computed using the t Ratio and the degrees of freedom for error (DF).

**RMSE**  The square root of the mean square error.

**DF**  The degrees of freedom associated with the error estimate used to construct the RMSE.

---

**Fit Group Orthogonal Supersaturated Platform Options**

The red triangle menu in the Fit Group Orthogonal Supersaturated Design platform contains the following options:

See *Using JMP* for more information about the following options:

**Redo**  Contains options that enable you to repeat or relaunch the analysis. In platforms that support the feature, the Automatic Recalc option immediately reflects the changes that you make to the data table in the corresponding report window.

**Save Script**  Contains options that enable you to save a script that reproduces the report to several destinations.

**Statistical Details for the Fit Group Orthogonal Supersaturated Platform**

A two-stage strategy is used to fit group orthogonal supersaturated designs. The first stage identifies which groups contain active effects.

- Obtain an estimate of $\sigma$ from the fake factors and then discard the fake factors from further analyses.
- Test for significance of each group of factors.

The second stage considers significance of individual factors in active groups. This stage uses a guided subsets procedure. See Jones and Nachtsheim (2016). For complete statistical details, see Jones, et al. (2019).
When planning experiments or studies, use the Sample Size Explorers to answer questions like these:

- How many units should I test?
- Will I be able to detect a difference in my treatment means?
- How many samples are needed to construct an interval with a specified width?
- How many units must I test to estimate failure time?

The Sample Size Explorers are a collection of interactive utilities that enable you to adjust study parameters and assumptions to explore different study designs. The tools are grouped by use:

- Power for hypothesis testing.
- Confidence intervals for interval estimation.
- Reliability demonstrations.

Overview of the Sample Size Explorers Platform

The Sample Size Explorers are used for sample size and power calculations. The Sample Size Explorers enable you to evaluate and compare the implications of your study assumptions on the number of observations (runs, experimental units, or samples) needed for your study. There are explorers for hypothesis testing, interval estimation, and reliability demonstrations.

For more information about power and sample size, see Barker (2011).

Example of Sample Size Explorers

You can use the Sample Size Explorers to help determine the number of units to test in a study of a new material. Suppose you are interested in demonstrating that the flammability of a new fabric being developed by your company has improved performance over current materials. Previous testing indicates that the standard deviation for time to burn of this fabric is 2 seconds.

Use the Power Explorer for One Sample Mean to calculate the number of fabric samples you need to test. You would like to design an experiment that has 90% power to detect a difference of 1.5 seconds at a significance level of \( \alpha = 0.05 \).

1. Select DOE > Sample Size Explorers > Power > Power for One Sample Mean.
2. Leave Alpha set to 0.05.
3. Enter 2 for Std Dev.
4. Enter 1.5 for Difference to detect.
5. Enter 0.9 for Power.
6. Click Save Settings to save these settings.
7. Use the sliders and or text boxes to explore other sample size and power possibilities for your study.
Figure 28.2 One Sample Mean Power Explorer

At a significance level of 0.05, 21 fabric samples are needed to have a 90.4% chance of detecting a significant difference of 1.5 seconds in the burn time.

Launch Sample Size Explorers

Launch Sample Size Explorers by selecting **DOE > Sample Size Explorers**. There are multiple calculators to select from.

For hypothesis testing, select **DOE > Sample Size Explorers > Power**:

- “Power for One Sample Mean” on page 743
- “Power for One Sample Proportion” on page 746
- “Power for One Sample Variance” on page 748
- “Power for One Sample Equivalence” on page 750
- “Power for Two Independent Sample Means” on page 752
- “Power for Two Independent Sample Means” on page 752
- “Power for Two Independent Sample Variances” on page 758
- “Power for Two Independent Sample Equivalence” on page 760
- “Power for ANOVA” on page 763

For interval estimation, select **DOE > Sample Size Explorers > Confidence Intervals**:

- “Margin of Error for One Sample Mean” on page 765
- “Margin of Error for One Sample Proportion” on page 768
- “Margin of Error for One Sample Variance” on page 770
Power Explorers for Hypothesis Tests

Use the power explorers to calculate sample size for hypothesis tests. Explore the impact of sample size on the power of a hypothesis test to detect a specified difference where the difference could be from a constant (one-sample case) or between two groups (two-sample case). For the one-sample case, the hypothesis is about the single parameter (mean, proportion, or variance). For the two-sample case, the hypothesis is about comparing two groups. For more than two groups, you can use the Power Explorer for ANOVA, see Power for ANOVA.

For hypothesis testing, select DOE > Sample Size Explorers > Power:

- “Power for One Sample Mean” on page 743
- “Power for One Sample Proportion” on page 746
- “Power for One Sample Variance” on page 748
- “Power for One Sample Equivalence” on page 750
- “Power for Two Independent Sample Means” on page 752
- “Power for Two Independent Sample Means” on page 752
- “Power for Two Independent Sample Variances” on page 758
- “Power for Two Independent Sample Equivalence” on page 760
- “Power for ANOVA” on page 763

Power for One Sample Mean

Use the Power Explorer for One Sample Mean to determine a sample size for a hypothesis test about one mean. Select DOE > Sample Size Explorers > Power > Power for One Sample Mean. Explore the trade-offs between variability assumptions, sample size, power, significance, and the hypothesized difference to detect. Sample size and power are associated with the following hypothesis test:
$H_0: \mu = \mu_0$

versus the two-sided alternative:

$H_a: \mu \neq \mu_0$

or versus a one-sided alternative:

$H_a: \mu < \mu_0 \text{ or } H_a: \mu > \mu_0$

where $\mu$ is the true mean and $\mu_0$ is the null mean or reference value. The difference to detect is an amount, $\Delta$, away from $\mu_0$ that one considers important to detect. For the same significance level and power, a larger sample size is needed to detect a small difference than to detect a large difference. It is assumed that the population of interest is normally distributed with mean $\mu$ and standard deviation $\sigma$.

**Power Explorer for One Sample Mean Options**

Set study assumptions and explore sample sizes using the radio buttons, text boxes, and sliders. The curve updates as you make changes to the settings. Alternatively, change settings by dragging the cross hairs on the curve or adjusting the values in the axis text boxes.

**Test Type**  Specifies a one or two-sided hypothesis test.

**Fixed Parameters**

**Alpha**  Specifies the probability of a type I error, which is the probability of rejecting the null hypothesis when it is true. It is commonly referred to as the *significance level* of the test. The default alpha level is 0.05.

**Std Dev (\(\sigma\))**  Specifies the assumed standard deviation.

**Tip:** Use a standard deviation of 1 to estimate the sample size needed to detect differences measured in standard deviation units.

**Population standard deviation known**  Specifies use of calculations based on a known population standard deviation.

**Test Parameters**  Parameters that are inter-related and update as you make changes.

**Difference to detect (\(\Delta\))**  Specifies smallest difference between the true mean and the hypothesized or reference mean that you want to be able to declare statistically significant.

**Sample Size**  Specifies the total number of observations (runs, experimental units, or samples) needed for your experiment.

**Power**  Specifies the probability of rejecting the null hypothesis when it is false. With all other parameters fixed, power increases as sample size increases.

**Save Settings**  Saves the current settings to the Saved Settings table. This enables you to save a set of alternative study plans. See “Saved Settings in the Sample Size Explorers” on page 780.

**Make Data Collection Table**  Creates a new data table that you can use for data collection.

### Statistical Details for One Sample Power

The one sample mean calculations are based on the traditional t test when σ is unknown. For the case when σ is known, the calculations use the z test. For the case when σ is unknown, the power is calculated according to the alternative hypothesis.

For a one-sided, higher alternative:

\[
Pr(\mu > \mu_0 | \mu = \mu_0 + \delta) = 1 - T\left(t_{1-\alpha, n-1}; n-1, \frac{\delta}{s/(\sqrt{n})}\right)
\]

For a one-sided, lower alternative:

\[
Pr(\mu < \mu_0 | \mu = \mu_0 - \delta) = T\left(-t_{1-\alpha, n-1}; n-1, \frac{\delta}{s/(\sqrt{n})}\right)
\]

For a two-sided alternative:

\[
Pr(\mu \neq \mu_0 | \mu = \mu_0 \pm \delta) = 1 - T\left(t_{1-\alpha/2, n-1}; n-1, \frac{\delta}{s/(\sqrt{n})}\right) + T\left(-t_{1-\alpha/2, n-1}; n-1, \frac{\delta}{s/(\sqrt{n})}\right)
\]

where:

- \(\alpha\) is the significance level
- \(n\) is the sample size
- \(s\) is the standard deviation
- \(\delta\) is the difference to detect
- \(t_{1-\alpha, \nu}\) is the \((1 - \alpha)\)th quantile of the central t-distribution with \(\nu\) degrees of freedom
- \(T(t; \nu, \lambda)\) is the cumulative distribution function of the non-central t distribution with \(\nu\) degrees of freedom and non-centrality parameter \(\lambda\).

When σ is known the z distribution and σ are used in the above equations for the power calculations. Because closed-form solutions for \(\delta\) and \(n\) do not exist, numerical routines are used to solve for them.
Power for One Sample Proportion

Use the Power Explorer for One Sample Proportion to determine a sample size for a hypothesis test about one proportion. Select **DOE > Sample Size Explorers > Power > Power for One Sample Proportion.** Explore the trade-offs between sample size, power, significance, and the hypothesized difference to detect. Sample size and power are associated with the following hypothesis test:

\[ H_0: p = p_0 \]

versus the two-sided alternative:

\[ H_a: p \neq p_0 \]

or versus a one-sided alternative:

\[ H_a: p < p_0 \text{ or } H_a: p > p_0 \]

where \( p \) is the population proportion and \( p_0 \) is the null proportion.

**Power Explorer for One Sample Proportion Options**

Set study assumptions and explore sample sizes using the radio buttons, text boxes, and sliders. The curve updates as you make changes to the settings. Alternatively, change settings by dragging the cross hairs on the curve or adjusting the values in the axis text boxes.

**Test Type**  Specifies a one or two-sided hypothesis test.

**Model Type**

- **Exact Test**  Specifies calculations based on the Clopper-Pearson methodology.
- **Normal Approximation**  Specifies calculations based on the normal approximation methodology.

**Tip:** Since the binomial distribution is discrete, the actual test size can differ significantly from the stated Alpha level for small samples or proportions near 0 or 1. To guarantee an alpha level equal to or greater than your stated level, use the Exact test.

**Fixed Parameters**

- **Alpha**  Specifies the probability of a type I error, which is the probability of rejecting the null hypothesis when it is true. It is commonly referred to as the significance level of the test. The default alpha level is 0.05.

**Test Parameters**  Parameters that are inter-related and update as you make changes.
**Assumed proportion (p0)**  Specifies the proportion that you anticipate or assume for your study, the null hypothesis value.

**Alternative proportion (pA)**  Specifies the proportion that you test against, the alternative hypothesis value.

**Sample Size**  Specifies the total number of observations (runs, experimental units, or samples) needed for your experiment.

**Power**  Specifies the probability of rejecting the null hypothesis when it is false. With all other parameters fixed, power increases as sample size increases.

**Save Settings**  Saves the current settings to the Saved Settings table. This enables you to save a set of alternative study plans. See “Saved Settings in the Sample Size Explorers” on page 780.

**Make Data Collection Table**  Creates a new data table that you can use for data collection.

**Statistical Details for the One Sample Proportion Explorer**

For the exact test, the power is computed based on the form of the alternative hypothesis.

For one-sided, higher alternative:

\[
\Pr(p > p_0 | p = p_a) = \sum_{x = x_1 - \alpha, n, p_0}^{n} \left( \frac{n}{x} \right) p_a^x (1 - p_a)^{n-x}
\]

for a one-sided, lower alternative:

\[
\Pr(p < p_0 | p = p_a) = \sum_{x = x_0}^{x_\alpha, n, p_0 - 1} \left( \frac{n}{x} \right) p_a^x (1 - p_a)^{n-x}
\]

for a two-sided alternative:

\[
\Pr(p \neq p_0 | p = p_a) = \sum_{x = x_1 - \alpha/2, n, p_0}^{n} \left( \frac{n}{x} \right) p_a^x (1 - p_a)^{n-x} + \sum_{x = x_0}^{x = x_{\alpha/2, n, p_0 - 1}} \left( \frac{n}{x} \right) p_a^x (1 - p_a)^{n-x}
\]

where \( x_{q,n,p} \) is the \( q \)th quantile of a binomial distribution with \( n \) trials and probability \( p \).

For the normal approximation, the power is computed based on the form of the alternative hypothesis.

For a one-sided, higher alternative:
Sample Size Explorers
Power Explorers for Hypothesis Tests
Chapter 28
Design of Experiments Guide

For a one-sided, lower alternative:

\[
\Pr(p < p_0|p = p_a) = \Phi \left( -z_{1-\alpha} \sqrt{\frac{\sigma_0^2(1-\sigma_0^2)}{\sigma_a^2(1-\sigma_a^2)}} - \frac{(p_a - p_0)}{\sqrt{n}} \right)
\]

For a two-sided alternative:

\[
\Pr(p \neq p_0|p = p_a) = 1 - \Phi \left( z_{1-\alpha/2} \sqrt{\frac{\sigma_0^2(1-\sigma_0^2)}{\sigma_a^2(1-\sigma_a^2)}} - \frac{(p_a - p_0)}{\sqrt{n}} \right) + \Phi \left( -z_{1-\alpha/2} \sqrt{\frac{\sigma_0^2(1-\sigma_0^2)}{\sigma_a^2(1-\sigma_a^2)}} - \frac{(p_a - p_0)}{\sqrt{n}} \right)
\]

**Power for One Sample Variance**

Use the Power Explorer for One Sample Variance to determine a sample size for a hypothesis test about one variance. Select **DOE > Sample Size Explorers > Power > Power for One Sample Variance**. Explore the trade offs between sample size, power, significance, and the hypothesized difference to detect (defined as a ratio between the null and alternative hypothesis values). Sample size and power are associated with the following hypothesis test:

\[H_0: \sigma = \sigma_0\]

versus the two-sided alternative:

\[H_a: \sigma \neq \sigma_0\]

or versus a one-sided alternative:

\[H_a: \sigma < \sigma_0\] or \[H_a: \sigma > \sigma_0\]
where \( \sigma \) is the true variance and \( \sigma_0 \) is the null variance or reference value. The difference to detect is an amount away from \( \sigma_0 \) that one considers as important to detect based on a set of samples. This difference is expressed as the ratio of \( \sigma_0/\sigma \), or the ratio of your null variance and your assumed variance under the alternative hypothesis. For the same significance level and power, a larger sample size is needed to detect a small difference in variances than to detect a large difference. It is assumed that the population of interest is normally distributed with mean \( \mu \) and standard deviation \( \sigma \).

**Power Explorer for One Sample Variance Options**

Set study assumptions and explore sample sizes using the radio buttons, text boxes, and sliders. The curve updates as you make changes to the settings. Alternatively, change settings by dragging the cross hairs on the curve or adjusting the values in the axis text boxes.

- **Test Type**  Specifies a one or two-sided hypothesis test.

- **Fixed Parameters**
  - **Alpha**  Specifies the probability of a type I error, which is the probability of rejecting the null hypothesis when it is true. It is commonly referred to as the significance level of the test. The default alpha level is 0.05.

- **Test Parameters**  Parameters that are inter-related and update as you make changes.
  - **Ratio of variances (Null/Alternative)**  Specifies the ratio of the variance under the null hypothesis (reference variance) to the variance under the alternative hypothesis (expected variance).
  - **Sample Size**  Specifies the total number of observations (runs, experimental units, or samples) needed for your experiment.
  - **Power**  Specifies the probability of rejecting the null hypothesis when it is false. With all other parameters fixed, power increases as sample size increases.

- **Save Settings**  Saves the current settings to the Saved Settings table. This enables you to save a set of alternative study plans. See “Saved Settings in the Sample Size Explorers” on page 780.

- **Make Data Collection Table**  Creates a new data table that you can use for data collection.

**Statistical Details for the One Sample Variance Explorer**

The power calculations for testing the variance of one sample group is based on the \( \chi^2 \) test. Calculations are based on the form of the alternative hypothesis.

For a one-sided, higher alternative:
\[ \Pr(\sigma > \sigma_0 \mid \sigma = \sigma_0 / \rho) = 1 - \chi^2(\rho x_{1-\alpha/2, n-1}; n-1) \]

for a one-sided, lower alternative:

\[ \Pr(\sigma < \sigma_0 \mid \sigma = \sigma_0 / \rho) = \chi^2(\rho x_{\alpha, n-1}; n-1) \]

for a two-sided alternative:

\[ \Pr(\sigma \neq \sigma_0 \mid \sigma = \sigma_0 / \rho) = 1 - \chi^2(\rho x_{1-\alpha/2, n-1}; n-1) + \chi^2(\rho x_{\alpha/2, n-1}; n-1) \]

where:

- \( \alpha \) is the significance level
- \( n \) is the sample size
- \( \rho = \sigma_d / \sigma_0 \)
- \( x_{1-\alpha,v} \) is the \((1 - \alpha)\)th quantile of a central \( \chi^2 \) distribution with \( v \) degrees of freedom
- \( \chi^2(x, v) \) is the cumulative distribution function of a central \( \chi^2 \) distribution with \( v \) degrees of freedom.

### Power for One Sample Equivalence

Use the Power Explorer for One Sample Equivalence to determine a sample size for an equivalence test about one mean. Select **DOE > Sample Size Explorers > Power > Power for One Sample Equivalence**. Explore the trade-offs between variability assumptions, sample size, power, significance, and the equivalence range. Sample size and power are associated with the following hypothesis test:

\[ H_0: \mu - \mu_0 \geq \delta_M \mid \text{or } H_0: \mu - \mu_0 \leq \delta_m \]

versus the alternative:

\[ H_a: \delta_m < \mu - \mu_0 < \delta_M \]

where \( \mu \) is the true mean, \( \mu_0 \) is the reference value, and \((\delta_m, \delta_M)\) is the equivalence range. For the same significance level and power, a larger sample size is needed to detect a small difference than to detect a large difference. It is assumed that the population of interest is normally distributed with mean \( \mu \) and standard deviation \( \sigma \).

### Power Explorer for One Sample Equivalence Options

Set study assumptions and explore sample sizes using the radio buttons, text boxes, and sliders. The curve updates as you make changes to the settings. Alternatively, change settings by dragging the cross hairs on the curve or adjusting the values in the axis text boxes.
**Equivalence Range**

**Maximum difference**  Specifies the maximum value, above which the mean is considered different from the reference mean.

**Minimum difference**  Specifies the minimum value, below which the mean is considered different from the reference mean.

**Note:** Typically, the equivalence range is symmetric.

**Fixed Parameters**

**Alpha**  The probability of a type I error, which is the probability of rejecting the null hypothesis when it is true. It is commonly referred to as the significance level of the test. The default alpha level is 0.05.

**Std Dev (σ)**  The assumed standard deviation.

**Population standard deviation known**  Specifies calculations based on a known population standard deviation.

**Test Parameters**  Parameters that are inter-related and update as you make changes.

**Difference in Means**  Specifies the difference between the true mean and the hypothesized or reference mean such that the two means are considered equivalent.

**Sample Size**  Specifies the total number of observations (runs, experimental units, or samples) needed for your experiment.

**Power**  Specifies the probability of rejecting the null hypothesis when it is false. With all other parameters fixed, power increases as sample size increases.

**Save Settings**  Saves the current settings to the Saved Settings table. This enables you to save a set of alternative study plans. See “Saved Settings in the Sample Size Explorers” on page 780.

**Make Data Collection Table**  Creates a new data table that you can use for data collection.

**Statistical Details for the One Sample Equivalence Explorer**

The power calculations for testing equivalence in one sample group is based on methods described in Chow et al. (2008).

If σ is unknown, the power (1-β) is computed as:

\[
1 - \beta = T\left(-t_{1 - \alpha, n - 1, n - 1}, \frac{\delta - \delta_M}{s/(\sqrt{n})}\right) - T\left(t_{1 - \alpha, n - 1, n - 1}, \frac{\delta - \delta_M}{s/(\sqrt{n})}\right)
\]
where:

\( \alpha \) is the significance level
\( n \) is the sample size
\( s \) is the standard deviation
\( \delta \) is the difference to detect
\( (\delta_{m_1}, \delta_{M}) \) is the equivalence range
\( t_{1-\alpha, v} \) is the \((1 - \alpha)\)th quantile of the central \( t \)-distribution with \( v \) degrees of freedom
\( T(t; v, \lambda) \) is the cumulative distribution function of the non-central \( t \) distribution with \( v \) degrees of freedom and non-centrality parameter \( \lambda \).

If \( \sigma \) is known, then power \((1-\beta)\) is computed as:

\[
1 - \beta = \Phi\left(\frac{\delta - \delta_M}{\sigma/\sqrt{n} - z_{1-\alpha}}\right) + \Phi\left(\frac{\delta - \delta_m}{\sigma/\sqrt{n} - z_{1-\alpha}}\right) - 1
\]

**Power for Two Independent Sample Means**

Use the Power Explorer for Two Independent Sample Means to determine a sample size for a hypothesis test about the means from two groups. Select **DOE > Sample Size Explorers > Power > Power for Two Independent Sample Means**. Explore the trade offs between sample size, power, significance, and the hypothesized difference to detect. Sample size and power are associated with the following hypothesis test:

\[ H_0: \mu_1 - \mu_2 = 0 \]

versus the two-sided alternative:

\[ H_a: \mu_1 - \mu_2 \neq 0 \]

or versus a one-sided alternative:

\[ H_a: \mu_1 - \mu_2 < 0 \text{ or } H_a: \mu_1 - \mu_2 > 0 \]

where \( \mu_1 \) and \( \mu_2 \) are the true means of the two populations. It is assumed that the populations of interest are normally distributed and that you want to detect a difference of \( \delta \) between the means.

**Power Explorer for Two Independent Sample Means Options**

Set study assumptions and explore sample sizes using the radio buttons, text boxes, and sliders. The curve updates as you make changes to the settings. Alternatively, change settings by dragging the cross hairs on the curve or adjusting the values in the axis text boxes.
Test Type  Specifies a one or two-sided hypothesis test.

Fixed Parameters

Alpha  Species the probability of a type I error, which is the probability of rejecting the null hypothesis when it is true. It is commonly referred to as the significance level of the test. The default alpha level is 0.05.

Group 1 StdDev (\(\sigma_1\))  Specifies the assumed standard deviation for one of your groups, Group 1. An estimate of the error standard deviation could be the root mean square error (RMSE) from a previous model fit.

Group 2 StdDev (\(\sigma_2\))  Specifies the assumed standard deviation for the second group, Group 2. An estimate of the error standard deviation could be the root mean square error (RMSE) from a previous model fit.

Population standard deviations known  Specifies calculations based on a known population standard deviations.

Test Parameters  Difference to detect (\(\Delta\))  Specifies the smallest difference between the group means that you want to be able to declare statistically significant.

Group 1 Sample Size  Specifies the number of observations (runs, experimental units, or samples) needed for Group 1 in your experiment. Select Lock to lock the Group 1 sample size.

Group 2 Sample Size  Specifies the number of observations (runs, experimental units, or samples) needed for Group 2 in your experiment. Select Lock to lock the Group 2 sample size.

Total Sample Size  Specifies the total number of observations (runs, experimental units, or samples) needed for your experiment. The power curve is based on total sample size.

Tip: Adjusting the sample size for one group impacts the sample size for the second group while the total sample size remains unchanged. Adjusting the total sample size adjusts the two groups proportionally, unless one group is locked. Only one group sample size can be locked.

Power  Specifies the probability of rejecting the null hypothesis when it is false. With all other parameters fixed, power increases as sample size increases.

Save Settings  Saves the current settings to the Saved Settings table. This enables you to save a set of alternative study plans. See “Saved Settings in the Sample Size Explorers” on page 780.

Make Data Collection Table  Creates a new data table that you can use for data collection.
Statistical Details for Two Independent Means

The power calculations for testing the difference in means of two sample groups are based on the traditional t test, or if \( \sigma_1 \) and \( \sigma_2 \) are known, the z test.

For the case when \( \sigma \) is unknown and it is assumed that \( \sigma_1=\sigma_2=\sigma \), the power is calculated based on the form of the alternative hypothesis. For a one-sided, higher alternative:

\[
\Pr(\mu_1 > \mu_2 \mid \mu_1 = \mu_2 + \delta) = 1 - T\left( t_{1-\alpha, n_1+n_2-2; n_1+n_2-2, \delta \sqrt{\frac{1}{n_1 + 1} + \frac{1}{n_2}}} \right)
\]

For a one-sided, lower alternative:

\[
\Pr(\mu_1 < \mu_2 \mid \mu_1 = \mu_2 - \delta) = T\left( -t_{1-\alpha, n_1+n_2-2; n_1+n_2-2, \delta \sqrt{\frac{1}{n_1 + 1} + \frac{1}{n_2}}} \right)
\]

For a two-sided alternative:

\[
\Pr(\mu_1 \neq \mu_2 \mid \mu_1 = \mu_2 \pm \delta) =
1 - T\left( t_{1-\alpha, n_1+n_2-2; n_1+n_2-2, \delta \sqrt{\frac{1}{n_1 + 1} + \frac{1}{n_2}}} \right) + T\left( t_{1-\alpha, n_1+n_2-2; n_1+n_2-2, \delta \sqrt{\frac{1}{n_1 + 1} + \frac{1}{n_2}}} \right)
\]

where:

- \( \alpha \) is the significance level
- \( n_1 \) and \( n_2 \) are the group sample sizes
- \( s \) is the pooled standard deviation
- \( \delta \) is the difference to detect
- \( t_{1-\alpha, v} \) is the \((1 - \alpha)\)th quantile of the central t-distribution with \( v \) degrees of freedom
- \( T(t; v, \lambda) \) is the cumulative distribution function of the non-central t distribution with \( v \) degrees of freedom and non-centrality parameter \( \lambda \).

When \( \sigma_1 \) and \( \sigma_2 \) are not assumed to be equal then the degrees of freedom, \( n_1 + n_2 - 2 \) in the above equations, are set to:
When $\sigma_1$ and $\sigma_2$ are known the $z$ distribution is used for the power calculation. The power is calculated based on the form of the alternative hypothesis. For a one-sided, higher alternative:

$$
Pr(\mu_1 > \mu_2 \mid \mu_1 = \mu_2 + \delta) = 1 - \Phi \left( z_{1-\alpha} - \frac{\delta}{\sqrt{\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}}} \right)
$$

For a one-sided, lower alternative:

$$
Pr(\mu_1 < \mu_2 \mid \mu_1 = \mu_2 - \delta) = \Phi \left( -z_{1-\alpha} - \frac{\delta}{\sqrt{\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}}} \right)
$$

For a two-sided alternative:

$$
Pr(\mu_1 \neq \mu_2 \mid \mu_1 = \mu_2 \pm \delta) = 1 - \Phi \left( z_{\frac{1-\alpha}{2}} - \frac{\delta}{\sqrt{\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}}} \right) + \Phi \left( -z_{1-\alpha} - \frac{\delta}{\sqrt{\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}}} \right)
$$

where:

- $\alpha$ is the significance level
- $n_1$ and $n_2$ are the group sample sizes
- $\sigma_1$ and $\sigma_2$ are known group standard deviations
- $\delta$ is the difference to detect
- $z_{1-\alpha}$ is the $(1 - \alpha)^{th}$ quantile of the $z$-distribution
- $\Phi(x)$ is the cumulative distribution function of the normal distribution.
Power for Two Independent Sample Proportions

Use the Power Explorer for Two Independent Sample Proportions to determine a sample size for a hypothesis test for proportions from two groups. Select **DOE > Sample Size Explorers > Power > Power for Two Independent Sample Proportions**. Explore the trade offs between sample size, power, significance, and the hypothesized difference to detect. Sample size and power are associated with the following hypothesis test:

$$H_0: p_1 - p_2 = D_0$$

versus the two-sided alternative:

$$H_a: p_1 - p_2 \neq D_0$$

or versus either of the following one-sided alternatives:

$$H_a: (p_1 - p_2) < D_0 \quad \text{or} \quad H_a: (p_1 - p_2) > D_0$$

where $p_1$ and $p_2$ are the population proportions from two populations, and $D_0$ is the hypothesized difference in proportions.

**Power Explorer for Two Independent Sample Proportions Options**

Set study assumptions and explore sample sizes using the radio buttons, text boxes, and sliders. The curve updates as you make changes to the settings. Alternatively, change settings by dragging the cross hairs on the curve or adjusting the values in the axis text boxes.

**Test Type**  Specifies a one or two-sided hypothesis test.

**Fixed Parameters**

**Alpha**  Specifies the probability of a type I error, which is the probability of rejecting the null hypothesis when it is true. It is commonly referred to as the significance level of the test. The default alpha level is 0.05.

**Test Parameters**  Parameters that are inter-related and update as you make changes.

**Group 1 proportion (p1)**  Specifies the proportion that you anticipate or assume for Group 1.

**Group 2 proportion (p2)**  Specifies the proportion that you anticipate or assume for Group 2.

**Group 1 Sample Size**  Specifies the number of observations (runs, experimental units, or samples) needed for Group 1 in your experiment. Select Lock to lock the Group 1 sample size.
**Group 2 Sample Size**  Specifies the number of observations (runs, experimental units, or samples) needed for Group 2 in your experiment. Select Lock to lock the Group 2 sample size.

**Total Sample Size**  Specifies the total number of observations (runs, experimental units, or samples) needed for your experiment. The power curve is based on total sample size.

**Tip:** Adjusting the sample size for one group impacts the sample size for the second group while the total sample size remains unchanged. Adjusting the total sample size adjusts the two groups proportionally, unless one group is locked. Only one group sample size can be locked.

**Power**  Specifies the probability of rejecting the null hypothesis when it is false. With all other parameters fixed, power increases as sample size increases.

**Save Settings**  Saves the current settings to the Saved Settings table. This enables you to save a set of alternative study plans. See “Saved Settings in the Sample Size Explorers” on page 780.

**Make Data Collection Table**  Creates a new data table that you can use for data collection.

### Statistical Details for Two Independent Sample Proportions

The power calculations for testing the difference in proportions from two sample groups are based on the normal approximation. The calculations depend on the form of the alternative hypothesis. For a one-sided, higher alternative:

\[
Pr(p_1 > p_2 \mid p_1 = p_2 + \delta) = 1 - \Phi \left( z_{1 - \alpha} - \frac{\delta}{\sqrt{\frac{p_1(1-p_1)}{n_1} + \frac{p_2(1-p_2)}{n_2}}} \right)
\]

For a one-sided, lower alternative:

\[
Pr(p_1 > p_2 \mid p_1 = p_2 - \delta) = \Phi \left( -z_{1 - \alpha} - \frac{\delta}{\sqrt{\frac{p_1(1-p_1)}{n_1} + \frac{p_2(1-p_2)}{n_2}}} \right)
\]

For a two-sided alternative:

\[
Pr(p_1 \neq p_2 \mid p_1 = p_2 \pm \delta) =
\]
where:

- $\alpha$ is the significance level
- $n_1$ and $n_2$ are the group sample sizes
- $p_1$ and $p_2$ are known group standard deviations
- $\delta$ is the difference to detect
- $z_{1-\alpha}$ is the $(1 - \alpha)^{th}$ quantile of the $z$-distribution
- $\Phi(x)$ is the cumulative distribution function of the normal distribution.

### Power for Two Independent Sample Variances

Use the Power Explorer for Two Independent Sample Variances to determine a sample size for a hypothesis test for variances from two groups. Select **DOE > Sample Size Explorers > Power > Power for Two Independent Sample Variances**. Explore the trade offs between sample size, power, significance, and the hypothesized difference to detect. Sample size and power are associated with the following hypothesis test:

$$H_0: \sigma_1 = \sigma_2$$

versus the two-sided alternative:

$$H_a: \sigma_1 \neq \sigma_2$$

or versus a one-sided alternative:

$$H_a: \sigma_1 < \sigma_2 \text{ or } H_a: \sigma_1 > \sigma_2$$

where $\sigma_1$ is the variance for Group 1 and $\sigma_2$ is the variance for Group 2. The difference to detect is an amount away from $\sigma_2$ that one considers as important to detect based on a set of samples. This difference is expressed as the ratio of $\sigma_2/\sigma_1$, or the ratio of your variances. For the same significance level and power, a larger sample size is needed to detect a small difference in variances than to detect a large difference. It is assumed that the populations of interest are normally distributed.
Power Explorer for Two Independent Sample Variances Options

Set study assumptions and explore sample sizes using the radio buttons, text boxes, and sliders. The curve updates as you make changes to the settings. Alternatively, change settings by dragging the cross hairs on the curve or adjusting the values in the axis text boxes.

Test Type  Specifies a one or two-sided hypothesis test.

Fixed Parameters

Alpha  Specifies the probability of a type I error, which is the probability of rejecting the null hypothesis when it is true. It is commonly referred to as the significance level of the test. The default alpha level is 0.05.

Test Parameters  Parameters that are inter-related and update as you make changes.

Ratio of variances (Group 2/Group 1)  Specifies the ratio of the variances.

Group 1 Sample Size  Specifies the number of observations (runs, experimental units, or samples) needed for Group 1 in your experiment. Select Lock to lock the Group 1 sample size.

Group 2 Sample Size  Specifies the number of observations (runs, experimental units, or samples) needed for Group 2 in your experiment. Select Lock to lock the Group 2 sample size.

Total Sample Size  Specifies the total number of observations (runs, experimental units, or samples) needed for your experiment. The power curve is based on total sample size.

Tip: Adjusting the sample size for one group impacts the sample size for the second group while the total sample size remains unchanged. Adjusting the total sample size adjusts the two groups proportionally, unless one group is locked. Only one group sample size can be locked.

Power  Specifies the probability of rejecting the null hypothesis when it is false. With all other parameters fixed, power increases as sample size increases.

Statistical Details for the Two Independent Sample Variances Explorer

The power calculations for testing the ratio of variances from two sample groups is based on the standard F test. The calculations depend on the form of the alternative hypothesis. For a one-sided, higher alternative:

\[
Pr(\sigma_0 > \sigma_1 \mid \sigma_1 = \sigma_0 \rho) = 1 - F(\rho f_1 - \alpha, n_1 - 1, n_2 - 1; n_1 - 1, n_2 - 1)
\]
For a one-sided, lower alternative:

\[
\Pr(\sigma_0 < \sigma_1 \mid \sigma_1 = \sigma_0 \rho) = F(\rho f_{\alpha}, n_1-1, n_2-1; n_1-1, n_2-1)
\]

For a two-sided alternative:

\[
\Pr(\sigma_0 \neq \sigma_1 \mid \sigma_1 = \sigma_0 \rho) =
1 - F\left(\rho f_{1-\alpha}, n_1-1, n_2-1; n_1-1, n_2-1\right) + F\left(\rho f_{\alpha}, n_1-1, n_2-1; n_1-1, n_2-1\right)
\]

where:

- \(\alpha\) is the significance level
- \(n_1\) and \(n_2\) are the group sample sizes
- \(\rho = \sigma_1 / \sigma_0\)
- \(f_{1-\alpha, v_1, v_2}\) is the \((1 - \alpha)\)th quantile of an \(F\) distribution with \(v_1\) and \(v_2\) degrees of freedom
- \(F(x, v)\) is the cumulative distribution function of an \(F\) distribution with \(v\) degrees of freedom.

**Power for Two Independent Sample Equivalence**

Use the Power Explorer for Two Sample Equivalence to determine a sample size for an equivalence test of two groups. Select **DOE > Sample Size Explorers > Power > Power for Two independent Sample Equivalence**. Explore the trade offs between variability assumptions, sample size, power, significance, and the equivalence range. Sample size and power are associated with the following hypothesis test:

\[
H_0: \mu_1 - \mu_2 \geq \delta_M \quad \text{or} \quad H_0: \mu_1 - \mu_2 \leq \delta_m
\]

versus the alternative:

\[
H_a: \delta_m < \mu_1 - \mu_2 < \delta_M
\]

where \(\mu_1\) and \(\mu_2\) the true group means and \((\delta_m, \delta_M)\) is the equivalence range. For the same significance level and power, a larger sample size is needed to detect a small difference than to detect a large difference. It is assumed that the populations of interest are normally distributed.
Power Explorer for Two Independent Sample Equivalence Options

Set study assumptions and explore sample sizes using the radio buttons, text boxes, and sliders. The curve updates as you make changes to the settings. Alternatively, change settings by dragging the cross hairs on the curve or adjusting the values in the axis text boxes.

Equivalence Range

- **Maximum difference**: Specifies the margin above which the mean is considered different from the reference mean.
- **Minimum difference**: Specifies the margin below which the mean is considered different from the reference mean.

**Note**: Typically, the equivalence margin is symmetric. However, it does not have to be symmetric.

Fixed Parameters

- **Alpha**: Specifies the probability of a type I error, which is the probability of rejecting the null hypothesis when it is true. It is commonly referred to as the significance level of the test. The default alpha level is 0.05.
- **Group 1 StdDev (σ₁)**: Specifies the assumed standard deviation for one of your groups, Group 1.
- **Group 2 StdDev (σ₂)**: Specifies the assumed standard deviation for the second group, Group 2.
- **Population standard deviations known**: Specifies calculations based on a known population standard deviations.

Test Parameters

- **Difference in Means**: Specifies the difference between group means that defines the equivalence range.
- **Group 1 Sample Size**: Specifies the number of observations (runs, experimental units, or samples) needed for Group 1 in your experiment. Select Lock to lock the Group 1 sample size.
- **Group 2 Sample Size**: Specifies the number of observations (runs, experimental units, or samples) needed for Group 2 in your experiment. Select Lock to lock the Group 2 sample size.
- **Total Sample Size**: Specifies the total number of observations (runs, experimental units, or samples) needed for your experiment. The power curve is based on total sample size.
**Tip:** Adjusting the sample size for one group impacts the sample size for the second group while the total sample size remains unchanged. Adjusting the total sample size adjusts the two groups proportionally, unless one group is locked. Only one group sample size can be locked.

**Power**  Specifies the probability of rejecting the null hypothesis when it is false. With all other parameters fixed, power increases as sample size increases.

**Save Settings**  Saves the current settings to the Saved Settings table. This enables you to save a set of alternative study plans. See “Saved Settings in the Sample Size Explorers” on page 780.

**Make Data Collection Table**  Creates a new data table that you can use for data collection.

**Statistical Details for the Two Independent Sample Equivalence Explorer**

The power calculations for testing equivalence of two group means is based on methods described in Chow et al. (2008).

If \( \sigma_1 \) and \( \sigma_2 \) are unknown, the power \((1-\beta)\) is computed as:

\[
1 - \beta = \begin{cases} 
-t_{1 - \alpha, df} \frac{\delta - \delta_M}{\sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}}} - T_{1 - \alpha, df} \frac{\delta - \delta_m}{\sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}}} \\
-t_{1 - \alpha, df} \frac{\delta - \delta_M}{\sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}}} + T_{1 - \alpha, df} \frac{\delta - \delta_m}{\sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}}} 
\end{cases}
\]

where:

\[
df = \begin{cases} 
\frac{n_1 + n_2 - 2}{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}} & \text{if } \sigma_1 = \sigma_2 \\
\frac{1}{n_1 - 1} \left(\frac{s_1^2}{n_1}\right)^2 + \frac{1}{n_2 - 1} \left(\frac{s_2^2}{n_2}\right)^2 & \text{if } \sigma_1 \neq \sigma_2
\end{cases}
\]

\( \alpha \) is the significance level

\( n_1 \) and \( n_2 \) are the group sample sizes

\( s_1 \) and \( s_2 \) are the group is the standard deviations

\( \delta \) is the difference to detect
(\delta_m, \delta_M) is the equivalence range

\( t_{1-\alpha,\nu} \) is the \((1 - \alpha)^{th}\) quantile of the central \(t\)-distribution with \( \nu\) degrees of freedom

\( T(t; \nu, \lambda) \) is the cumulative distribution function of the non-central \(t\) distribution with \( \nu\) degrees of freedom and non-centrality parameter \( \lambda\).

If \( \sigma\) is known, then power \((1-\beta)\) is computed as:

\[
1 - \beta = \Phi \left( \frac{\delta - \delta_M}{\sqrt{\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}}} - z_{1-\alpha} \right) + \Phi \left( \frac{\delta - \delta_M}{\sqrt{\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}}} - z_{1-\alpha} \right) - 1
\]

**Power for ANOVA**

Use the Power Explorer for ANOVA to determine a sample size for a study of \( k \) groups or treatments to be analyzed using ANOVA. Select **DOE > Sample Size Explorers > Power > Power for ANOVA**. Explore the trade offs between variability assumptions, sample size, power and significance. Sample size and power are associated with the following hypothesis test:

\[
H_0: \mu_1 = \mu_2 = \ldots = \mu_k
\]

versus the two-sided alternative:

\[
H_a: \text{not all means equal}
\]

where:

\[
X_{ij} \sim N(\mu_j, \sigma^2) \text{ for } i = 1, \ldots, n, \ j = 1, \ldots, k
\]

**Power Explorer for ANOVA Options**

Set study assumptions and explore sample sizes using the radio buttons, text boxes, and sliders. The curve updates as you make changes to the settings. Alternatively, change settings by dragging the cross hairs on the curve or adjusting the values in the axis text boxes.

**Fixed Parameters**

- **Alpha** Specifies the probability of a type I error, which is the probability of rejecting the null hypothesis when it is true. It is commonly referred to as the significance level of the test. The default alpha level is 0.05.

- **Number of groups** Specifies the number of groups or treatments in your experiment.
**Within-group variance** \((\sigma^2)\)  Specifies the assumed variance for each group where the standard deviation is assumed to be equal across groups.

**Test Parameters**  Parameters that are inter-related and update as you make changes.

- **Between-group variance**  Specifies the variance of the individual group means around the grand mean.

- **Sample size (per group)**  Specifies the number of observations (runs, experimental units, or treatments) needed for each group in your experiment.

- **Power**  Specifies the probability of rejecting the null hypothesis when it is false. With all other parameters fixed, power increases as sample size increases.

**Save Settings**  Saves the current settings to the Saved Settings table. This enables you to save a set of alternative study plans. See “Saved Settings in the Sample Size Explorers” on page 780.

**Make Data Collection Table**  Creates a new data table that you can use for data collection.

**Statistical Details for the ANOVA Explorer**

The power calculations for testing differences among means from multiple groups assuming equal standard deviations for each group is based on the standard F test. The power \((1-\beta)\) is computed as:

\[
1 - \beta = F\left( f_{1 - \alpha, N - K, n - 1}, \frac{\sigma^2_{BG}}{\sigma^2} \right)
\]

where

- \(F(df_1, df_2, \lambda)\) is a non-central F-distribution with noncentrality parameter \(\lambda\).
- \(K\) is the number of groups.
- \(n\) is the number of samples within each group (assumed equal for all groups).
- \(N = nK\)
- \(\sigma^2_{BG}\) is the variation of the group means around the grand mean.
- \(\sigma^2\) is the within group variance (assumed equal for all groups).
Confidence Interval Calculators

Use the confidence interval calculators to select a study sample size to obtain an interval estimate with pre-specified characteristics. Explore the impact of sample size on the margin of error of an interval estimate. Explore sample size for a confidence, prediction, or tolerance interval for one mean. Explore sample size for a confidence interval for two means, or one or two proportions or variances.

For interval estimation, select DOE > Sample Size Explorers > Confidence Intervals:

- “Margin of Error for One Sample Mean” on page 765
- “Margin of Error for One Sample Proportion” on page 768
- “Margin of Error for One Sample Variance” on page 770
- “Margin of Error for Two Independent Sample Means” on page 771
- “Margin of Error for Two Independent Sample Proportions” on page 773
- “Margin of Error for Two Independent Sample Variances” on page 776

Margin of Error for One Sample Mean

Use the Interval Explorer for one sample mean to determine a sample size for a confidence, prediction, or tolerance interval. Select DOE > Sample Size Explorers > Confidence Intervals > Margin of Error for One Sample Mean. Explore the trade offs between variability assumptions, sample size, significance, and the margin of error.

Interval Explorer for One Sample Mean Options

Set study assumptions and explore sample sizes using the radio buttons, text boxes, and sliders. The curve updates as you make changes to the settings. Alternatively, change settings by dragging the cross hairs on the curve or adjusting the values in the axis text boxes.

Interval Purpose

- **Confidence** Specifies a confidence interval for a mean.
- **Prediction** Specifies a prediction interval for one future observation.
- **Tolerance** Specifies a tolerance interval to cover a proportion of the population.

Interval Type

- **Bound** Specifies a one-sided interval (upper or lower bound)
- **Interval** Specifies a two-sided interval.
Fixed Parameters

**Alpha**  Specifies the confidence level is $1 - \alpha$. The default alpha level is 0.05 for a 95% confidence interval.

**Std Dev ($\sigma$)**  Specifies the assumed standard deviation.

**Proportion**  (Available only when Tolerance is selected for Interval Purpose.) Specifies the proportion of the population for the tolerance interval to cover.

**Population standard deviation known**  Specifies calculations based on a known population standard deviation.

Interval Parameters  Parameters that are inter-related and update as you make changes.

**Sample Size**  Specifies the total number of observations (runs, experimental units, or samples) needed to construct your interval.

**Margin of Error**  (Available only when Interval is selected for Interval Type.) Specifies the half-width of the interval. With all other parameters fixed, margin of error decreases as sample size increases.

**Bound Size**  (Available only when Bound is selected for Interval Type.) Specifies the distance from the bound to the estimate. With all other parameters fixed, the bound decreases as sample size increases.

**Save Settings**  Saves the current settings to the Saved Settings table. This enables you to save a set of alternative study plans. See “Saved Settings in the Sample Size Explorers” on page 780.

**Make Data Collection Table**  Creates a new data table that you can use for data collection.

Statistical Details for the One Sample Interval Explorer

The calculation for each interval type uses the standard normal-based procedures if $\sigma$ is known and $t$ distribution procedures or approximations otherwise.

Confidence Intervals

The margin of error (MOE) for confidence intervals is calculated as follows:

$$MOE = \begin{cases} 
  z_{1 - \alpha/2} \frac{\sigma}{\sqrt{n}} & \text{if } \sigma \text{ known} \\
  t_{1 - \alpha/2, n - 1} \frac{s}{\sqrt{n}} & \text{if } \sigma \text{ unknown}
\end{cases}$$

The bound is calculated as:
bound = \begin{cases} 
\pm z_{1 - \alpha} \frac{\sigma}{\sqrt{n}} & \text{if } \sigma \text{ known} \\
 t_{1 - \alpha, n - 1} \frac{s}{\sqrt{n}} & \text{if } \sigma \text{ unknown} 
\end{cases}

\textbf{Prediction Intervals}

The margin of error (MOE) for prediction intervals is calculated as follows:

\text{MOE} = \begin{cases} 
z_{1 - \alpha/2} \sigma \sqrt{\frac{1 + 1}{n}} & \text{if } \sigma \text{ known} \\
t_{1 - \alpha/2, n - 1} s \sqrt{\frac{1 + 1}{n}} & \text{if } \sigma \text{ unknown} 
\end{cases}

The bound is calculated as:

\text{bound} = \begin{cases} 
\pm z_{1 - \alpha} \sigma \sqrt{\frac{1 + 1}{n}} & \text{if } \sigma \text{ known} \\
\pm t_{1 - \alpha, n - 1} s \sqrt{\frac{1 + 1}{n}} & \text{if } \sigma \text{ unknown} 
\end{cases}

\textbf{Tolerance Intervals}

For the tolerance interval on a proportion \( q \) of the population, the margin of error or bound is computed based on approximate procedures described in Krishnamoorthy and Mathew (2009).

The margin of error (MOE) for tolerance intervals is calculated as follows:
Margin of Error for One Sample Proportion

Use the Interval Explorer for One Sample Proportion to determine a sample size for a confidence interval. Select DOE > Sample Size Explorers > Confidence Intervals > Margin of Error for One Sample Proportion. Explore the trade offs between the assumed proportion, sample size, significance, and the margin of error for your interval. Calculations use the Normal approximation.

Interval Explorer for One Sample Proportion Options

Set study assumptions and explore sample sizes using the radio buttons, text boxes, and sliders. The curve updates as you make changes to the settings. Alternatively, change settings by dragging the cross hairs on the curve or adjusting the values in the axis text boxes.

Interval Type

- **Bound**  Specifies a one-side of the interval (upper or lower bound)
- **Interval**  Specifies a two-sided interval.
Fixed Parameters

**Alpha**  Specifies the confidence level, 1 - Alpha. The default alpha level is 0.05 for a 95% confidence interval.

**Interval Parameters**  Parameters that are inter-related and update as you make changes.

**Proportion**  Specifies the assumed proportion for the interval.

**Sample Size**  Specifies the total number of observations (runs, experimental units, or samples) needed to construct your interval.

**Margin of Error**  Specifies the half-width of the interval. With all other parameters fixed, margin of error decreases as sample size increases.

**Save Settings**  Saves the current settings to the Saved Settings table. This enables you to save a set of alternative study plans. See “Saved Settings in the Sample Size Explorers” on page 780.

**Make Data Collection Table**  Creates a new data table that you can use for data collection.

Statistical Details for the One Sample Proportion Interval Explorer

The interval calculations for capturing a population proportion is based on the Agresti-Coull method, see Agresti and Coull(1998).

The margin of error (MOE) for confidence intervals is calculated as follows:

\[
\text{MOE} = z_{1 - \alpha/2} \sqrt{\frac{\hat{p}(1 - \hat{p})}{\tilde{n}}}
\]

The bound is calculated as:

\[
\text{bound} = \pm z_{1 - \alpha/2} \sqrt{\frac{\hat{p}(1 - \hat{p})}{\tilde{n}}}
\]

where

\[
\tilde{n} = n + z^2 \sqrt{\frac{q}{1 - q}}
\]

and

\[
\tilde{p} = \frac{np + z^2 q / 2}{\tilde{n}}
\]

and \( q = 1 - \alpha/2 \) for an interval or \( q = 1 - \alpha \) for a bound.
Margin of Error for One Sample Variance

Use the Interval Explorer for One Sample Variance to determine a sample size for a confidence interval. Select **DOE > Sample Size Explorers > Confidence Intervals > Margin of Error for One Sample Variance**. Explore the trade offs between sample size, significance, and the margin of error for your interval.

**Interval Explorer for One Sample Variance Options**

Set study assumptions and explore sample sizes using the radio buttons, text boxes, and sliders. The curve updates as you make changes to the settings. Alternatively, change settings by dragging the cross hairs on the curve or adjusting the values in the axis text boxes.

**Interval Type**
- **Lower Bound**  Specifies a one-sided lower interval.
- **Upper Bound**  Specifies a one-sided upper interval.
- **Interval**  Specifies a two-sided interval.

**Fixed Parameters**
- **Alpha**  Specifies the confidence level, 1 - Alpha. The default alpha level is 0.05 for a 95% confidence interval.

**Interval Parameters**  Parameters that are inter-related and update as you make changes.
- **Sample Size**  Specifies the total number of observations (runs, experimental units, or samples) needed to construct your interval.
- **Interval Width**  Specifies the full width of the interval. With all other parameters fixed, interval width decreases as sample size increases.

**Save Settings**  Saves the current settings to the Saved Settings table. This enables you to save a set of alternative study plans. See “Saved Settings in the Sample Size Explorers” on page 780.

**Make Data Collection Table**  Creates a new data table that you can use for data collection.

**Statistical Details for the One Sample Variance Interval Explorer**

The interval calculations for capturing a population variance is based on the $\chi^2$ distribution. Note that the interval bounds are not symmetric around the sample estimate.

The interval width is computed as:
width = \((n - 1) \left( \frac{1}{\chi_{\alpha/2, n-1}^2} - \frac{1}{\chi_{1-\alpha/2, n-1}^2} \right)\)

The lower bound is computed as:

\[
\text{lower bound} = \frac{n - 1}{\chi_{1-\alpha, n-1}^2}
\]

The upper bound is computed as:

\[
\text{upper bound} = \frac{n - 1}{\chi_{\alpha, n-1}^2}
\]

Margin of Error for Two Independent Sample Means

Use the Interval Explorer for Two Independent Sample Means to determine a sample size for a confidence interval. Select **DOE > Sample Size Explorers > Confidence Intervals > Margin of Error for Two Independent Sample Means**. Explore the trade offs between variability assumptions, sample size, significance, and the margin of error for your interval.

Interval Explorer for Two Independent Sample Mean Options

Set study assumptions and explore sample sizes using the radio buttons, text boxes, and sliders. The curve updates as you make changes to the settings. Alternatively, change settings by dragging the cross hairs on the curve or adjusting the values in the axis text boxes.

**Interval Type**

- **Bound**  Specifies a one-sided interval (upper or lower bound)
- **Interval**  Specifies a two-sided interval

**Fixed Parameters**

- **Alpha**  Specifies the confidence level, 1 - Alpha. The default alpha level is 0.05 for a 95% confidence interval.
- **Group 1 StdDev \((\sigma_1)\)**  Specifies the assumed standard deviation for one of your groups, Group 1.
- **Group 2 StdDev \((\sigma_2)\)**  Specifies the assumed standard deviation for the second group, Group 2.
- **Population standard deviations known**  Specifies calculations based on known population standard deviations.
### Interval Parameters
Parameters that are inter-related and update as you make changes.

**Group 1 Sample Size**  Specifies the number of observations (runs, experimental units, or samples) needed for Group 1 in your experiment. Select Lock to lock the Group 1 sample size.

**Group 2 Sample Size**  Specifies the number of observations (runs, experimental units, or samples) needed for Group 2 in your experiment. Select Lock to lock the Group 2 sample size.

**Total Sample Size**  Specifies the total number of observations (runs, experimental units, or samples) needed for your experiment. The margin of error curve is based on total sample size.

**Tip:** Adjusting the sample size for one group impacts the sample size for the second group while the total sample size remains unchanged. Adjusting the total sample size adjusts the two groups proportionally, unless one group is locked. Only one group sample size can be locked.

**Margin of Error**  Specifies the half-width of the interval. With all other parameters fixed, margin of error decreases as sample size increases.

**Save Settings**  Saves the current settings to the Saved Settings table. This enables you to save a set of alternative study plans. See “Saved Settings in the Sample Size Explorers” on page 780.

**Make Data Collection Table**  Creates a new data table that you can use for data collection.

### Statistical Details for the Two Independent Sample Interval Explorer

The interval calculations for capturing the difference in population means is based on the standard normal or $t$ distributions based on whether $\sigma_1$ and $\sigma_2$ are known or unknown.

The margin of error (MOE) is calculated as:

$$
MOE = \begin{cases} 
    z_{1 - \alpha/2} \sqrt{\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}} & \text{if } \sigma_1 \text{ and } \sigma_2 \text{ known} \\
    t_{1 - \alpha/2, n_1 + n_2} \sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}} & \text{if } \sigma_1 \text{ and } \sigma_2 \text{ unknown}
\end{cases}
$$

When $\sigma_1$ and $\sigma_2$ are unknown, the bounds are calculated as:
bound = \pm t_{1 - \alpha, df} \sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}}

where

$$df = \begin{cases} \frac{n_1 + n_2 - 2}{\left(\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}\right)^2} & \text{if } \sigma_1 = \sigma_2 \\ \frac{1}{n_1 - 1} \left(\frac{s_1^2}{n_1}\right)^2 + \frac{1}{n_2 - 1} \left(\frac{s_2^2}{n_2}\right)^2 & \text{if } \sigma_1 \neq \sigma_2 \end{cases}$$

When \(\sigma\) is known, the bounds are calculated as:

$$\text{bound} = \pm z_{1 - \alpha} \sqrt{\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}}$$

**Margin of Error for Two Independent Sample Proportions**

Use the Interval Explorer for Two Independent Sample Proportions to determine a sample size for a confidence interval for the difference in two proportions, for log relative risk, or for log odds. Select **DOE > Sample Size Explorers > Confidence Intervals > Margin of Error for Two Independent Sample Proportions.** Explore the trade offs between variability assumptions, sample size, significance, and the margin of error for your interval.

**Interval Explorer for Two Independent Sample Proportions Options**

Set study assumptions and explore sample sizes using the radio buttons, text boxes, and sliders. The curve updates as you make changes to the settings. Alternatively, change settings by dragging the cross hairs on the curve or adjusting the values in the axis text boxes.

**Interval Type**

- **Bound** Specifies one side of the interval (upper or lower bound)
- **Interval** Specifies a two-sided interval.

**Comparison Method**
**Difference in Proportions**  Specifies a confidence interval for the difference in two proportions \((p_1 - p_2)\).

**Log Relative Risk**  Specifies a confidence interval for the relative risk \((p_1/p_2)\) on a log scale.

**Log Odds**  Specifies a confidence interval for the odds \((p_1/(1-p_2))\) on a log scale.

**Fixed Parameters**

**Alpha**  Specifies the confidence level, 1 - Alpha. The default alpha level is 0.05 for a 95% confidence interval.

**Interval Parameters**  Parameters that are inter-related and update as you make changes.

**Group 1 Proportion**  Specifies the assumed proportion for Group 1.

**Group 2 Proportion**  Specifies the assumed proportion for Group 2.

**Group 1 Sample Size**  Specifies the number of observations (runs, experimental units, or samples) needed for Group 1 in your experiment. Select Lock to lock the Group 1 sample size.

**Group 2 Sample Size**  Specifies the number of observations (runs, experimental units, or samples) needed for Group 2 in your experiment. Select Lock to lock the Group 2 sample size.

**Total Sample Size**  Specifies the total number of observations (runs, experimental units, or samples) needed for your experiment. The margin of error curve is based on total sample size.

**Tip:** Adjusting the sample size for one group impacts the sample size for the second group while the total sample size remains unchanged. Adjusting the total sample size adjusts the two groups proportionally, unless one group is locked. Only one group sample size can be locked.

**Margin of Error**  Specifies the half-width of the interval. With all other parameters fixed, margin of error decreases as sample size increases.

**Bound Size**  Specifies the bound of the interval. With all other parameters fixed, margin of error decreases as sample size increases.

**Save Settings**  Saves the current settings to the Saved Settings table. This enables you to save a set of alternative study plans. See “Saved Settings in the Sample Size Explorers” on page 780.

**Make Data Collection Table**  Creates a new data table that you can use for data collection.
Statistical Details for the Two Independent Proportions Interval Explorer

The calculations for each interval type are based on normal approximations.

Difference in Proportions

For intervals about the difference in proportions the margin of error (MOE) is calculated as:

\[
MOE = z_{1-\alpha/2} \sqrt{\frac{p_1(1-p_1)}{n_1} + \frac{p_2(1-p_2)}{n_2}}
\]

The bounds are calculated as:

\[
\text{bound} = \pm z_{1-\alpha/2} \sqrt{\frac{p_1(1-p_1)}{n_1} + \frac{p_2(1-p_2)}{n_2}}
\]

Log Relative Risk

For the logarithm of the relative risk the margin of error (MOE) is calculated as:

\[
MOE = z_{1-\alpha/2} \sqrt{\frac{(1-p_1)}{n_1 p_1} + \frac{(1-p_2)}{n_2 p_2}}
\]

The bounds are calculated as:

\[
\text{bound} = \pm z_{1-\alpha} \sqrt{\frac{(1-p_1)}{n_1 p_1} + \frac{(1-p_2)}{n_2 p_2}}
\]

Log Odds

For the logarithm of the relative risk the margin of error is calculated as:

\[
MOE = z_{1-\alpha/2} \sqrt{\frac{1}{n_1 p_1} + \frac{1}{n_1(1-p_1)} + \frac{1}{n_2 p_2} + \frac{1}{n_2(1-p_2)}}
\]

The bounds are calculated as:

\[
\text{bound} = \pm z_{1-\alpha} \sqrt{\frac{1}{n_1 p_1} + \frac{1}{n_1(1-p_1)} + \frac{1}{n_2 p_2} + \frac{1}{n_2(1-p_2)}}
\]
Margin of Error for Two Independent Sample Variances

Use the Interval Explorer for Two Independent Sample Variance to determine a sample size for a confidence interval. Select **DOE > Sample Size Explorers > Confidence Intervals > Margin of Error for Two Independent Sample Variances.** Explore the trade offs between sample size, significance, and the margin of error for your interval.

Interval Explorer for Two Independent Sample Variances Options

Set study assumptions and explore sample sizes using the radio buttons, text boxes, and sliders. The curve updates as you make changes to the settings. Alternatively, change settings by dragging the cross hairs on the curve or adjusting the values in the axis text boxes.

Interval Type

- **Lower Bound** Specifies a one-sided lower interval.
- **Upper Bound** Specifies a one-sided upper interval.
- **Interval** Specifies a two-sided interval.

Fixed Parameters

- **Alpha** Specifies the confidence level, \(1 - \alpha\). The default alpha level is 0.05 for a 95% confidence interval.

Interval Parameters

- **Group 1 Sample Size** Specifies the number of observations (runs, experimental units, or samples) needed for Group 1 in your experiment. Select Lock to lock the Group 1 sample size.
- **Group 2 Sample Size** Specifies the number of observations (runs, experimental units, or samples) needed for Group 2 in your experiment. Select Lock to lock the Group 2 sample size.
- **Total Sample Size** Specifies the total number of observations (runs, experimental units, or samples) needed for your experiment. The margin of error curve is based on total sample size.

Tip: Adjusting the sample size for one group impacts the sample size for the second group while the total sample size remains unchanged. Adjusting the total sample size adjusts the two groups proportionally, unless one group is locked. Only one group sample size can be locked.

- **Interval Width** Specifies the full width of the interval. With all other parameters fixed, interval width decreases as sample size increases.
Save Settings  Saves the current settings to the Saved Settings table. This enables you to save a set of alternative study plans. See “Saved Settings in the Sample Size Explorers” on page 780.

Make Data Collection Table  Creates a new data table that you can use for data collection.

Statistical Details for the Ratio Two Independent Variances Interval Explorer

The interval calculations for capturing the ratio of two population variances is based on the $F$-distribution. The margin of error (MOE) is calculated as:

$$MOE = F_{1-\alpha/2, n_1-1, n_2-1} - F_{\alpha/2, n_1-1, n_2-1}$$

The lower bound is calculated as:

$$\text{lower bound} = F_{\alpha, n_1-1, n_2-1}$$

The upper bound is calculated as:

$$\text{upper bound} = F_{1-\alpha, n_1-1, n_2-1}$$

Reliability Demonstration Calculators

Use the Reliability Demonstration calculators to test a specified number of units for a specified period of time. If fewer than $k$ units fail, the demonstration passes, and you can conclude that the product reliability meets or exceeds a reliability standard.

For reliability demonstrations, select **DOE > Sample Size Explorers > Reliability**:

- “Parametric Reliability Demonstration” on page 777
- “Nonparametric Reliability Demonstration” on page 779

Parametric Reliability Demonstration

Use the Demonstration Explorer for Parametric Reliability to determine the number of units to put on test for a reliability demonstration. Select **DOE > Sample Size Explorers > Reliability > Parametric Reliability Demonstration**. Explore the trade offs between time, significance, number of failures, and the number of units to test.
Demonstration Explorer for Parametric Reliability Options

Set study assumptions and explore sample sizes using the radio buttons, text boxes, and sliders. The curve updates as you make changes to the settings. Alternatively, change settings by dragging the cross hairs on the curve or adjusting the values in the axis text boxes.

Fixed Parameters

- **Alpha**  Specifies the probability of a type I error, which is the probability of rejecting the null hypothesis when it is true. It is commonly referred to as the significance level of the test. The default alpha level is 0.05.

- **Distribution**  Specifies the assumed failure time distribution. Distributions available are: Weibull and Lognormal. For more information about these distributions, see Reliability and Survival Methods.

- **Demonstration Time**  Specifies the minimum length of time that an item under test should survive with the intended reliability.

- **Demonstration Reliability**  Specifies the probability that an item under test survives until the defined Demonstration Time of the reliability standard

- **Scale parameter**  Specifies the scale parameter for the failure time distribution.

**Note:** The Scale field is denoted Weibull $\beta$ when the specified Distribution is Weibull.

Demonstration Parameters  Parameters that are inter-related and update as you make changes.

- **Maximum failures allowed**  Specifies the maximum number of failures allowed for a successful test demonstration.

- **Sample Size**  Specifies the total number of units on test needed for your demonstration.

- **Test Time**  Specifies the length of the demonstration test in time.

**Save Settings**  Saves the current settings to the Saved Settings table. This enables you to save a set of alternative study plans. See “Saved Settings in the Sample Size Explorers” on page 780.

**Make Data Collection Table**  Creates a new data table that you can use for data collection.

Statistical Details for the Parametric Reliability Demonstration Explorer

For a parametric reliability demonstration test, the test time needed to demonstrate that the product achieves a demonstration time $T_d$ with reliability $R_d$ is computed using a Binomial distribution with probability of success computed using the assumed lifetime distribution.
Chapter 28
Sample Size Explorers
Design of Experiments Guide
Reliability Demonstration Calculators

The test time for the Weibull distribution is computed as:
\[
\text{test time} = T_d \left( \frac{-\log(P)}{\log(R_d)} \right)^{1/\beta}
\]

The test time for the lognormal distribution is computed as:
\[
\text{test time} = \exp \left( \frac{Z}{1 - e^{-\log P} - z_1 - R_d} \right)
\]

where
\[
\log P = -\log \left( \frac{S_f}{S_f + 1} \right)
\]
\[
S_f = \frac{n - c}{c + 1} \alpha, 2(n - c), 2(c + 1)
\]

and \(c\) is the maximum number of failures allowed during the demonstration.

Nonparametric Reliability Demonstration

Use the Demonstration Explorer for Nonparametric Reliability to determine the number of units to put on test for a reliability demonstration when there is not an assumed failure rate distribution. Select **DOE > Sample Size Explorers > Reliability > Nonparametric Reliability Demonstration**. Explore the trade-offs between time, significance, number of failures, and the number of units to test.

Demonstration Explorer for Nonparametric Reliability Options

Set study assumptions and explore sample sizes using the radio buttons, text boxes, and sliders. The curve updates as you make changes to the settings. Alternatively, change settings by dragging the cross hairs on the curve or adjusting the values in the axis text boxes.

**Fixed Parameters**

**Alpha**  Specifies the probability of a type I error, which is the probability of rejecting the null hypothesis when it is true. It is commonly referred to as the significance level of the test. The default alpha level is 0.05.

**Demonstration Parameters**  Parameters that are inter-related and update as you make changes.

**Maximum failures allowed**  Specifies the maximum number of failures allowed for a successful test demonstration.
Sample Size Explorers

**Sample Size**  Specifies the total number of units on test needed for your demonstration.

**Demonstration Reliability**  Specifies the probability that the item under test survives until the defined Demonstration Time of the reliability standard.

**Save Settings**  Saves the current settings to the Saved Settings table. This enables you to save a set of alternative study plans. See “Saved Settings in the Sample Size Explorers” on page 780.

**Make Data Collection Table**  Creates a new data table that you can use for data collection.

### Statistical Details for the Nonparametric Reliability Demonstration Explorer

For a nonparametric reliability demonstration test, the demonstrated reliability is computed based on the Binomial distribution. The $\alpha$ quantile of the Binomial cdf can be computed by a transformation to an $\alpha$ quantile from the $F$-distribution, see Jowett, (1963).

The reliability is calculated as:

$$ R = \frac{Sf}{Sf + 1} $$

where

$$ Sf = \frac{n - c}{c + \frac{1}{2}} \alpha, 2(n - c), 2(c + 1) $$

and $c$ is the maximum number of failures allowed during the demonstration.

### Saved Settings in the Sample Size Explorers

The Saved Settings report provides a table of saved settings enabling you to compare study scenarios. Each time you click the **Save Settings** button, a new row is added to the table. Click on a row in the table to reset the explorer to those settings. Right-click in the table and select **Columns** to display additional parameter values in the table.

The Saved Settings red triangle contains the following options:

- **Clear Selected Rows**  Removes the selected rows from the Saved Settings table.
- **Clear All**  Clears all rows from the Saved Setting table.
- **Make Table**  Creates a new a data table that contains all Saved Settings table columns including those that are hidden.
When you construct a design using the DOE platforms, column properties are saved to the data table that contains the resulting design. This appendix provides detail about only those column properties that are saved to designs that the DOE platform constructs. Examples illustrate how each column property is assigned and used by the DOE platforms. Descriptions of column properties not assigned by the DOE platforms are provided in *Using JMP*.

Some of the column properties described in this appendix are useful in general modeling situations. To use the properties more generally, you can specify them yourself. This ability is particularly useful when your design has not been created by a DOE platform. Some of the examples in this appendix illustrate situations where you add a column property on your own.

Adding and Viewing Column Properties

The DOE platforms automatically save certain column properties to the design tables that they construct. However, some of the column properties associated with designed experiments are useful in general modeling situations. To use these column properties with data tables that have not been created using DOE platforms, you can add them yourself.

Adding a Column Property

To assign a column property to one or more columns, do the following:

1. Select the column or columns to which you want to assign a property.
2. Do one of the following:
   - Right-click the header area, select Column Properties, and select the property.
   - Right-click the header area, select Column Info, and select the property from the Column Properties menu.
   - Select Cols > Column Info and select the property from the Column Properties menu.
3. In the column property panel that appears, specify values and select options as appropriate.
4. Click Apply to add the column property or click OK to add the column property and close the column properties window.

Tip: A column might already contain a property that you want to apply to other columns. Use the Standardize Attributes command to apply that property to other columns. See Using JMP.

Viewing a Column Property

To view the properties assigned to a specific column, in the columns panel, click the column property asterisk icon *. Click a property to see its settings or to edit it. Figure A.2 shows the column properties assigned to Stretch in the Bounce Data.jmp sample data table, located in the Design Experiment folder.
You can also view column properties by accessing the Column Properties list in the Column Info menu. Select the column or columns whose column properties you want to view and do one of the following:

- Right-click the header area, select **Column Info**, and select the property from the Column Properties list.
- Select **Cols > Column Info** and select the property from the Column Properties list.

### Response Limits

Using the Response Limits column property, you can specify the following:

- bounds on the range of variation for a response
- a desirability goal
- a measure of the importance of the response
- desirability values

The Response Limits column property defines a desirability function for the response. The Profiler and Contour Profiler use desirability functions to find optimal factor settings. See **Profilers**.

Figure A.3 shows the Response Limits panel in the Column Info window for the response Stretch in the Bounce Data.jmp sample data table, found in the Design Experiment folder.
The Response Limits panel consists of the following areas:

**Goal**  Select your response goal from the menu. Available goals are Maximize, Match Target, Minimize, and None. JMP defines a desirability function for the response to match the selected goal. If you specify limits, the desirability function is defined using these limits. If you do not specify limits, JMP bases the desirability function on conservative limit values derived from the distribution of the response. If None is selected as the goal, then all response values are considered equally desirable. See also “Responses” on page 87 in the “Custom Designs” chapter.

**Importance**  Enter a relative weighting for each of several responses in computing the overall desirability function. The Importance value can be any positive number. When no Importance value is specified, JMP treats all responses in a given analysis as having equal Importance values. If there is only one response, it receives Importance 1.

**Value**  Specify Lower and Upper limits and a Middle value for your response. JMP uses these values to construct a desirability function for the response. If you do not specify limits, JMP bases the desirability function on conservative limit values. If your goal is Match Target and no Middle value is specified, then the target is defined to be the midpoint of the Lower and Upper limits.

**Desirability**  Specify values that reflect the desirability of your Lower, Middle, and Upper values. Desirability values should be between 0 and 1. If you do not specify Desirability values, JMP assigns values in accordance with the selected Goal.

**Show as Graph Reference Lines**  Shows horizontal reference lines for the Lower, Middle, and Upper values in the Actual by Predicted Plot and the Prediction Profiler. This option applies only if limits are specified.
Response Limits Example

The Coffee Data.jmp sample data table (located in the Design Experiment folder) contains the results of an experiment that was performed to optimize the Strength of coffee. For a complete description of the experimental design and analysis, see “The Coffee Strength Experiment” on page 44 in the “Starting Out with DOE” chapter.

Your goal is to find factor settings that enable you to brew coffee with a target strength of 1.3, which is considered to be the most desirable value. Values less than 1.2 and greater than 1.4 are completely undesirable. The desirability of values between 1.2 and 1.4 decreases as their distance from 1.3 increases.

1. Select Help > Sample Data Library and open Design Experiment/Coffee Data.jmp.
2. In the Table panel, click the green triangle next to the DOE Dialog script.
   
   The DOE Dialog script re-creates the Custom Design dialog that was used to create the experimental design in Coffee Data.jmp.
3. Open the Responses outline.

   Figure A.4 Responses Outline in Custom Design Window

   When you designed this experiment, you specified a response Goal of Match Target with a Lower Limit of 1.2 and an Upper Limit of 1.4. Since there is only one response, you did not specify a value for Importance, because it is 1 by default. When you constructed the design table, JMP assigned the Response Limits column property to Strength.

4. Close the Custom Design window.
5. In the Coffee Data.jmp sample data table, select the Strength column and select Cols > Column Info.
6. Select Response Limits in the Column Properties list.
Notice the following:

– The Goal is set to Match Target.

– Importance is missing. When Importance is missing, JMP treats all responses in a given analysis as having equal Importance values. So JMP assigns Strength an Importance value of one.

– The Lower limit is 1.2.

– The Upper limit is 1.4.

– No Middle value is specified.

    Because no Middle value is specified, the target is defined to be the midpoint of the Lower and Upper limits, which is 1.3.

– No Desirability values are specified.

7. Select the Show as Graph Reference Lines option.

   This option shows horizontal reference lines for the Lower, Middle, and Upper values in the Actual by Predicted Plot and the Prediction Profiler.

8. Click OK.

9. In the Coffee Data.jmp data table, click the green triangle next to the Reduced Model script.

10. Click Run.

    The Prediction Profiler appears at the bottom of the report.
The desirability function for Strength appears in the plot at the right above Desirability. This plot appears because the data table contains a Response Limits column property for Strength. The Prediction Profiler also shows reference lines for the Lower and Upper limits for Strength.

11. Press Ctrl and click the Strength plot for Desirability.

Notice the following:
- JMP determines the Middle value to be the midpoint of the High and Low limits that you specified in the Response Limits column property.
- Because the Goal is set to Match Target, JMP sets the Desirability for the Middle value to 1.
- JMP sets the Desirability for the High and Low values to very small numbers, 0.0183.
- The Desirability plot in Figure A.6 shows how JMP uses the Desirability values shown in Figure A.7. The Desirability function for Strength is essentially 0 beyond the Low and High values and it increases to 1 gradually as Strength approaches the target of 1.3. The Importance value is set to 1 since there is only one response in the model.

12. Click Cancel to exit the window.
13. Click the Prediction Profiler red triangle and select **Optimization and Desirability > Maximize Desirability**.

The settings for Time and Charge are updated to show settings for the factors that maximize the desirability function for Strength. However, many other settings also maximize the desirability function. See **Profiler**s for information about how to identify other settings that maximize the desirability function.

**Editing Response Limits**

In the Vinyl Data.jmp sample data table, a Response Limits column property is already assigned to the response **thickness**. The property has a goal of maximizing **thickness**. Suppose that instead of maximizing **thickness**, you want the sheets of vinyl to have a **thickness** between 6 and 10, with a target **thickness** of 8.5.

1. Select **Help > Sample Data Library** and open Design Experiment/Vinyl Data.jmp.
2. Select the **thickness** column and select **Cols > Column Info**.
   
   The Response Limits property appears in the Column Properties list as the only property assigned to **thickness**. The Response Limits panel appears to the right of the list.
3. Click **Maximize** and select **Match Target**.
4. Type 1 for the **Importance** value.
5. Under **Value**, type 6 for the Lower value, 8.5 for the Middle value, and 10 for the Upper value.
   
   This is an example of asymmetric response limits. Values of **thickness** as small as 6 or as large as 10 are acceptable. However, the target for **thickness** is 8.5.
6. Select **Show as Graph Reference Lines**.
   
   This option shows horizontal reference lines for the Lower, Middle, and Upper values in the Actual by Predicted Plot and the Prediction Profiler.
7. Click OK.

8. In the Vinyl Data.jmp data table, click the green triangle next to the Model script.

   Note that m1, m2, and m3 are mixture factors. Also, the design involves a random Whole Plots factor. Because of this, the default Method is REML (Recommended).

9. Click Run.

10. Click the Response thickness red triangle and select **Row Diagnostics > Plot Actual by Predicted**.

    The reference lines for the Lower, Middle, and Upper limits appear on the Actual by Predicted Plot.

11. Click the Response thickness red triangle and select **Factor Profiling > Profiler**.
**Figure A.9** Prediction Profiler Showing Asymmetric Desirability Function

The plot at the right above Desirability shows the desirability function that JMP has constructed for thickness. The desirability is 1 at the Middle limit of 8.5. The desirability is essentially 0 for thickness values below 6 and above 10.

12. Press Ctrl and click the thickness plot for Desirability.

**Figure A.10** Response Goal Window for Thickness

This window shows your settings for the High, Middle, and Low Values. It also shows the Desirability values that JMP assigns, based on your goal of Match Target. The Desirability function shown in Figure A.9 is a continuous curve that matches the Desirability settings in Figure A.10 at the High, Middle, and Low Values. At other values, the Desirability function assigns desirabilities that are consistent with the selected goal.

13. Click **Cancel**.

14. Click the Prediction Profiler red triangle and select **Optimization and Desirability > Maximize Desirability**.

The settings for the factors are updated to show values that maximize the desirability function for thickness. Keep in mind that many other settings also maximize the desirability function. The predicted response at these optimal settings is 8.5. Recall that you set 8.5 as the target setting, with limits of 6 and 10.

15. Close the Vinyl Data.jmp sample data table without saving the changes.
Detection Limits

The Detection Limits column property defines bounds beyond which the response cannot be measured. You can use these limits to specify a censored response in the Generalized Regression platform.

Functional Response

The FDE X column property specifies a column as a functional response. Multiple Y columns with the FDE column property can be used in the Functional Data Explorer platform with the DOE factors as supplementary factors.

Design Role

Factors in designed experiments, as well as in more general models, can behave in various ways. JMP uses the design role column property to describe these behaviors. These are the possible design roles:

- Continuous
- Discrete Numeric
- Categorical
- Blocking
- Covariate
- Mixture
- Constant
- Uncontrolled
- Random Block
- Signal
- Noise
In many of the JMP DOE platforms, you can specify factors with different design roles. In some platforms, your design requirements cause JMP to define factors. For example, Whole Plots and Subplots are factors that JMP creates when you specify very-hard-to-change and hard-to-change factors. In platforms where various design roles can occur, when JMP creates the design table for your design, each factor is assigned the Design Role column property.

- For descriptions of the design roles other than Random Block, Signal, and Noise, see “Factor Types” on page 91 in the “Custom Designs” chapter.
- For a description of the Random Block design role, see “Changes and Random Blocks” on page 93 in the “Custom Designs” chapter.
- For descriptions of the Signal and Noise design roles, see “Factors” on page 430 in the “Taguchi Designs” chapter.

**Design Role Example**

The experiment in the Odor Control Original.jmp sample data table studies the effect of three factors on odor. You designed the 15-run experiment and it was conducted. However, when the results were reported to you, you learned that the experiment was conducted over three days. The first 5 runs were conducted on Day 1, the second 5 runs on Day 2, and the remaining 5 runs on Day 3.

Since variations in temperature and humidity might have an effect on the response, you want to include Day as a random blocking factor. It is easy to add a column for Day to the design table. But you want to use the Evaluate Design platform to compare the design with the unexpected block to your original design. You also want the ability to use the Augment Design platform in case you need to augment the design. To use the Evaluate Design and Augment Design platforms, you need to add the Design Role column property to your new Day column.

1. Select Help > Sample Data Library and open Odor Control Original.jmp.
2. Select the first column, Run.
4. Next to Column Name, type Day.
5. From the Initialize Data list, select Sequence Data.
6. Enter the following:
   - 1 for From
   - 3 for To
   - 1 for Step
   - 5 for Repeat each value N times
7. Next to **Number of columns to add**, type 1.

**Figure A.11** Completed New Columns Window

8. Click **OK**.
   
   The Day column is added as the second column in the data table.

9. Select the Day column.

10. Select **Cols > Column Info**.

11. From the Column Properties list, select **Design Role**.

12. In the Design Role panel, click **Continuous** and select **Random Block**.

13. Click **OK**.
   
   In the columns panel, an asterisk appears next to Day.

14. Click the asterisk next to Day to verify that the Design Role column property has been assigned.

15. Close the Odor Control Original.jmp sample data table without saving the changes.
Coding

The Coding column property applies only to columns with a numeric data type. It applies a linear transformation to the data in the column. In the Coding column property window, you specify a Low Value and a High Value. The Low Value and High Value in your original data are transformed to \(-1\) and \(+1\). JMP uses the transformed data values whenever the column is entered as a model effect in the Fit Model platform.

The coding property is useful for the following reasons:

- Coded predictors lead to parameter estimates that are more easily interpreted and compared.
- Coded predictors help reduce multicollinearity in models with interaction and higher-order terms.

When any DOE platform other than Accelerated Life Test Design creates a design, JMP defines a Coding column property for each non-mixture factor with a numeric data type. Figure A.12 shows the Coding column property panel for the column Feed Rate in the Reactor 20 Custom.jmp sample data table, found in the Design Experiment folder.

**Figure A.12** Coding Property Panel for Feed Rate

Low and High Values

When the Coding property is applied as part of design construction in a DOE platform, the Low Value is initially set to the minimum setting of the factor and the High Value is initially set to the maximum setting.
When you apply the Coding property to a column that does not contain that property, JMP inserts the minimum value as the Low Value and the maximum value as the High Value. You can change these values as needed.

**Caution:** After the Coding column property is assigned to a column, JMP does not automatically update it when you make changes to the values in the column. If you change the values in a column that has a Coding column property, review the High Value and Low Value to ensure that they are still appropriate.

The Coding column property centers each value in a column by subtracting the midpoint of the High Value and Low Value. It then divides by half the range. Suppose that \( H \) is the High Value and \( L \) is the Low Value. Then every \( X \) in the column is transformed to the following:

\[
\frac{X - (H + L)/2}{(H - L)/2}
\]

For each factor, the transformed values have a midpoint equal to 0 and range from -1 to +1.

**Coding Column Property and Center Polynomials**

The Center Polynomials option is located in the Fit Model launch window, within the Model Specification red triangle menu. Center Polynomials centers a continuous column involved in a polynomial term by subtracting the mean of each value in the column. See *Fitting Linear Models*.

If the Coding column property is assigned to a column, then the Center Polynomials option has no effect on that column. In a polynomial term involving that column, the values are centered and scaled as specified by their Coding property. Suppose that another column in the model does not have the Coding property and that you select Center Polynomials. Then that column is centered by its mean in any polynomial term where it appears.

**Coding Example**

The Reactor 20 Custom.jmp sample data table contains data from a 20-run design that was constructed using the Custom Design platform. The experiment investigates the effects of five factors on a yield response (Percent Reacted) for a chemical process.

1. Select **Help > Sample Data Library** and open **Design Experiment/Reactor 20 Custom.jmp**.
2. In the Table panel, click the green triangle next to the **DOE Dialog** script.
3. Open the **Factors** outline.
Notice that the settings for Temperature range from 140 to 180. When the design was generated, the Coding column property was assigned to Temperature. The Low Value is set to 140 and the High Value is set to 180.

4. Close the Custom Design window.

5. In the Reactor 20 Custom.jmp sample data table, click the asterisk next to Temperature in the columns panel and select Coding.

The Column Info window appears and shows the Coding column property panel. You can see that JMP added the column property, specifying the Low Value and High Value, when it constructed the design table. In fact, by repeating this step, you can verify that JMP added the Coding property for all five factors.

6. Click Cancel to close the Column Info window.

7. In the Reactor 20 Custom.jmp sample data table, click the green triangle next to the Reduced Model script.

This script fits a model that contains only the five effects determined to be significant based on an analysis of the full model.
8. Click Run.

**Figure A.15** Effect Summary Report for Reduced Model

In the Source list, the High and Low values used in the Coding column property appear in parentheses to the right of the main effects, Catalyst, Temperature, and Concentration. The ranges imposed by the Coding property are not shown for the interaction effects.

**Tip:** Notice the “^” symbols to the right of the PValues for Temperature and Concentration. These symbols indicate that these main effects are components of interaction effects with smaller $p$-values. If an interaction effect is included in the model, then the principle of effect heredity requires that all component effects are also in the model. See “Effect Heredity” on page 64 in the “Starting Out with DOE” chapter.

9. Click the Response Percent Reacted red triangle and select **Estimates > Show Prediction Expression**.

Look at the Prediction Expression outline to see how coding affects the prediction formula.
Each factor is transformed as specified by the Coding column property. For example, for Temperature, notice the following:

- The Low Value in the Coding property was set to 140. The Temperature value of 140 is transformed to -1.
- The High Value in the Coding property was set to 180. The Temperature value of 180 is transformed to +1.
- The midpoint of the Low and High values is 160. The Temperature value of 160 is transformed to 0.

The transformed values help you compare the effects. The estimated coefficient for Catalyst is 9.942 and the estimated coefficient for Concentration is -3.077. It follows that the predicted effect of Catalyst on Percent Reacted is more than three times as large as the effect of Concentration on Percent Reacted. Also, the coefficients indicate that predicted Percent Reacted increases as Catalyst increases and decreases as Concentration increases.

The transformed values help you interpret the coefficients:

- When all factors are at their midpoints, their transformed values are 0. The predicted Percent Reacted is the intercept, which is 65.465.
- When Catalyst and Concentration are at their midpoints, a 20 unit increase in Temperature increases the Percent Reacted by 5.558 units.
- Suppose that Concentration is at its midpoint, so that its transformed value is 0:
– When Catalyst is at its midpoint, a 20 unit increase in Temperature increases the Percent Reacted by 5.558 units.
– When Catalyst is at its high setting, a 20 unit increase in Temperature increases the Percent Reacted by 5.558 + 6.035 = 11.593 units.

It follows that the coefficient of the interaction term, 6.035, is the increase in the slope of the model for predicted Percent Reacted for a 0.5 unit change in Catalyst.

**Assigning Coding**

The experimental data in the Tiretread.jmp sample data table results from an experiment to study the effects of SILICA, SILANE, and SULFUR on four measures of tire tread performance. In this example, you will consider only one of the responses, ABRASION.

You will first fit a model using the uncoded factors. Then you will assign the coding property to the factors and rerun the model to obtain meaningful parameter estimates.

1. Select Help > Sample Data Library and open Tiretread.jmp.
2. Select Analyze > Fit Model.
3. Select ABRASION and click Y.
4. Select SILICA, SILANE, and SULFUR and click Macros > Response Surface.
5. Check Keep dialog open.
6. Click Run.
7. Click the Response ABRASION red triangle and select Estimates > Show Prediction Expression.
The coefficients do not help you compare effect sizes. The sizes of the coefficients do not reflect the impact of the effects on ABRASION over the range of their settings. Also, the coefficients are not easily interpreted. For example, the coefficients do not facilitate your understanding of the predicted response when SILICA is at the midpoint of its range.

Apply the Coding column property to the three factors to see how coding makes the coefficients more meaningful.

8. In the Tiretread.jmp data table, select SILICA, SILANE, and SULFUR in the Columns panel. Click the Columns red triangle and select Standardize Attributes.

10. Click OK.

An asterisk appears in the Columns panel next to SILICA, SILANE, and SULFUR indicating that these have been assigned a column property.

11. In the Fit Model window, click Run.

12. Click the Response ABRASTION red triangle and select Estimates > Show Prediction Expression.
Figure A.18 Prediction Expression for Model with Coded Factors

The coefficients for the coded factors enable you to compare effect sizes. SILANE has the largest effect on ABRASION over the range of design settings. The effects of SILICA and the SILANE*SULFUR interaction are large as well.

The coefficients for the coded factors are also more easily interpreted. For example, when all factors are at the center of their ranges, the predicted value of ABRASION is the intercept, 139.12.

13. Close the Tiretread.jmp sample data table without saving the changes.
Mixture

The Mixture column property is useful when a column in a data table represents a component of a mixture. The components of a mixture are constrained to sum to a constant. Because of this, they differ from non-mixture factors. The Mixture column property serves two purposes:

- It identifies a column as a mixture component.

  If you add a column with the Mixture column property as a model effect in the Analyze > Fit Model window, JMP automatically generates a no-intercept model.

- It defines the coding for a mixture component.

  Coding for mixture components differs from that for non-mixture factors. However, as with non-mixture factors, a benefit of coding for mixture factors is that it helps you interpret parameter estimates. See “PseudoComponent Coding” on page 804.

Figure A.19 shows the Mixture column property panel for the factor m1 in the Vinyl Data.jmp sample data table, found in the Design Experiment folder.

**Figure A.19** Mixture Column Property Panel

In the Mixture column property panel, you can specify the following:

**Lower Limit**  Specifies the low value used in PseudoComponent Coding. When the Mixture property is applied as part of design construction in a DOE platform, the Lower Limit is set to the minimum setting of the factor. When you apply the Mixture property to a column that does not contain that property, JMP inserts the minimum value as the Lower Limit. You can change this value as needed.
Upper Limit  Specifies the high value used in PseudoComponent Coding. When the Mixture property is applied as part of design construction in a DOE platform, the Upper Limit is set to the maximum setting of the factor. When you apply the Mixture property to a column that does not contain that property, JMP inserts the maximum value as the Upper Limit. You can change this value as needed.

Sum of Terms  Specifies the sum of the mixture components. When you apply the Mixture property to a column that does not contain that property, JMP inserts a default value of 1 for the Sum of Terms.

L PseudoComponent Coding  Transforms data values so that the Lower Limit corresponds to 0.

U PseudoComponent Coding  Transforms data values so that the Upper Limit corresponds to 0.

PseudoComponent Coding

A pseudo-component is a linear transformation. Let $S$ denote the sum of the mixture components. Suppose that $q$ columns $X_1, X_2, \ldots, X_q$ have been assigned the Mixture column property. Suppose that the columns and effects constructed from these columns are entered as effects in the Fit Model window.

Define the following:

$$L = \sum_{i=1}^{q} L_i, \text{ where } L_i \text{ is the Lower Limit for } X_i$$

$$U = \sum_{i=1}^{q} U_i, \text{ where } U_i \text{ is the Upper Limit for } X_i$$

Let $x_i$ denote a value of the column $X_i$. The L PseudoComponent at $x_i$ is defined as follows:

$$x_i^L = (X_i - L_i)/(S - L)$$

The U PseudoComponent at $x_i$ is defined as follows:

$$x_i^U = (U_i - X_i)/(U - S)$$

If you select both L PseudoComponent Coding and U PseudoComponent Coding, the Fit Model platform uses the $L$ coding if $(S - L) < (U - S)$. Otherwise, the $U$ coding is used.
In Fit Model, mixture factors are transformed using pseudo-components before computing parameter estimates. This helps make parameter estimates more meaningful. In reports dealing with parameter estimates, the mixture main effects are given by the coding transformation. Other reports, such as the profilers, are based on the uncoded values.

**Mixture Example**

The data in the Donev Mixture Data.jmp sample data table, found in the Design Experiment folder, are based on an example from Atkinson and Donev (1992). The design includes three mixture factors and one non-mixture factor:

- The response is the electromagnetic Damping of an acrylonitrile powder.
- The three mixture ingredients are copper sulphate (CuSO₄), sodium thiosulphate (Na₂S₂O₃), and Glyoxal.
- The non-mixture environmental factor of interest is the Wavelength of light.

Though Wavelength is theoretically continuous, the researchers were interested only in predictions at three discrete wavelengths. As a result, Wavelength is treated as a categorical factor with three levels.

For more information about using Custom Design to construct a design for this situation, see “Mixture Experiments” on page 178 in the “Examples of Custom Designs” chapter.

1. Select Help > Sample Data Library and open Design Experiment/Donev Mixture Data.jmp.
2. Click the asterisk next to CuSO₄ in the columns panel and select Mixture.

**Figure A.20** Mixture Column Property Panel for CuSO₄
Notice the following:

- The Lower Limit is 0.2, the minimum design setting for CuSO4.
- The Upper Limit is 0.8, the maximum design setting for CuSO4.
- The Sum of Terms is set to 1. This is the sum of the three mixture factors.
- The L PseudoComponent Coding option is selected. See “PseudoComponent Coding” on page 804.

3. Click Cancel.

4. Click the asterisk next to Glyoxal in the columns panel and select Mixture.

   For this factor, note the following:

   - The Lower Limit is 0, the minimum design setting for Glyoxal.
   - The Upper Limit is 0.6, the maximum design setting for Glyoxal.

5. Click Cancel.

6. In the Donev Mixture Data.jmp data table, click the green triangle next to the Model script.

   The model contains the main effects of the mixture factors and two-way interactions for all four factors.

7. Click Run.

   In the Parameter Estimates report, the mixture factors appear in their pseudo-component coded form. When the mixture factors appear in interactions, they are not denoted in coded form. Nevertheless, the model fitting is based on the pseudo-components. The first three terms in the Parameter Estimates report (Figure A.21), show the coded form for the mixture factors.

**Figure A.21 Parameter Estimates Report**

| Term                  | Estimate | Std Error | t Ratio | Prob>|l| |
|-----------------------|----------|-----------|---------|------|
| CuSO4:0.2|0.6       | 6.191021  | 0.918805| 6.74 | 0.0005* |
| Na2SO3:0.2|0.6       | 4.089179  | 0.918805| 4.36 | 0.048*  |
| Glyoxal:0.6         | 8.166667  | 0.921638  | 8.86   | 0.0001* |
| CuSO4*Na2SO3       | 11.293949 | 4.728222  | 2.39   | 0.0542  |
| CuSO4*Glyoxal       | 4.351592  | 4.512775  | 0.96   | 0.3722  |
| CuSO4*Wavelength[L1]| -3.847943 | 1.113399  | -3.46  | 0.0015* |
| CuSO4*Wavelength[L2]| 1.878509  | 1.079113  | 1.74   | 0.1324  |
| Na2SO3*Glyoxal      | -18.4845  | 4.512775  | -4.08  | 0.0006* |
| Na2SO3*Wavelength[L1]| -0.279509 | 1.064036  | -0.28  | 0.8042  |

| Glyoxal*Wavelength[L1]| 0.198283  | 1.090687  | 0.18   | 0.8617  |
| Glyoxal*Wavelength[L2]| 0.1905384 | 1.090647  | 0.17   | 0.8671  |

8. Click the Response Damping red triangle and select Estimates > Show Prediction Expression.

   The Prediction Expression report shows the model that was fit. Note that the mixture factors are transformed using the L PseudoComponent coding.
Suppose that you are interested in predictions at Wavelength L2. Suppose also that Na2S2O3 and Glyoxal are set to their low values, 0.2 and 0 respectively, and that CuSO4 is set to its high value, 0.8. In this case, the predicted Damping equals the parameter estimate for CuSO4 (6.191) plus the parameter estimate for CuSO4*Wavelength[L2] (1.878). You can verify this in the Prediction Profiler.

9. Click the Response Damping red triangle and select Save Columns > Save Coding Table.
For this particular design, the L Pseudo Component coding transforms the mixture factors to range between 0 and 1. Note that this does not happen in general.

**Factor Changes**

The Factor Changes column property indicates how difficult it is to change factor settings in a designed experiment. The possible specifications for Factor Changes are Easy, Hard, and Very Hard. For example, Figure A.24 shows the Factor Changes column property panel for the factor A1 in the Battery Data.jmp sample data table, located in the Design Experiment folder.

**Figure A.24  Factor Changes Column Property Panel**
• When a design contains factors that are hard-to-change and very-hard-to-change, it must also include a subplot and a whole plot factor:
  – The levels of the whole plot factor define the groups of runs for which the levels of the very-hard-to-change factors are held constant.
  – The levels of the subplot factor define the groups of runs for which the levels of the hard-to-change factors are held constant.

• When a design contains only factors that are hard-to-change, but no factors that are very-hard-to-change, it should include a whole plot factor. The levels of the whole plot factor define the groups of runs for which the levels of the hard-to-change factors are held constant. See “Changes and Random Blocks” on page 93 in the “Custom Designs” chapter.

Augment and Evaluate Design

For the Evaluate Design and Augment Design platforms, the Factor Changes column property identifies factors with Changes specified as Hard or Very Hard. However, these platforms also require that the whole plot and subplot factors be entered as model effects in the launch windows. This is because the whole plot and subplot factors are part of the design structure.

Custom Design

The Custom Design platform enables you to create designs where all factor changes are Easy. You can also construct split-plot, split-split plot, or two-way split-plot (strip-plot) designs. When constructing these designs, you need to identify the factors whose values are hard-to-change or very-hard-to-change. In the Factors outline, you can identify factors as having Changes that are Easy, Hard, or Very Hard. When the Custom Design platform constructs the design table, the Factor Changes property is assigned to every factor that appears in the Factors outline.

The Custom Design platform is the only platform that constructs designs for factors with Changes that are Hard or Very Hard. Other DOE platforms also assign the Factor Changes column property to factors that they construct, but the value of the column property is set to Easy for their factors.

If you Load Factors in the Custom Design window using a table of factors, you can assign the Factor Changes column property to columns in that table. When you Load Factors using that table, your Factor Changes specifications appear in the Factors outline.
Factor Changes Example

The Battery Data.jmp sample data table, found in the Design Experiment folder, contains data from an experiment that studies the open current voltage of batteries (OCV). The design is a two-way split-plot design. For further background, see the “Examples of Custom Designs” chapter on page 202.

1. Select Help > Sample Data Library and open Design Experiment/Battery Data.jmp.
2. Click the asterisk to the right of the factor C1 in the columns panel.
3. Select Factor Changes.

Figure A.25  Factor Changes Panel for C1

The value of Factor Changes for C1 is Hard. Figure A.24 shows that the value of Factor Changes for A1 is Very Hard.

4. Click OK.
5. In the data table, click the green triangle next to the DOE Dialog script.
6. Open the Factors outline.

Figure A.26  Factors Outline for Battery Experiment
The factors A1, A2, A3, and A4 have Changes set to Very Hard, and the factors C1 and C2 have Changes set to Hard. When the Custom Design platform constructs the design table, it saves these specifications to the appropriate columns as Factor Changes column properties.

In the Design outline, notice the Whole Plots and Subplots factors.

**Figure A.27** Design Outline Partial View

![Design Outline Partial View](image)

To account for the factor changes that are Hard and Very Hard, two factors are created by the Custom Design platform. The Whole Plots factor groups the runs where the Very Hard factor levels are constant and the Subplots factor groups the runs where the Hard factors levels are constant. These factors need to be included as model effects when you enter columns with the Factor Changes column property in the Evaluate Design and Augment Design platforms.

---

**Value Order**

The Value Order column property assigns an order to the values in a column. That order is then used in plots and analyses. You can specify the order in which you want values to appear in reports.

**Note:** For certain values that have a natural ordering, such as days of the week, JMP automatically orders these in the appropriate way in reports. See *Using JMP*.

Figure A.28 shows the Value Order panel for the Type column in the Car Physical Data.jmp sample data table. Reports that involve the values of Type place these levels in the order Sporty, Small, Compact, Medium, and Large. Use the buttons to the right of the Value Order list to specify your desired ordering for the values.
In designs created using most DOE platforms, categorical factors, including the constructed factors Whole Plots and Subplots, and blocking factors are assigned the Value Order property. This property orders the levels according to the order in which they appear in the Factors outline. The levels of constructed factors are consecutive integers and the Value Order property specifies this natural ordering. You can modify the Value Order specification for any factor to meet your needs.

The Value Order property is not assigned by the Covering Array or Taguchi Arrays platforms. The Covering Array platform assigns the Value Labels column property. See “Value Labels” on page 815.
Value Order Example

Suppose that you want the values for a factor to appear in a different order in the Prediction Profiler. Consider an example of a wine tasting experiment, constructed using Custom Design. Wine is rated by five experts, each listed as a Rater in the Wine Data.jmp sample data table. Rater is a fixed blocking factor. Nine factors are studied. Rating is the response.

1. Select Help > Sample Data Library and open Design Experiment/Wine Data.jmp.
2. In the Table panel, click the green triangle next to the Reduced Model script.
3. Click Run.

   The Prediction Profiler appears at the bottom of the report.

Figure A.29 Profiler with Original Value Order

Notice that the values for De-Stem and Filtering appear in the order No followed by Yes. You want to reverse these, so that the Yes level appears first.

Tip: To arrange the profiler click the Prediction Profiler red triangle and select Appearance > Arrange in rows. For this example enter 7 and click OK.

5. In the data table, click the asterisk next to De-Stem in the columns panel and select Value Order.
6. Click Reverse.
7. Click OK.
8. Click the asterisk next to Filtering in the columns panel and select Value Order.
9. Click Reverse.
10. Click OK.
11. Again, click the green triangle next to the Reduced Model script.
12. Click **Run**.

**Figure A.30** Profiler with New Value Orders

The levels for De-Stem and Filtering now appear in the order Yes followed by No.

13. Close the Wine Data.jmp sample data table without saving the changes.

**Assigning Value Order**

Consider the Candy Bars.jmp sample data table. Of the 18 brands lists under Brand, Hershey and M&M/Mars have the largest numbers of types of candy as listed in the Name column. You want these two brands to appear first in reports.

1. Select **Help > Sample Data Library** and open Candy Bars.jmp.
2. Select the Brand column.
3. Select **Cols > Column Info.**
4. Under Column Properties, select Value Order.
5. In the Value Order list, select Hershey.
6. Click the up arrow five times. 
   Hershey is now first in the Value Order list.
7. In the Value Order list, select M&M/Mars.
8. Click the up arrow seven times.
   M&M/Mars is now second in the Value Order list.
9. Click **OK**.
   An asterisk indicating the Value Order column property appears next to Brand in the columns panel. JMP now lists Hershey and M&M/Mars first in reports involving Brand.
10. Select **Analyze > Distribution**.
11. Select Calories and click **Y, Columns**.
12. Select Brand and click **By**.
13. Click **OK**.
14. Press Ctrl, click the Calories red triangle, and select **Display Options > Horizontal Layout**.

   Note that the Distribution reports for Hershey and M&M/Mars appear first among the 18 brands.

15. Close the Candy Bars.jmp sample data table without saving the changes.

---

**Value Labels**

The Value Labels column property represents values in a column with specified labels. These labels are displayed in the data table and are used in plots and reports. In the data table, you can view the original values by double-clicking within a cell. For more information about how to assign and work with the Value Labels column property, see *Using JMP*.

The Covering Arrays platform is the only DOE platform that assigns the Value Labels column property. The Covering Arrays platform saves factors to the data table with a Nominal modeling type. The underlying values are consecutive integers ranging from 1 to the number of levels that you specify in the Covering Array Factors outline. The Values that you specify in the Factors outline are the Value Labels that are assigned to the underlying integers.

**Value Labels Example**

You want to test an internet-based software application to detect issues arising from components in the operating environment. The four components of interest consist of a browser, the operating system, the computer’s RAM, and the connection speed. To minimize testing time, you restrict yourself to testing two-way interactions.

Construct a Strength 2 covering array to test the required combinations of factor levels.

1. Select **DOE > Special Purpose > Covering Array**.
2. Select **Help > Sample Data Library** and open Design Experiment/Software Factors.jmp.
3. Click the Covering Array red triangle and select **Load Factors**.
   
   The factors and their levels appear in the Factors outline.
Notice that the Role of the four factors is described as Categorical.

4. Click **Continue**.

   The Restrict Factor Level Combinations outline opens. Since all combinations of settings are possible, leave this set to **None**.

5. Click **Make Design**.

6. Click **Make Table**.

7. In the columns panel, click the asterisk next to **Web Browser** and select **Value Labels**.

---

**Figure A.31**  Factors Outline for Software Factors

<table>
<thead>
<tr>
<th>Name</th>
<th>Role</th>
<th>Values</th>
</tr>
</thead>
<tbody>
<tr>
<td>Web Browser</td>
<td>Categorical</td>
<td>Safari, IE, Firefox, Chrome, Other</td>
</tr>
<tr>
<td>Operating System</td>
<td>Categorical</td>
<td>Macintosh, Windows</td>
</tr>
<tr>
<td>RAM</td>
<td>Categorical</td>
<td>16 MB, 4 MB, 8 MB</td>
</tr>
<tr>
<td>Connection Speed</td>
<td>Categorical</td>
<td>0-1 Mbps, 1-5 Mbps, &gt;5 Mbps</td>
</tr>
</tbody>
</table>

---

**Figure A.32**  Column Info Window for Factor A

Notice that **Web Browser** has a Numeric data type and a Nominal modeling type. The underlying values of **Web Browser** are the integers 1, 2, 3, 4, and 5. These values are assigned value labels corresponding to the values that you entered when you constructed the design.
Change the value label for 2 from IE to Internet Explorer.

8. Select $2 = \text{IE}$ in the Value Labels list.

**Figure A.33** Value Labels Panel with Selection

![Value Labels Panel with Selection](image)

9. Type **Internet Explorer** next to Label.

10. Click **Change**.

    The change appears in the data table.

**Note:** To use the numeric values and not the labels, deselect **Use Value Labels**.

---

**RunsPerBlock**

When you use the DOE platforms to construct a design containing a blocking factor, the factor is assigned the Design Role column property with the value Blocking. JMP also assigns the RunsPerBlock column property to each Blocking factor. The RunsPerBlock property indicates the maximum allowable number of runs in each block. This property is used by the Evaluate Design and Augment Design platforms to indicate the blocking structure for the factor. See “Blocking” on page 92 in the “Custom Designs” chapter.

**Note:** The RunsPerBlock column property is assigned by JMP as part of design construction. You cannot directly assign this column property.
**RunsPerBlock Example**

Consider the wine tasting experiment described in “Example of a Custom Design” on page 70 in the “Custom Designs” chapter. Wine samples are tasted by five raters (Rater) and each rater tastes eight samples.

1. Select *Help > Sample Data Library* and open *Design Experiment/Wine Data.jmp*.
2. Click the asterisk next to Rater in the columns panel and select *Design Role*.
   
   Notice that the Design Role is set to Blocking.
3. Click *Cancel*.
4. Click the asterisk next to Rater in the columns panel and select *RunsPerBlock*.

**Figure A.34** RunsPerBlock Column Property Panel for Rater

Notice that the value of RunsPerBlock is 8. The design constructed by the DOE Dialog script has 40 runs. Since there are five raters, JMP constructs a design with 40/5 = 8 runs for each rater.

**ConstraintState**

In the Custom and Mixture Design platforms, you can Save Constraints that you specify for a design. When you select Save Constraints, the coefficients of each linear constraint appear in a column in a data table. The value that bounds the inequality is given in the last row of the table.
Each constraint column is assigned the ConstraintState column property. This property specifies the direction of the inequality that defines the constraint. When you select Load Constraints from a design platform, the ConstraintState column property tells JMP the direction of the inequality.

**Note:** The ConstraintState column property is assigned by JMP as part of design construction. You cannot directly assign this column property.

### ConstraintState Example

The sample data table Piepel.jmp, located in the Design Experiment folder, contains a mixture design with three continuous factors. The design is based on an experiment presented in Snee (1979) and Piepel (1988), where there are boundary constraints on each factor and three additional linear constraints. In this example, you do the following:

1. Change one of the three additional constraints
2. Save the constraints to a table
3. Observe how the ConstraintState column property describes the direction of the inequality in the constraint

For further development of this example, see “An Extreme Vertices Example with Linear Constraints” on page 409 in the “Mixture Designs” chapter.

1. Select Help > Sample Data Library and open Design Experiment/Piepel.jmp.
2. In the Table panel, click the green triangle next to the DOE Dialog script.

   Notice the three linear constraints below the Factors outline. To make the constraints more interpretable, you want to reformulate the first constraint in terms of a “greater than or equal to” inequality.

### Figure A.35  Linear Constraints beneath Factors Outline

3. In the first constraint, do the following:
   - Type 85 next to X1.
   - Type 90 next to X2.
– Type 100 next to X3.
– Select ≥ from the inequality menu.
– Type 90 to the right of the inequality sign.

4. Click the Mixture Design red triangle and select **Save Constraints**.

A table containing information about the constraints appears.

**Figure A.36** Constraint Table

<table>
<thead>
<tr>
<th></th>
<th>Constraint 1</th>
<th>Constraint 2</th>
<th>Constraint 3</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>-85</td>
<td>85</td>
<td>-0.7</td>
</tr>
<tr>
<td>2</td>
<td>-90</td>
<td>90</td>
<td>0</td>
</tr>
<tr>
<td>3</td>
<td>-100</td>
<td>100</td>
<td>-1</td>
</tr>
<tr>
<td>4</td>
<td>-90</td>
<td>95</td>
<td>-0.4</td>
</tr>
</tbody>
</table>

Each column contains the coefficients of the factors X1, X2, and X3 in rows 1 through 3. Row 4 contains the value that appeared to the right of the inequality sign.

5. Click the asterisk next to Constraint 1.

6. Click **ConstraintState**.

**Figure A.37** ConstraintState Column Property Panel

The ConstraintState panel for X1 indicates that the direction of the inequality is “greater than” indicating greater than or equal to ≥.

7. Click **Cancel**.
This appendix contains information on the Alias Matrix, power calculations and the Relative Prediction Variance.

• “The Alias Matrix” on page 823
• “Power Calculations” on page 824
• “Relative Prediction Variance” on page 827
 Contents

Designs with Hard or Very Hard Factor Changes ...................................................... 823
Designs with If Possible Effects .............................................................................. 824
Power Calculations .................................................................................................. 824
  Power for a Single Parameter .............................................................................. 824
  Power for a Categorical Effect ........................................................................... 826
Relative Prediction Variance .................................................................................. 827
The Alias Matrix

The Alias Matrix entries represent the degree of bias imparted to model parameters by the effects that you specified in the Alias Terms outline. The Alias Matrix is also used in defining alias optimality. See “Alias Optimality” on page 132 in the “Custom Designs” chapter.

Calculations for the Alias Matrix are based on the model matrix. See “Model Matrix” on page 114 in the “Custom Designs” chapter.

Let $X_1$ be the model matrix corresponding to the terms in the Model outline. Denote the matrix of model terms for the effects specified in the Alias Terms outline by $X_2$.

The assumed model is given as follows:

$$ Y = X_1 \beta_1 + \varepsilon $$

Suppose that some of the alias terms are active and that the true model is given as follows:

$$ Y = X_1 \beta_1 + X_2 \beta_2 + \varepsilon $$

The least squares estimator of $\beta_1$ is given by:

$$ \hat{\beta}_1 = (X_1'X_1)^{-1}X_1'Y $$

Under the usual regression assumptions, the expected value of $\hat{\beta}_1$ is given by:

$$ E[\hat{\beta}_1] = \beta_1 + A\beta_2 $$

where $A = (X_1'X_1)^{-1}X_1'X_2$.

The matrix $A$ is called the alias matrix.

Designs with Hard or Very Hard Factor Changes

For designs with hard-to-change or very-hard-to-change factors, the alias matrix is given as follows:

$$ A = (X_1'V^{-1}X_1)^{-1}X_1'(V^{-1}X_2) $$

where $V$ is the block diagonal covariance matrix of the responses.
**Designs with If Possible Effects**

For designs with If Possible effects (Bayesian D- and I-optimal designs), the alias matrix is given as follows:

\[
A = (X_1'X_1 + K^2)^{-1}X_1'X_2
\]

where \( K \) is a diagonal matrix with these values:

- \( k = 0 \) for Necessary terms
- \( k = 1 \) for If Possible main effects, powers, and interactions involving a categorical factor with more than two levels
- \( k = 4 \) for all other If Possible terms

In the Bayesian case, the alias matrix gives the aliasing of effects corresponding to a ridge regression with a prior variance of \( K^{-1} \). For additional detail on Bayesian designs, see “Bayesian D-Optimality” on page 129 in the “Custom Designs” chapter and “Bayesian I-Optimality” on page 131 in the “Custom Designs” chapter.

In the Custom Design platform, you can control the weights used for If Possible terms by selecting **Advanced Options > Prior Parameter Variance** from the red triangle menu. There you can set prior variances for all model terms by specifying the diagonal elements of \( K \). The option updates to show the default weights when you click Make Design.

---

**Power Calculations**

The Power Analysis report gives power calculations for single parameter values and, when the design includes a categorical factor with three or more levels, for whole effects. This section describes the calculations in the two cases:

- “Power for a Single Parameter” on page 824
- “Power for a Categorical Effect” on page 826

**Power for a Single Parameter**

This section describes how power for the test of a single parameter is computed. Use the following notation:

\( X \) The model matrix. See *Fitting Linear Models* for information on the coding for nominal effects. Also, See “Model Matrix” on page 114 in the “Custom Designs” chapter.
Note: You can view the model matrix by running Fit Model. Then select **Save Columns > Save Coding Table** from the red triangle menu for the main report.

\( \beta_i \)  The parameter corresponding to the term of interest.

\( \hat{\beta}_i \)  The least squares estimator of \( \beta_i \)

\( \beta_i^A \)  The Anticipated Coefficient value. The difference you want to detect is \( 2\beta_i^A \).

The variance of \( \hat{\beta}_i \) is given by the \( i^{th} \) diagonal entry of \( \sigma^2 (X'X)^{-1} \), where \( \sigma^2 \) is the error variance. Denote the \( i^{th} \) diagonal entry of \( (X'X)^{-1} \) by \( (X'X)_{ii}^{-1} \).

The error variance, \( \sigma^2 \), is estimated by the MSE, and has \( n - p - 1 \) degrees of freedom, where \( n \) is the number of observations and \( p \) is the number of terms other than the intercept in the model. If \( n - p - 1 = 0 \), then JMP sets the degrees of freedom for the error to 1. This allows the power to be estimated for parameters in a saturated design.

The test of \( H_0: \beta_i = 0 \) is given by:

\[
\frac{\beta_i}{\sqrt{\text{MSE}(X'X)^{-1}_{ii}}}
\]

or equivalently by:

\[
F_0 = \frac{\hat{\beta}_i^2}{\text{MSE}(X'X)^{-1}_{ii}}
\]

Under the null hypothesis, the test statistic \( F_0 \) has an \( F \) distribution on 1 and \( n - p - 1 \) degrees of freedom.

If the true value of \( \beta_i \) is \( \beta_i^A \), then \( F_0 \) has a noncentral \( F \) distribution with noncentrality parameter given by:

\[
\lambda = \frac{(\beta_i^A)^2}{\sigma^2 (X'X)^{-1}_{ii}}
\]

To compute the power of the test, first solve for the \( \alpha \)-level critical value \( F_c \):

\[
\alpha = 1 - \text{FDist}(F_c, 1, n - p - 1)
\]

Then calculate the power as follows:

\[
\text{Power} = 1 - \text{FDist}(F_c, 1, n - p - 1, \lambda)
\]
Power for a Categorical Effect

This section describes how power for the test for a whole categorical effect is computed. Use the following notation:

- \( \mathbf{X} \): Model matrix. See “The Alias Matrix” on page 823 in the “Technical Details” appendix.
- \( \mathbf{\beta} \): Vector of parameters.
- \( \hat{\mathbf{\beta}} \): Least squares estimate of \( \mathbf{\beta} \).
- \( \mathbf{\beta}^A \): Vector of Anticipated Coefficient values.
- \( \mathbf{L} \): Matrix that defines the test for the categorical effect. The matrix \( \mathbf{L} \) identifies the values of the parameters in \( \mathbf{\beta} \) corresponding to the categorical effect and sets them equal to 0. The null hypothesis for the test of the categorical effect is given by:
  \[
  H_0: \mathbf{L}\mathbf{\beta} = \mathbf{0}
  \]
- \( r \): Rank of \( \mathbf{L} \). Alternatively, \( r \) is the number of levels of the categorical effect minus one.

**Note:** You can view the design matrix by running Fit Model. Then select **Save Columns > Save Coding Table** from the red triangle menu for the main report.

The covariance matrix of \( \hat{\mathbf{\beta}} \) is given by \( \sigma^2 (\mathbf{X}'\mathbf{X})^{-1} \), where \( \sigma^2 \) is the error variance.

The error variance, \( \sigma^2 \), is estimated by the MSE, and has \( n - p - 1 \) degrees of freedom, where \( n \) is the number of observations and \( p \) is the number of terms other than the intercept in the model. If \( n - p - 1 = 0 \), then JMP sets the degrees of freedom for the error to 1. This allows the power to be estimated for parameters in a saturated design.

The test of \( H_0: \mathbf{L}\mathbf{\beta} = \mathbf{0} \) is given by:

\[
F_0 = \left( (\hat{\mathbf{L}}\mathbf{\beta})'[\mathbf{L}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{L}']^{-1}(\hat{\mathbf{L}}\mathbf{\beta}) \right) / (r\text{MSE})
\]

Under the null hypothesis, the test statistic \( F_0 \) has an \( F \) distribution on \( r \) and \( n - p - 1 \) degrees of freedom.

If the true value of \( \mathbf{\beta} \) is \( \mathbf{\beta}^A \), then \( F_0 \) has a noncentral \( F \) distribution with noncentrality parameter given by:

\[
\lambda = \left( (\mathbf{L}\mathbf{\beta}^A)'[\mathbf{L}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{L}']^{-1}(\mathbf{L}\mathbf{\beta}^A) \right) / \sigma^2
\]
To compute the power of the test, first solve for the $\alpha$-level critical value $F_c$:

$$\alpha = 1 - FDist(F_c, r, n - p - 1)$$

Then calculate the power as follows:

$$Power = 1 - FDist(F_c, r, n - p - 1, \lambda)$$

---

**Relative Prediction Variance**

Consider the following notation:

- $X$  Model matrix. See “Model Matrix” on page 114 in the “Custom Designs” chapter. Custom designs provide a script that shows the model matrix. See “Save X Matrix” on page 114 in the “Custom Designs” chapter.

- $\sigma^2$  Error variance.

- $\hat{\beta}$  Vector of least squares estimates of the parameters.

- $x_i$ The $i^{th}$ row of $X$.

Using this notation, the predicted response for the $i^{th}$ row of $X$ is given by:

$$\hat{Y} = x_i \hat{\beta}$$

The relative prediction variance at the settings defined by $x_i$ is given by:

$$\frac{x_i \text{var}(\hat{Y})x_i}{\sigma^2} = \frac{x_i \text{var}(x_i \hat{\beta})x_i}{\sigma^2} = x_i' (X'X)^{-1} x_i$$

Using the Fit Model platform, you can specify complex models efficiently. Your task is simplified by Macros, Attributes, and transformations. Fit Model is your gateway to fitting a broad variety of models and effect structures.

These include:

- simple and multiple linear regression
- analysis of variance and covariance
- random effect, nested effect, mixed effect, repeated measures, and split plot models
- nominal and ordinal logistic regression
- multivariate analysis of variance (MANOVA)
- canonical correlation and discriminant analysis
- loglinear variance (to model the mean and the variance)
- generalized linear models (GLM)
- parametric survival and proportional hazards
- response screening, for studying a large number of responses

In JMP Pro, you can also fit the following:

- mixed models with a range of covariance structures
- generalized regression models including the elastic net, lasso, and ridge regression
- partial least squares

The Fit Model platform lets you fit a large variety of types of models by selecting the desired personality. This chapter focuses on the elements of the Model Specification window that are common to most personalities.

Overview of the Fit Model Platform

The Fit Model platform gives you an efficient way to specify models that have complex effect structures. These effect structures are linear in the model parameters. Once you have specified your model, you can select the appropriate fitting technique from a number of fitting personalities. Once you choose a personality, the Fit Model window provides choices that are relevant for the chosen personality. This chapter focuses on the elements of the Model Specification window that are common to most personalities. For a description of all personalities, see “Fit Model Launch Window Elements” on page 36.

Fit Model can be used to specify a wide variety of models that can be fit using various methods. Table 2.1 lists some typical models that can be defined using Fit Model. In the table, the effects X and Z represent columns with a continuous modeling type, while A, B, and C represent columns with a nominal or ordinal modeling type.

See “Examples of Model Specifications and Their Model Fits” on page 51 for the clicking sequences that produce these model effects, plots of the model fits, and some examples.

**Example of a Regression Analysis Using Fit Model**

You have data resulting from an aerobic fitness study, and you want to predict the oxygen uptake from several continuous variables.

1. Select **Help > Sample Data Library** and open Fitness.jmp.
2. Select **Analyze > Fit Model**. Note that the Personality box is empty.
3. Select **Oxy** and click **Y**.
   
   When you specify a continuous response, the Personality defaults to Standard Least Squares, but you are free to choose another personality. Also, the Emphasis defaults to Effect Leverage.

4. Press Ctrl and select **Sex, Age, Weight, Runtime, RunPulse, RstPulse, and MaxPulse**. Click **Add** to add these to the Construct Model Effects list. Note that you can select **Keep dialog open** if you want to have this window available later on. Your Model Specification window should appear as shown in Figure 2.1.

5. Click **Run**. Figure 2.2 gives a partial view of the report.
Figure 2.1 Model Specification Window for Fitness Regression Model
The plot and reports for the whole model appear in the left-most report column. The columns to the right show leverage plots for each of the effects that you specified in the model. Due to space limitations, Figure 2.2 shows only the column for Sex, but the report shows columns for the other six effects as well. The red triangle menus contain additional options that add reports and plots to the report window. For more information about the Standard Least Squares report window, see “Fit Least Squares Report” on page 84 in the “Standard Least Squares Models” chapter.

Looking at the p-values in the Parameter Estimates report, you can see that Runtime, RunPulse, and MaxPulse appear to be significant predictors of oxygen uptake. The next step might be to reduce the model by removing insignificant predictors. See the “Stepwise Regression Models” chapter on page 249.
Launch the Fit Model Platform

Launch the Fit Model platform by selecting **Analyze > Fit Model**. Figure 2.3 shows an example of the launch window for the Fitness.jmp sample data table. The Fit Model launch window is a common launch window for many platforms that are called Personalities. See “Fitting Personalities” on page 45.

**Figure 2.3 Fit Model Launch Window**

**Note:** When you select **Analyze > Fit Model** in a data table that has a script named **Model** (or **model**), the launch window is automatically filled in based on the script.

The Fit Model launch window contains the following major areas:

- **Select Columns** is a list of the columns in the current data table. If the current data table contains excluded columns, they do not appear in the list. For more information about the options in the Select Columns red triangle menu, see *Using JMP*.
- **Pick Role Variables** contains standard JMP launch window buttons. For a description of these buttons, see “Fit Model Launch Window Elements” on page 36.
- **Construct Model Effects** contains options that you use to enter effects into your model. See “Construct Model Effects” on page 39.
- **Personality** is a list of the model types that you can choose from. Once you have selected a personality, different options appear, depending on the personality that you have selected. See “Fitting Personalities” on page 45.
Fit Model Launch Window Elements

The following Fit Model launch window elements are common to most personalities:

**Model Specification**  The Model Specification menu contains the following options:

- **Center Polynomials**  Centers the effects when polynomials are included in the model.
- **Informative Missing**  Creates a coding system that accommodates missing values in effects.
- **Set Alpha Level**  Sets the alpha level for confidence intervals in the model reports.
- **Save to Data Table**  Saves the model specifications to a script in the current data table.
- **Save to Script Window**  Saves the model specifications to a script window.
- **Create SAS Job**  Saves SAS code for the current model specification to a SAS Program window.
- **Submit to SAS**  Submits SAS code for the current model specification to a SAS session.
- **Convergence Settings**  Contains options for setting the maximum iterations and convergence limit used in the convergence of models in some personalities.

For more information about any of these options, see “Model Specification Options” on page 47.

**Select Columns**  Lists the unexcluded columns in the current data table.

**Y**  Identifies one or more response variables (the dependent variables) for the model.

**Note:**  Response columns with vector values are not supported in Fit Model.

**Weight**  Identifies a column whose values assign a weight to each row for the analysis. See “Weight” on page 38.

**Freq**  Identifies a column whose values assign a frequency to each row for the analysis. In general terms, the effect of a frequency column is to expand the data table, so that any row with integer frequency \( k \) is expanded to \( k \) rows. You are allowed to specify fractional frequencies. See “Frequency” on page 38.

**Validation**  In JMP Pro, for some personalities, you can enter a Validation column. See the appropriate Personality chapter for more information about how each personality handles a Validation column. If you click the Validation button with no columns selected in the Select Columns list, you can add a validation column to your data table. For more information about the Make Validation Column utility, see Predictive and Specialized.
Model Specification
Launch the Fit Model Platform

Chapter 2  Model Specification  37
Fitting Linear Models

Modeling. For more information about how a Validation column is used in JMP modeling platforms, see Predictive and Specialized Modeling.

**By**  Identifies a column that creates a report consisting of separate analyses for each level of the variable. If more than one By variable is assigned, a separate analysis is produced for each possible combination of the levels of the By variables.

**Add**  Adds effects to the model. See “Add” on page 39.

**Cross**  Creates interaction and polynomial effects by crossing two or more variables. See “Cross” on page 39.

**Nest**  Creates nested effects. See “Nest” on page 40.

**Macros**  Generates effects for commonly used models. See “Macros” on page 40.

**Degree**  Applies the specified degree to models with factorial or polynomial effects generated using Macros. See Factorial to Degree and Polynomial to Degree in “Macros” on page 40.

**Attributes**  Applies attributes to model effects. These attributes determine how the effects are treated. See “Attributes” on page 42.

**Transform**  Transforms selected continuous effects or Y columns. See “Transform” on page 43.

**No Intercept**  Excludes the intercept term from the model.

**Personality**  Specifies the fitting methodology. See “Fit Model Launch Window Elements” on page 36. Different options appear depending on the personality that you select.

**Target Level**  (Available only in certain personalities and when Y is binary and has a nominal modeling type.) Specifies the level whose probability you want to model. The default value is the higher of the two levels based on the order of the levels.

**Help**  Takes you to Help topics for the Fit Model launch window.

**Recall**  Populates the launch window with the last model specification that you ran.

**Remove**  Removes the selected variable from the assigned role. Alternatively, double-click the effect or select the effect and press Backspace.

**Run**  Generates the report window for the specified model and personality.

**Keep dialog open**  Keeps the launch window open after you run the analysis, enabling you to alter and re-run the analysis at any time.
Frequency

Frequency variables, entered in the Freq text box, are supported in most Fit Model personalities. In general, a frequency is interpreted in the following manner. Suppose that a row has a frequency \( f \). Then the computed results are identical to those for a data table containing \( f \) copies of that row, each having a frequency of one.

Rows with zero or missing frequency values are excluded from analyses. Rows with negative frequency values are permitted only for censored observations, otherwise they are excluded from analyses. When used with censored observations, negative frequency values can be used to fit truncated distributions.

Frequency values do not need to be integers. The technical details describing how frequency columns, including those with non-integer values, are handled are given in “Frequencies” on page 552.

Weight

Weight variables can be useful in situations where there are observations with different variances. For example, this can happen when one performs regression modeling on data where each row consists of pre-summarized means. Here, rows involving a larger number of observations (smaller variance) should contribute more heavily to the loss function than rows involving a smaller number of observations (larger variance). You can ensure that this occurs by using appropriately defined weights.

Weight variables are supported in many Fit Model personalities. Each personality that supports weight variables uses one of the following methods:

- Variance Scaling
- Frequency Symmetry

Variance Scaling

When estimation is performed using least squares or normal theory maximum likelihood, the weight \( w \) for a given row scales that row’s contribution to the loss function by \( w^{-1/2} \).

Weight variables have an impact on estimates and standard errors. However, unlike frequency variables, they do not affect the degrees of freedom used in hypothesis tests.

Rows with negative or zero values for Weight are excluded from analyses.

Frequency Symmetry

In the Nominal Logistic and Ordinal Logistic personalities, weight variables are handled as if they were frequency variables. If weight and frequency variables are both specified, these personalities handle each observation as if it has a frequency value equal to the product of the weight and frequency values.
Construct Model Effects

This section describes the options that you can use to facilitate entering effects into your model. Examples of how these options can be used to obtain specific types of models are given in “Examples of Model Specifications and Their Model Fits” on page 51.

Add

Adds effects to the model. These effects can either be added directly from the Select Columns list or they can be selected in that list and modified using Macros or Attributes. Effects can also be created and added, or modified, using Cross and Nest. The modeling types of the variables involved in the effect, as well as any Attribute assigned to the effect, determine how that effect is treated in the model.

Note: To remove an effect from the Construct Model Effects list, double-click the effect, or select it and click Remove or press Backspace or Delete.

Cross

Creates interaction or polynomial effects. Select two or more variables in the Select Columns list and click Cross. Or, select one or more variables in the Select Columns list and one or more effects in the Construct Model Effects list and click Cross.

See “Statistical Details” on page 529, for a discussion of how crossed effects are parameterized and coded.

Note: You can construct effects that combine up to ten columns as crossed and nested.

Example of Crossed Effects

Suppose that a product coating requires a dye to be applied. Both Dye pH and Dye Concentration are suspected to have an effect on the coating color. To understand their effects, you design an experiment where Dye pH and Dye Concentration are each set at a high and low level. It is possible that the effect of Dye pH on the color is more pronounced at the high level of Dye Concentration than at its low level. This is known as an interaction. To model this possible interaction, you include the crossed term, Dye pH * Dye Concentration, in the Construct Model Effects list. This enables JMP to test for an interaction.
Nest

Creates nested effects. If the levels of one effect (B) occur only within a single level of another effect (A), then B is said to be nested within A. The notation B[A], which is read as "B nested within A," is typically used. Note that nesting defines a hierarchical relationship. A is called the outside effect and B is called the inside effect. Nested terms must be categorical.

Note: The nesting terms must be specified in order from outer to inner. For example, if B is nested within A, and C is nested within B, then the model is specified as A, B[A], C[B, A] (or, equivalently, A, B[A], C[A, B]). You can construct effects that combine up to ten columns as crossed and nested.

Example of Nested Effects

As an illustration of nesting, consider the math teachers in each of two schools. One school has three math teachers; the other school has two math teachers. Each teacher in each school teaches two or three classes consisting of non-overlapping groups of students. In this example, classes (C) are nested within teachers (B), and teachers (B) are nested within schools (A). Enter these effects in the Fit Model launch window:

1. Add both A and B to the Construct Model Effects panel.
2. In the Construct Model Effects panel, select B.
3. In the Select Columns list, select A.
4. Click Nest. This converts B to the effect B[A].
5. Add C to the Construct Model Effects panel.
6. In the Construct Model Effects panel, select C.
7. In the Select Columns list, select A and B.
8. Click Nest. The converts C to the effect C[A, B].

Macros

In the Macros list, select options to automatically generate the effects for commonly used models and enter them into the Construct Model Effects list:

Full Factorial  Creates all main effects and interactions for the columns selected in the Select Columns list. These are entered in an order that is based on the order in which the main effects are listed in the Select Columns list. For an alternate ordering, see Factorial Sorted, in this table.

Factorial to Degree  Creates all main effects, but only interactions up to a specified degree (order). Specify the degree in the Degree box beneath the Macros button.
**Factorial Sorted**  Creates the same set of effects as the **Full Factorial** option but lists them in order of degree. All main effects are listed first, followed by all two-way interactions, then all three-way interactions, and so on.

**Response Surface**  Creates main effects, two-way interactions, and quadratic terms. The selected main effects are given the response surface attribute, denoted **RS**. When the RS attribute is applied to main effects and the Standard Least Squares personality is selected, a Response Surface report is provided. This report gives information about critical values and the shape of the response surface.

See also Response Surface Effect in “Attributes” on page 42 and the Design of Experiments Guide.

**Mixture Response Surface**  Creates main effects and two-way interactions. Main effects have the response surface (RS) and mixture (Mixture) attributes. In the Standard Least Squares personality, the Mixture attribute causes a mixture model to be fit. The RS attribute creates a Response Surface report that is specific to mixture models.

See also Mixture Effect in “Attributes” on page 42 and the Design of Experiments Guide.

**Polynomial to Degree**  Creates main effects and polynomial terms up to a specified degree. Specify the degree in the Degree box beneath the Macros button.

**Scheffé Cubic**  Creates main effects, interactions, and Scheffé cubic terms, which are useful in specifying response surfaces for mixture experiments. This macro creates a complete cubic model.

When you fit a third-degree polynomial model to a mixture, you must not introduce even-powered terms, for example, X1*X1*X2, because they are not estimable. However, it turns out that a complete polynomial specification of the surface can include terms of the form X1*X2*(X1 – X2), which are called Scheffé cubic terms.

Scheffé cubic terms are also included if you enter a 3 in the Degree box and then select the Mixture Response Surface macro command.

**Grouped Regressors**  Creates a single effect for a set of continuous factors that are treated as one effect in various parts of the report. You can add or remove the grouped effect in the Effect Summary. There is one leverage plot and one effect test for each group effect, rather than individual plots and tests for each factor in the group. This can be useful if your data table contains indicator columns that represent levels of a categorical effect.

**Note:** Non-continuous factors included in a group of regressors are not included in the analysis.
Attributes

In the Attributes list, select attributes that you can assign to an effect selected in the Construct Model Effects list.

**Random Effect**  Assigns the Random attribute to an effect. For more information about random effects, see “Specifying Random Effects and Fitting Method” on page 190 in the “Standard Least Squares Models” chapter.

**Response Surface Effect**  Assigns the RS attribute to an effect. Note that the relevant model terms must be included in the Construct Model Effects list. The Response Surface option in the Macros list automatically generates these terms and assigns the RS attribute to the main effects. To obtain the Response Surface report, interaction and polynomial terms do not need to have the RS attribute assigned to them. You need only assign this attribute to main effects.

**LogVariance Effect**  Assigns the LogVariance attribute to an effect. This attribute indicates that the effect is to be included in a model of the variance of the response.

To include an effect in models for both the mean and variance of the response, you must specify the effect twice. In the tabbed interface, it must appear on both the Mean Effects and Variance Effects tabs. Otherwise, you can enter it twice on the Mean Effects tab, once without the LogVariance Effect attribute and once with the LogVariance Effect attribute.

**Mixture Effect**  Assigns the Mixture attribute to main effects. This is used to specify the main effects involved in the mixture. Note that the Mixture Response Surface option in the Macros list automatically assigns the mixture attribute to selected effects, and provides a Response Surface report when possible.

**Excluded Effect**  Assigns the Excluded attribute to an effect. This excludes the effect from the model fit. However, the effect is used to group observations for lack-of-fit tests. In the Standard Least Squares personality, a table of least square means is provided for this effect.

**Knotted Spline Effect**  Assigns the Knotted attribute to a continuous main effect. This implicitly adds cubic splines for the effect to the model specification. See “Knotted Spline Effect” on page 42.

**Knotted Spline Effect**

Knotted splines are used to fit a response $Y$ using a flexible function of a predictor. Consider the single predictor $X$. When the Knotted Spline Effect is assigned to $X$, and $k$ knots are specified, then $k - 2$ additional effects are implicitly added to the set of predictors. Each of these effects is a piecewise cubic polynomial spline whose segments are defined by the knots. See Stone and Koo (1985).
The number of splines is determined by the number of knots, which you are asked to specify. The coefficients associated with the splines are estimated based on the method used by the personality.

The placement of knots follows guidance given in the literature. In particular, if there are 100 or fewer points, the first and last knots are the fifth smallest and largest points, respectively. Otherwise, the first and last knots are placed at the 0.05 and 0.95 quantiles for 5 or fewer knots, or the 0.025 and 0.975 quantiles for more than 5 knots. The default number of knots is 5 for more than 30 observations, and 3 for fewer than 30 observations.

**Note:** Knotted splines are implemented only for main-effect continuous terms.

### Transform

The Transform options transform selected Y columns or main effects that are selected in the Construct Model Effects text box.

**Note:** You can also transform a column by right-clicking it in the Select Columns list and selecting Transform. A reference to the transformed column appears in the Select Columns list. You can then use the column in the Fit Model window as you would any data table column. See *Using JMP*.

- **None**   Removes any Transform options that have been applied.
- **Log**   Applies the natural logarithm transformation to the selected variable.
- **Sqrt**   Applies the square root of the values of the selected variable.
- **Square**   Applies the square of the values of the selected variable.
- **Reciprocal**   Applies the transformation 1/X to the variable X.
- **Exp**   Applies the exponential transformation to the selected variable.
- **Arrhenius**   Applies the Arrhenius transformation to the variable T (temperature in degrees Centigrade):

\[
X = \frac{11604.5181215503}{T + 273.15}
\]

This is the component of the Arrhenius relationship that is multiplied by the activation energy.

- **ArrheniusInv**   Applies the inverse of the Arrhenius transformation to the variable X:

\[
T = \frac{11604.5181215503}{X} - 273.15
\]
Logit  Calculates the inverse of the logistic function for the selected column (where $p$ is in the range of 0 to 1):

$$\text{Logit}(p) = \log \left( \frac{p}{1-p} \right)$$

Logistic  Calculates the logistic (also known as Squish and Logist) function for the selected column (where the result is in the range of 0 to 1):

$$\text{Logistic}(x) = \frac{1}{1 + e^{-x}}$$

LogitPct  Calculates the logit as a percent for the selected column (where $pct$ is a percent in the range of 0 to 100):

$$\text{LogitPct}(pct) = \log \left( \frac{\left( \frac{pct}{100} \right)}{1 - \left( \frac{pct}{100} \right)} \right)$$

LogisticPct  Calculates the logistic (or logist) as a percent for the selected column (where the result is in the range of 0 to 100):

$$\text{LogisticPct}(x) = \frac{100}{1 + e^{-x}}$$

No Intercept

Select No Intercept if you want to fit a model with no intercept term. Certain modeling structures require no intercept models. For these, the No Intercept box is checked by default.

Construct Model Effects Tabs

For the following personalities, you can enter model effects using a tabbed interface:

**Note:** If you apply Attributes to effects on the first (main) tab, the attributes determine how the effects are treated in the model. If you run the model and then request Model Dialog from the report's red triangle menu, you find that those effects appear on the appropriate tabs.

Standard Least Squares  Enter model effects:

**Fixed Effects tab**  Enter effects to be modeled as fixed effects. A fixed effect is one whose specific treatment levels are of interest. You want to compare the mean response across its treatment levels.
**Random Effects tab**  Enter effects to be modeled as random effects. A random effect is one whose levels are considered a random sample from a larger population. You want to estimate the variation in the response that is attributable to this effect.

**Mixed Model**  Enter model effects:

- **Fixed Effects tab**  Enter effects to be modeled as fixed effects. See Standard Least Squares in this table.

- **Random Effects tab**  Enter effects to be modeled as random effects. Use for variance component models and random coefficients models.

- **Repeated Structure tab**  Use to select a covariance structure for repeated effects.

**Loglinear Variance**  Enter model effects:

- **Mean Effects tab**  Enter effects for which you want to model expected values.

- **Variance Effects tab**  Enter effects for which you want to model variance.

If you want to model both the expected value and variance of an effect, you must enter it on both tabs.

**Parametric Survival**  Enter model effects:

- **Location Effects tab**  Enter effects that you want to use in modeling the location parameter, mu, or in the case of the Weibull distribution, the shape parameter.

- **Scale Effects tab**  Enter effects that you want to use in modeling the scale parameter.

**Fitting Personalities**

In the Fit Model launch window, you select your fitting and analysis method by specifying a Personality. Based on the response (or responses) and the factors that you enter, JMP makes an initial context-based guess at the desired personality, but you can alter this selection in the Personality menu.

The following fitting personalities are available:

- **Standard Least Squares**  Fits models where the response is continuous. Techniques include regression, analysis of variance, analysis of covariance, mixed models, and analysis of designed experiments. See the “Standard Least Squares Models” chapter on page 73 and “Emphasis Options for Standard Least Squares” on page 82.

- **Stepwise**  Facilitates variable selection for standard least squares and ordinal logistic analyses (or nominal with a binary response). For continuous responses, cross validation, p-value, BIC, and AICc criteria are provided. Also provided are options for fitting all
possible models and for model averaging. For logistic fits, \( p \)-value, BIC, and AICc criteria are provided. See the “Stepwise Regression Models” chapter on page 249.

**Generalized Regression**  Fits generalized linear models using regularized, also known as penalized, regression techniques. The regularization techniques include ridge regression, the lasso, the adaptive lasso, the elastic net, and the adaptive elastic net. The response distributions include the normal, binomial, Poisson, zero-inflated Poisson, negative binomial, zero-inflated negative binomial, and gamma. See the “Generalized Regression Models” chapter on page 283 and “Distribution” on page 292.

**Mixed Model**  Fits a wide variety of linear models for continuous-responses with complex covariance structures. The situations addressed include:

- Split plot experiments
- Random coefficients models
- Repeated measures designs
- Spatial data
- Correlated response data

See the “Mixed Models” chapter on page 357.

**Manova**  Fits models that involve multiple continuous Y variables. Techniques include multivariate analysis of variance, repeated measures, discriminant analysis, and canonical correlations. See the “Multivariate Response Models” chapter on page 437.

**Loglinear Variance**  For a continuous Y variable, constructs models for both the mean and the variance. You can specify different sets of effects for the two models. See the “Loglinear Variance Models” chapter on page 463.

**Nominal Logistic**  Fits a logistic regression model to a nominal response. See the “Logistic Regression Models” chapter on page 475.

**Ordinal Logistic**  Fits a logistic regression model to an ordinal response. See the “Logistic Regression Models” chapter on page 475.

**Proportional Hazard**  Fits a semiparametric regression model (the Cox proportional hazards model) to assess the effect of explanatory variables on survival times, taking censoring into account.

You can also launch this personality by selecting Analyze > Reliability and Survival > Fit Proportional Hazards. See Reliability and Survival Methods.

**Parametric Survival**  Fits a general linear regression model to survival times. Use this option if you have survival times that can be expressed as a function of one or more explanatory variables. Takes into account various survival distributions and censoring.
You can also launch this personality by selecting Analyze > Reliability and Survival > Fit Parametric Survival. See Reliability and Survival Methods.

**Generalized Linear Model**  Fits generalized linear models using various distribution and link functions. Techniques include logistic, Poisson, and exponential regression. See the “Generalized Linear Models” chapter on page 505.

**Partial Least Squares**  Fits models to one or more Y variables using latent factors. This permits models to be fit when explanatory variables (X variables) are highly correlated, or when there are more X variables than observations.

You can also launch a partial least squares analysis by selecting Analyze > Multivariate Methods > Partial Least Squares. See Multivariate Methods.

**Response Screening**  Automates the process of conducting tests for linear model effects across a large number of responses. Test results and summary statistics are presented in data tables and plots. A False-Discovery Rate (FDR) approach guards against incorrect declarations of significance. A robust estimation method reduces the sensitivity of tests to outliers.

**Note:** This personality allows only continuous responses. Response Screening for individual factors is also available by selecting Analyze > Screening > Response Screening. This platform supports categorical responses, and also provides equivalence tests and tests of practical significance. See Predictive and Specialized Modeling.

---

**Model Specification Options**

The Model Specification red triangle menu contains the following options:

**Center Polynomials**  Centers by its mean any continuous term that is involved in an effect with a degree greater than one. This option is checked by default, except when a term involved in the effect is assigned the Mixture Effect attribute or has the Mixture column property. Terms with the Coding column property are centered midway between their specified High and Low values.

Centering is useful in making regression coefficients more interpretable and in reducing collinearity between low-order and high-order effects.

**Informative Missing**  Provides a coding system for missing values. This system allows estimation of a predictive model despite the presence of missing values. It is useful in situations where missing data are informative. See “Informative Missing” on page 49.

This option is available for the following personalities: Standard Least Squares, Stepwise, Generalized Regression, MANOVA, Loglinear Variance, Nominal Logistic, Ordinal
Logistic, Proportional Hazard, Parametric Survival, Generalized Linear Model, and Response Screening.

**Set Alpha Level**  Sets the alpha level for confidence intervals in the Fit Model analysis. The default alpha level is 0.05.

**Error Specification**  (Available only for the Standard Least Squares personality when there are no random effects.) Specifies the error variance and the error degrees of freedom that are used for standard errors and tests in the Fit Least Squares report. Note that the Studentized Residuals plot and the Box Cox Transformations report are not affected by changing the Error Specification. When the Error Specification is Pure Error or Specified, an additional column appears in the Analysis of Variance report. See “Analysis of Variance” on page 93.

**Default Estimate**  Uses the standard root mean square error and error degrees of freedom from the model to calculate all tests and standard errors.

**Pure Error**  Uses the Pure Error mean square and associated degrees of freedom from the Lack of Fit report to calculate all tests and standard errors. See “Lack of Fit” on page 111.

**Caution:** If the pure error degrees of freedom is 1, a warning message is displayed indicating that tests are weak and confidence limits are large.

**Specified**  Uses user-specified values for the error variance and error degrees of freedom to calculate all tests and standard errors.

**Save to Data Table**  Saves your Fit Model launch window specifications as a script that is attached to the data table. The script is named Model. When a table contains a script called Model, this script automatically populates the launch window when you select Analyze > Fit Model. (Simply rename the script if this is not desirable.) For more information about JSL scripting, see the Scripting Guide.

**Save to Script Window**  Copies your Fit Model launch window specifications to a script window. You can save the script window and re-create the model at any time by running the script.

**Create SAS job**  Creates a SAS program that can re-create the current analysis and data table in SAS in a script window. Once created, you have several options for submitting the code to SAS.

1. Copy and paste the code into the SAS Program Editor. This method is useful if you are running an older version of SAS (pre-version 8.2).

2. Select Edit > Submit to SAS.
3. Save the file and double-click it to open it in a local copy of SAS. This method is useful if you would like to take advantage of SAS ODS options, such as generating HTML or PDF output from the SAS code.

See Using JMP.

Submit to SAS  Submits code to SAS and displays the results in JMP. If you are not connected to a SAS server, prompts guide you through the connection process.

See Using JMP.

Convergence Settings  The Convergence Settings menu contains the following options:

- **Maximum Iterations**  Specifies the maximum number of iterations that are used in the model fitting. By default, the maximum number of iterations is 100. If your model does not readily converge, you might want to increase the number of iterations. If you have a very large data set or a complicated model, you might want to limit the number of iterations.

- **Convergence Limit**  Specifies the convergence limit for the model fitting. If your model does not readily converge, you might want to increase the convergence limit. By default, the convergence limit is 0.00000001.

**Note:** The Convergence Settings menu appears only for certain personalities. In the Standard Least Squares personality, the Convergence Settings menu appears only when there is a random effect and REML is selected as the Method in the launch window.

Informative Missing

The Informative Missing option constructs a coding system that allows estimation of a predictive model despite the presence of missing values. It codes both continuous and categorical model effects.

Continuous Effects

When a continuous main effect has missing values, a new design matrix column is created. This column is an indicator variable, with values of one if the main effect column is missing and zero if it is not missing. In addition, missing values for the continuous main effect are replaced with the mean of the nonmissing values for rows included in the analysis. The mean is a neutral value that maintains the interpretability of parameter estimates.

The parameter associated with the indicator variable estimates the difference between the response predicted by the missing value grouping and the predicted response if the covariate is set at its mean.
For a higher-order effect, missing values in the covariates are replaced by the covariate means. This makes the higher-order effect zero for rows with missing values, assuming that Center Polynomials is checked (the default setting). This is because Center Polynomials centers the individual terms involved in a polynomial by their means.

In the Effect Tests report, each continuous main effect with missing values has Nparm = 2. In the Parameter Estimates report, the parameter for a continuous main effect with missing values is labeled <colname> Or Mean if Missing and the indicator parameter is labeled <colname> Is Missing. Prediction formulas that you save to the data table are given in terms of expressions corresponding to these model parameters.

**Categorical Effects**

When a nominal or ordinal main effect has missing values, the missing values are coded as a separate level of that effect. As such, in the Effect Tests report, each categorical main effect with missing values has one additional parameter.

In the Parameter Estimates report, the parameter for a nominal effect is labeled <colname>[]. For an ordinal effect, the parameter is labeled <colname>[-x], where x denotes the level with highest value ordering.

As with continuous effects, prediction formulas that you save to the data table are given in terms of expressions corresponding to the model parameters.

**Coding Table**

When you are using the Standard Least Squares personality, you can view the design matrix columns used in the Informative Missing model by selecting **Save Columns > Save Coding Table**.

**Validity Checks**

**Fit Model** checks your model for errors such as duplicate effects or missing effects in a hierarchy. If you receive an alert message, you can either click **Continue** to proceed with fitting, or click **Cancel** to stop the fitting process.
Examples of Model Specifications and Their Model Fits

This section gives templates for entering the effects for various model types that you can specify using the Construct Model Effects panel in the Fit Model platform.

- The model effects X and Z represent continuous columns.
- The model effects A, B, and C represent nominal or ordinal columns.

For most models, visual views of their model fits are also given.

- “Simple Linear Regression”
- “Polynomial in X to Degree k”
- “Polynomial in X and Z to Degree k”
- “Multiple Linear Regression”
- “One-Way Analysis of Variance”
- “Two-Way Analysis of Variance”
- “Two-Way Analysis of Variance with Interaction”
- “Three-Way Full Factorial”
- “Analysis of Covariance, Equal Slopes”
- “Analysis of Covariance, Unequal Slopes”
- “Two-Factor Nested Random Effects Model”
- “Three-Factor Fully Nested Random Effects Model”
- “Simple Split Plot or Repeated Measures Model”
- “Two-Factor Response Surface Model”
- “Knotted Spline Effect”

Simple Linear Regression

Effects to be entered: X

1. In the Select Columns list, select X.
2. Click Add.

Example of Simple Linear Regression Model

You are interested in the relationship between the population in thousands of the given city, and ozone levels. Ozone is the response of interest, and POP is the continuous model effect.

1. Select Help > Sample Data Library and open Polycity.jmp.
2. Select **Analyze > Fit Model**.
3. In the Select Columns list, select Ozone and click **Y**.
4. In the Select Columns list, select POP.
5. Click **Add**.

**Figure 2.4** Fit Model Window for Simple Linear Regression

When you click **Run**, the Fit Least Squares report appears, showing various results, including a Regression Plot. The Regression Plot shows the data and a simple linear regression model fit to the data.

**Figure 2.5** Model Fit for Simple Linear Regression
Polynomial in X to Degree k

Effects to be entered: X, X*X,..., X^k

1. Type k into the text box for Degree.
2. In the Select Columns list, select X.
3. Select Macros > Polynomial to Degree.

Figure 2.6 shows a plot of the data and a cubic polynomial model fit to the data for the Growth.jmp sample data table. This is one of the fits produced when you run the Bivariate data table script.

Figure 2.6  Model Fit for a Degree-Three Polynomial in One Variable

Polynomial in X and Z to Degree k

Effects to be entered: X, X*X,..., X^k, Z, Z*Z,..., Z^k

1. Type k into the text box for Degree.
2. In the Select Columns list, select X and Z.
3. Select Macros > Polynomial to Degree.

Multiple Linear Regression

Effects to be entered: Selected columns

1. In the Select Columns list, select the continuous effects of interest.
2. Click Add.
Figure 2.7 shows a surface profiler plot of the data and of the multiple linear regression fit to the data for the Grandfather Clocks.jmp sample data table. The model effects are Age and Bidders. The response is Price. You can obtain the plot by running the data table script **Fit Model with Surface Profiler Plot**.

**Figure 2.7** Model Fit for a Multiple Linear Regression Model with Two Predictors

---

**Example of Multiple Linear Regression Model**

See also “Example of a Regression Analysis Using Fit Model” on page 32 for an example with several predictors.

---

**One-Way Analysis of Variance**

Effects to be entered: A

1. In the Select Columns list, select one nominal or ordinal effect, A.
2. Click **Add**.

Consider the Golf Balls.jmp sample data table. You are interested in whether Durability varies by Brand. Figure 2.8 shows two plots.

The first is a plot, obtained using Fit Y by X, that shows the data by brand. Horizontal lines are plotted at the mean for each brand and line segments connect the means. To produce this plot, run the script **Oneway: Durability by Brand** in the Golf Balls.jmp sample data table.
The second plot is a profiler plot obtained using Fit Model. This second plot shows the predicted responses for each brand, connected by line segments. To produce this plot, run the script Fit Model: Durability by Brand in the Golf Balls.jmp sample data table. Drag the vertical dashed red line to the brand of interest. The horizontal dashed red line updates to intersect the vertical axis at the predicted response.

**Figure 2.8** Model Fit for One-Way Analysis of Variance

---

### Two-Way Analysis of Variance

Effects to be entered: A, B

1. In the Select Columns list, select two nominal or ordinal effects, A and B.
2. Click **Add**.

Figure 2.9 shows two profiler plots of the fit to the data for the Analgesics.jmp sample data table. The model effects are gender and drug. The response is pain. To obtain this plot, select **Analyze > Fit Model**, select pain as Y, select gender and drug as model effects, and then click **Run**. Click the Response Pain red triangle and select **Factor Profiling > Profiler**.

The line segments in each plot connect the predicted values for the settings defined by the vertical dashed red lines. Move these to see predictions at other settings.
The top plot in Figure 2.9 shows predictions for females, whereas the bottom plot shows predictions for males. Note that the relative effects of the three drugs are consistent across the levels of gender. This is because there is no interaction term in the model. For an example with interaction, see Figure 2.11.

**Figure 2.9** Model Fit for a Two-Way Analysis of Variance with No Interaction

---

**Two-Way Analysis of Variance with Interaction**

Effects to be entered: A, B, A*B

1. In the Select Columns list, select two nominal or ordinal effects, A and B.
2. Select **Macros > Full Factorial**.

Or:

1. In the Select Columns list, select two nominal or ordinal effects, A and B.
2. Click **Add**.
3. In the Select Columns list, select A and B again and click **Cross**.
Example of Two-Way Analysis of Variance with Interaction

You have data about the yield of popcorn and are interested in whether the type of popcorn and the size of the batch have an effect on yield.

1. Select **Help > Sample Data Library** and open Popcorn.jmp.
2. Select **Analyze > Fit Model**.
3. In the Select Columns list, select **yield** and click **Y**.
4. In the Select Columns list, select **popcorn** and **batch**.
5. Select **Macros > Full Factorial**.

**Figure 2.10** Fit Model Window for Two-Way Analysis of Variance with Interaction

Figure 2.11 shows a profiler plot of the fit for this example. To obtain this plot, click **Run** in the Fit Model window shown in Figure 2.10. Then, click the Response yield red triangle and select **Factor Profiling > Profiler**.

In the top plot, **popcorn** is set to gourmet, and in the bottom plot, it is set to plain. Note how the predicted values for the settings of **batch** depend on the type of **popcorn**. This is a consequence of the interaction between **popcorn** and **batch**.

**Three-Way Full Factorial**

1. In the Select Columns list, select three nominal or ordinal effects, A, B, and C.
2. Select **Macros > Full Factorial**.

**Example of Three-Way Full Factorial**

You are interested in whether Speed, Angle, and Material, or their interactions, have an effect on the Wear of a cutting tool.

1. Select **Help > Sample Data Library** and open Tool Wear.jmp.
2. Select **Analyze > Fit Model**.
3. In the Select Columns list, select Wear and click **Y**.
4. In the Select Columns list, select Speed, Angle, and Material.
5. Select **Macros > Full Factorial**.
The Surface Profiler plots in Figure 2.13 show the predicted response for Wear in terms of the two continuous effects Speed and Angle. The plot on the left shows the predicted response when Material is A; the plot on the right shows the predicted response when Material is B. The points for which Material is A are colored red, whereas those for which Material is B are colored blue. The difference in the form of the response surfaces across the levels of Material is a consequence of the three-way interaction.

To obtain Surface Profiler plots, click Run in the Fit Model window shown in Figure 2.12. Click the Response Wear red triangle and select Factor Profiling > Surface Profiler. To add points to the plot, open the Appearance panel and click Actual. If you want to make the points appear larger, right-click in the plot, select Settings and adjust the Marker Size.

To show plots for both Materials A and B, use the slider marked Material in the Independent Variables panel, setting it at 0 for Material A and 1 for Material B. Note that the table contains two data table scripts that produce Surface Profiler plots: Prediction and Surface Profilers and Surface Profilers for Two Materials.
Figure 2.13 Model Fit for a Three-Way Full Factorial Design - Material A on Left, Material B on Right

Analysis of Covariance, Equal Slopes

Here you are interested in testing for the effect of A with X as a covariate. Suppose that you have reason to believe that the effect of X on the response does not depend on the level of A.

Effects to be entered: A, X

1. In the Select Columns list, select one nominal or ordinal effect, A, and one continuous effect, X.
2. Click Add.

Figure 2.14 shows the data from the Cleansing.jmp sample data table. You are interested in which Polymer removes the most Coal particles from a cleansing tank. However, you suspect that the pH of the tank also has an effect on removal. The plot shows an analysis of covariance fit. Here the slopes relating pH and Coal particles are assumed equal across the levels of Polymer.

You can obtain the plot in Figure 2.14 using the following steps. In the Fit Model window, enter Coal particles as Y and both pH and Polymer in the Construct Model Effects box. Click Run. The Regression Plot appears in the Fit Least Squares report. To color the points, select Rows > Color or Mark by Column, select Polymer from the Mark by Column list, and click OK.

However, a more complete analysis indicates that pH and Polymer do interact in their effect on Coal particles. The appropriate model fit is shown in “Analysis of Covariance, Unequal Slopes” on page 61.
Chapter 2
Fitting Linear Models

Model Specification
Examples of Model Specifications and Their Model Fits

Figure 2.14  Model Fit for Analysis of Covariance, Equal Slopes

Analysis of Covariance, Unequal Slopes

Here you are again interested in testing for the effect of A with X as a covariate. But you construct your model so as to admit the possibility that the effect of X on the response depends on the level of A.

Effects to be entered: A, X, A*X

1. In the Select Columns list, select one nominal or ordinal effect, A, and one continuous effect, X.
2. Select Macros > Full Factorial.

Or:

1. In the Select Columns list, select one nominal or ordinal effect, A, and one continuous effect, X.
2. Click Add.
3. In the Select Columns list, select A and X again and click Cross.

Example of Analysis of Covariance, Unequal Slopes

You are interested in whether any of the three polymers (Polymer) has an effect on coal particle removal (Coal particles). The tank pH is included as a covariate as it might affect a polymer’s ability to clean the tank. You allow for possibly different slopes when modeling the relationship between pH and Coal particles for the three Polymer types.

1. Select Help > Sample Data Library and open Cleansing.jmp.
2. Select Analyze > Fit Model.
3. In the Select Columns list, select Coal particles and click Y.
4. In the Select Columns list, select \texttt{pH} and \texttt{Polymer}.

5. Select \texttt{Macros > Full Factorial}.

**Figure 2.15** Fit Model Window for Analysis of Covariance, Unequal Slopes

When you click \texttt{Run}, the Fit Least Squares report appears. The Effect Tests report indicates that the interaction between \texttt{pH} and \texttt{Polymer} is significant and should be included in the model.

The Regression Plot given in the report is shown in Figure 2.16. This plot shows the points and the model fit. The interaction allows the slopes of the lines that relate \texttt{pH} to \texttt{Coal particles} to depend on the \texttt{Polymer}. Note that, despite this interaction, over the range of interest, \texttt{Polymer A} consistently has the highest removal. If you want to color the points as shown in Figure 2.16, select \texttt{Rows > Color or Mark by Column}, select \texttt{Polymer} from the \texttt{Mark by Column} list, and click \texttt{OK}. 
Two-Factor Nested Random Effects Model

Consider a model with two factors, A and B, but where B is nested within A. Although there are situations where a nested effect is treated as a fixed effect, in most situations a nested effect is treated as a random effect. For this reason, in the model described below, the nested effect is entered as a random effect.

Effects to be entered: A, B[A]&Random

1. In the Select Columns list, select two nominal or ordinal effects, A and B.
2. Click Add.
3. To nest B within A: In the Construct Model Effects list, select B. In the Select Columns list, select A. The two effects should be highlighted.
4. Click Nest.

Example of Two-Factor Nested Random Effects Model

As part of a measurement systems analysis study, 24 randomly chosen parts are measured. These parts are evenly divided among the six operators who typically measure these parts. Each operator makes three independent measurements of each of the four assigned parts.

Since the parts measured by one operator are measured only by that specific operator, Part is nested within Operator. Since the parts are a random sample of production, Part is considered a random effect. Since these specific six operators are of interest, Operator is treated as a fixed effect. Specify the appropriate model.

1. Select Help > Sample Data Library and open Variability Data/2 Factors Nested.jmp.
2. Select Analyze > Fit Model.
3. In the Select Columns list, select Y and click Y.
4. In the Select Columns list, select Operator and Part.
5. Click Add.
6. To nest Part within Operator: In the Construct Model Effects list, select Part. In the Select Columns list, select Operator. The two effects should be highlighted.
7. Click Nest.

Figure 2.17 Fit Model Window for Two-Factor Nested Random Effects Model

9. Click Run to obtain the Fit Least Squares report.

Figure 2.18 shows two plots. The first is a Variability Chart showing the three measurements by each Operator on each of the four parts. Horizontal line segments show the mean measurement for each Operator.

To construct the Variability Chart in Figure 2.18, in the 2 Factors Nested.jmp sample data table, run the data table script Variability Chart - Nested. Click the Variability Gauge red triangle, deselect Show Range Bars, and select Show Group Means.
The second plot is the Fit Least Squares report Prediction Profiler plot for Operator. This plot shows the predicted response for each operator. The vertical dashed red line set at Jane indicates that Jane's predicted response is 0.997. You can see the correspondence between the model predictions given in the Prediction Profiler plot and the raw data in the Variability Chart.

To obtain the Prediction Profiler plot, click the Response Y red triangle and select **Factor Profiling > Profiler**.

These plots show how the predicted measurements for each Operator are modeled. However, keep in mind that you are not only interested in whether the operators differ in how they measure parts. You are also interested in the variability of the part measurements themselves, which requires estimation of the variance component associated with Part.

**Figure 2.18** Model Fit for Two-Factor Nested Random Effects Model

---

**Three-Factor Fully Nested Random Effects Model**

Consider a model with three factors, A, B, and C, but where B is nested within A and C is nested within both A and B. Also consider B and C to be random effects.
Effects to be entered: A, B[A]&Random, C[A,B]&Random

1. In the Select Columns list, select three nominal or ordinal effects, A, B, and C.
2. Click Add.
3. To nest B within A: In the Construct Model Effects list, select B. In the Select Columns list, select A. The two effects should be highlighted.
4. Click Nest.
5. To nest C within A and B: In the Construct Model Effects list, select C. In the Select Columns list, select A and B. The three effects should be highlighted.
6. Click Nest.
7. With both B[A] and C[A,B] highlighted in the Construct Model Effects list, select Attributes > Random Effect.

Simple Split Plot or Repeated Measures Model

Here A is the whole plot variable, B[A] is the whole plot ID, and C is the split plot, or repeated measures, variable.

Effects to be entered: A, B[A]&Random, C, C*A

1. In the Select Columns list, select two nominal or ordinal effects, A and B.
2. Click Add.
3. To nest B within A: In the Construct Model Effects list, select B. In the Select Columns list, select A. The two effects should be highlighted.
4. Click Nest.
5. In the Construct Model Effects list, select B[A].
7. In the Select Columns list, select a third nominal or ordinal effect, C.
8. Click Add.
9. In the Construct Model Effects list, select C. In the Select Columns list, click A. Both effects should be highlighted.
10. Click Cross.
Example of a Simple Repeated Measures Model

You have data on the distance traveled by each of six animals in each of the four seasons. There are two species and the animal identifier is nested within species. Since these six animals are representatives of larger species populations, you decide to treat subject as a random effect. You want to model the response, miles, as a function of species and season, accounting for the fact that there are repeated measures for each animal.

1. Select Help > Sample Data Library and open Animals.jmp.
2. Select Analyze > Fit Model.
3. In the Select Columns list, select miles and click Y.
4. In the Select Columns list, select species and subject.
5. Click Add.
6. To nest subject within species: In the Construct Model Effects list, select subject. In the Select Columns list, select species. The two effects should be highlighted.
7. Click Nest.
8. In the Construct Model Effects list, select subject[species].
9. Select Attributes > Random Effect.
10. In the Select Columns list, select season.
11. Click Add.
12. In the Construct Model Effects list, select season. In the Select Columns list, click species. Both effects should be highlighted.
13. Click Cross.
Two-Factor Response Surface Model

Effects to be entered: X&RS, Z&RS, X*X, X*Z, Z*Z

1. In the Select Columns list, select two continuous effects, X and Z.
2. Select Macros > Response Surface.

Example of Two-Factor Response Surface Model

In the Odor Control Original.jmp sample data table, you want to fit a response surface to model the response, odor, as a function of temp and gl ratio. (Although you could include ht, as shown in the data table script Response Surface, for this illustration do not.)

1. Select Help > Sample Data Library and open Odor Control Original.jmp.
2. Select Analyze > Fit Model.
3. In the Select Columns list, select odor and click Y.
4. In the Select Columns list, select temp and gl ratio.
5. Select Macros > Response Surface.
Figure 2.20  Fit Model Window for Two-Factor Response Surface Model

6. Click **Run**.

Figure 2.21 shows a Surface Profiler plot of the data and a quadratic response surface fit to the data for the Odor Control Original.jmp sample data table. To obtain this plot, click the Response odor red triangle and select **Factor Profiling > Surface Profiler**. To show the points, click the disclosure icon to open the **Appearance** panel and click **Actual**. If you want to make the points appear larger, right-click in the plot, select **Settings** and adjust the **Marker Size**.
**Knotted Spline Effect**

Effects to be entered: X&Knotted

1. In the Select Columns list, select a continuous effect, X.
2. Click **Add**.
3. Select X in the Construct Model Effects list.
4. Select **Attributes > Knotted Spline Effect**.
5. In the menu that appears, specify the number of knots or accept the default number.
6. Click **OK**.

Figure 2.22 shows the Regression Plot for a model fit to the data in the *XYZ Stock Averages (plots).jmp* sample data table. Here Date is assigned the Knotted Spline Effect and five knots are specified. DJI Close is the response.
Figure 2.22 Model Fit for a Knotted Spline with Five Knots
The Standard Least Squares personality within the Fit Model platform fits a wide spectrum of standard models. These models include regression, analysis of variance, analysis of covariance, and mixed models, as well as the models typically used to analyze designed experiments. Use the Standard Least Squares personality to construct linear models for continuous-response data using least squares or, in the case of random effects, restricted maximum likelihood (REML).

Analytic results are supported by compelling dynamic visualization tools such as profilers, contour plots, and surface plots (see Profilers). These visual displays stimulate, complement, and support your understanding of the model. They enable you to optimize several responses simultaneously and to explore the effect of noise.
